The unit of length we might expect to be the yard, or units derived from it, such as the foot or the inch. But nearly all countries have abandoned such absurd measurements—absurd because wholly arbitrary and inconvenient—and have adopted the *decimal system* for their units. As our methods of counting are based on this system (ultimately derived from the fact that we have ten fingers), it is obviously a matter of very great convenience to use it throughout. Hence the student of science in this country has to make the acquaintance of measurements which are familiar to every fortunate French child, and which are used by men of science everywhere "from China to Peru," but which are not yet in general use in this country.

The unit of length (the simplest kind of unit of space) is the *metre*. When used in England we need not add the accent, and we may pronounce the word in English fashion, with the *e* like the *ea* in "eat." The metre is equal to rather more than thirty-nine and a third English inches. Space, however, has three dimensions—physics knows nothing of a supposed fourth dimension—and so there are units of surface derived from the metre and units of volume similarly derived. The thousandth part of a metre is called a millimetre; the hundredth part, a centimetre; the tenth part, a decimetre, whilst ten metres make a decametre. Each of these words may be used with the adjective *square* or *cubic* before it to indicate measures of area or of volume. We may note one special name in wide use—that of the cubic decimetre, which is usually known as a litre.

The Unit of Mass. Next we must obtain a *unit of mass*, and this has been conveniently agreed upon in the following fashion. As one of the most common and important of substances, water is chosen, and is considered at its temperature of maximum density—*i.e.* when

* The kinematograph has taught everybody that kinema is the Greek for a movement; but unfortunately the fashion now is to spell the word with a c, and people pronounce the "c" soft, so that the meaning of the word is being made as obscure as possible.

its matter, or "stuff," is as shrunken as possible. This point is at 4° above the zero on the Centigrade scale—in which the zero is the freezing point of water. Our unit of mass is, then, *the mass of one cubic centimetre of pure water at the temperature of 4° C.*, and this is known as a *gramme*. This excellent unit yields sub-divisions and multiples as the metre does—the milligramme, centigramme, decigramme (one thousandth, one hundredth, and one tenth part of a gramme respectively), the decagramme, which has ten times the mass of the gramme, and so forth.

The reader will observe that, in the above account, the word *weight* would apparently make just as good sense as the word *mass*. Why, we may ask, should we not talk of a unit of *weight*—the *weight* of a cubic centimetre of water, and so on ?

Mass and Weight. Occasionally a strict sequence must be sacrificed in order that we may not leave the reader with an unexplained term or assertion ; and this is a case in point. We shall therefore deliberately anticipate a future chapter—that on gravitation—in order that the distinction between weight and mass may be made clear.

The mass of a body is the quantity of matter or stuff that it contains. Mass is a radical and unalterable property of matter ; the amount of stuff in a pound of lead is the same whether the lead remain on the earth or be transported to the moon. But though all matter has weight, weight is a property not radical at all, and still less is it unalterable.

Indeed, we may positively assert that the weight of a given mass of unchanging matter never remains constant for two successive seconds. This may well seem to be an absurd assertion, but its truth will become apparent when we consider upon what the weight of a given mass of matter depends.

Weight is Always Changing. Weight is none other than an assertion of the force of gravity, in virtue of which every particle of matter in the universe attracts every other. But this force varies at different distances between the masses of matter in question, and varies with the amount of mass concerned. Hence a pound of lead would weigh far less than a pound on the moon, far more on Jupiter or the sun, simply because the moon has much less mass than the earth, whilst Jupiter has far more, with the consequence that the force of gravity is much less on the moon than it is on the earth, whereas it is much greater on Jupiter. Hence the weight of any mass depends on the position in space of all the other portions of matter that exist : and, as these portions of matter are incessantly changing their positions, it follows that, as has been said, the weight of a given mass of matter never remains constant for two successive seconds, though the mass is absolutely invariable.

If gravitation were abolished, there would henceforth be no such thing as weight : but plainly the mass of the matter in the universe would be unaffected : the mass would be still there, unchanged, though its different portions would not possess that attraction for one another which expresses itself to us as weight.

Weight an Imperfect Standard. While this cardinal distinction must never be forgotten, we may, nevertheless, conveniently use *weight* as an indication of mass. Our experiments are conducted at the surface of the earth, where the force of gravity is, for practical purposes, quite constant—the earth remaining constant in mass, and no other large body interfering practically with its attraction for small bodies on its surface. Hence, since the weight of any body is most strictly proportional to its mass, provided that other factors are unchanged, we are free to estimate the mass or amount of matter in a body by means of its weight.

Nevertheless, this method is plainly imperfect, for we ought to be able to measure mass without reference to a variable thing such as weight. We should be able to determine the masses of two similar cubes of different substances by some other means than by weighing them. We should be able to do so if we had them in empty space, with no more weight than depended on their attraction for each other. This can be done ; but before we see how it can be done, we must study another aspect of motion, and attempt to find for it also a unit of measurement.

Speed. This aspect of motion is its *velocity* or *speed*. Now it is quite evident that when we think of the speed of any moving body—say a man running a race—we are combining the two ideas of *space* and *time*. When we say that an athlete has run a hundred yards in ten seconds we have indicated his average velocity or speed, because we have stated the factor of space—the distance run ; and the factor of time—the number of seconds taken in traversing that distance. Then if v stands for velocity, s for space, and t for time we can say that $v = \frac{s}{t}$, a simple formula which may be illustrated from the case already quoted. The total distance or space, divided by the total time, is 100 (yards) divided by 10 (seconds), and thus v, the velocity, must be ten yards per second—*i.e.* $v = \frac{s}{t}$.

Now we know that the speed of a moving body may undergo diminution or increase ; and under certain natural conditions, where the cause of the motion is constant and continuous in action, we find that this diminution or increase is regular.

If the rate of increase of velocity is regular, it is given a special name, *positive acceleration* (from the Latin *celer*, swift), and a regular rate of diminution of velocity is called *negative acceleration*. This use of terms may be confusing, and is in defiance of the derivation of the word acceleration ; so we shall do better to call increase of speed *acceleration*, and decrease of speed *retardation*. We note, again, that these are of interest and importance to us only in so far as they are regular. By this is plainly meant that during each unit of time—during each

second—there is a constant increase or diminution in velocity; as, for instance, when a body moves, in successive seconds, through 32 ft. more of space than it moved in each preceding second—dropping, say, 32 ft. in the first second, but 64 ft. in the next; so that at the end of two seconds it has passed through, not 64 ft.—as would have been the case had there been no acceleration—but through 96 ft. Later we shall have to return to acceleration and retardation, in especial relation to the force of gravity.

But now, having understood what is meant by velocity, we are in a position to return to the problem already stated—as to the possibility of measuring the mass of bodies without weighing them, and in a manner which is wholly independent of the fact that they have weight.

The Action of Force. We find that a given force, acting on a given mass for a given time, always produces the same velocity; hence two different bodies—one, perhaps, "light" and bulky, the other "heavy" and dense—can be shown to possess the same mass, *if the same force, acting on each for the same period, imparts to each the same velocity.*

By combining in a different way the definitions already noted, we can obtain a measure of force and a unit of force. For we can measure a force by the velocity which it imparts to a given mass when applied to it for a given period of time. The unit of force is called the *dyne*, and is that amount of force which, applied for one second to a gramme, imparts to it a velocity of one centimetre per second.

And now at last, having defined force and motion, and having agreed upon modes of measuring them, we are in a position to study the laws of motion.

The basis of the science of kinetics consists of three laws enunciated by Newton and known as Newton's laws of motion. He himself called them *axioms or laws of motion.*

Sir Isaac Newton. The formation of these laws is scarcely less important than the discovery of universal gravitation and the law of its action, which Newton also achieved. Sir Isaac Newton was born in Lincolnshire in 1643, his father being the lord of Woolsthorpe Manor. He was reared with great difficulty, having been prematurely born. For some time he had to help his widow mother with her farm, and he left school at Grantham for this purpose, but at the age of seventeen he was allowed to go to Cambridge University, which counts him as incomparably the greatest of her sons in sheer magnificence of intellect. At Cambridge he made most signal discoveries in pure mathematics, which, however, do not greatly concern us here. In the terrible year 1665, when he was twenty-two, the marvellous boy, who had already made an immortal name, was compelled to leave Cambridge owing to risk of the plague, and it was then that the fall of an apple from a tree in the family orchard led him to the discovery of gravitation.

His mind, by the exercise of its supremely great scientific imagination, "leapt from a falling apple to a falling moon." At the age of twenty-three, the boy who had already discovered "how the heavens are balanced" proceeded to demonstrate the fact that white light consists of a combination of rays of light of many colours.

His chief work, the *Principia* (the translation of the full title is "The Mathematical Principles of Natural Philosophy"), was finished in 1686. Six years later the results of years of work were destroyed by the overturning of a lighted candle by his pet dog "Diamond."

Newton died in 1727, and was buried in Westminster Abbey. He spent the greater part of his eighty-four years, as has been finely said of him, in

"Voyaging through strange seas of thought
alone."

The Laws of Motion. Newton's Laws of Motion are enunciated in his *Principia*. The Latin may be thus freely translated so as to reduce the laws to their simplest and most intelligible form:

1. If a body be at rest, it will remain at rest unless it is compelled by some external force to change its state; and similarly if it be in motion, it will continue to move in a straight line and at a uniform velocity for ever, unless its state of motion be affected by some external force.

2. Change of motion of any body is proportional to the external force that causes it, and takes place in the straight line in which the force acts.

3. To every action there is always an equal and contrary reaction; or, the mutual actions of any two bodies are always equal and oppositely directed. This law is often briefly stated thus: Action and reaction are equal and opposite.

Fully to illustrate and apply these laws and the deductions from them would be practically to state the science of dynamics, including both statics and kinetics, in a perfect and final form. We must devote, at least, many pages to their consideration.

The first law is the simplest and the most important. It expresses the property of matter which is often called *inertia*, implying that "matter is passive, or has no power in itself to change its state, whether of rest or motion." This sentence, quoted from a well-known text-book, is however, an inaccurate expression of the property of inertia. We who have lately become familiar with radium and radio-activity are aware that matter is very far from being "dead" or "passive," and that it contains sources of energy till lately unsuspected. But the principle of inertia may be expressed as meaning that the state of rest or motion of any body can be changed *only in virtue of the action of a new force.*

Inertia. Common experience has taught us that tumblers do not fall off tables "by themselves," that, in general, things stay where they are unless something moves them; and we say that this characteristic of things is due to their *inertia*, which seems to us to be the most

natural thing in the world. The observed facts of material nature are often used as foundations for figures of speech, as when we speak of the inertia of a man's mind, or of a political party. But the present writer has not yet met any metaphorical use of the fact that inertia is expressed in two ways, each of which Newton stated in his first law of motion. That law states not merely that a resting body remains at rest until some force causes it to move, but also that a moving body continues to move *for ever* in a straight line at a constant velocity until some external force is applied to it. Now this property of " going on " when once started is as much a result of inertia as is the remaining at rest when at rest. In each case the body in question—we assume for the moment that no new force is being evolved inside it—is passive; passive, though it be a "flying star" like Arcturus, rushing through space at the rate of one hundred miles a second. It is *force* that causes the motion—not Arcturus, which is as inert, so far as this motion is concerned, as is a penny lying on a mantel-shelf. The one moves, the other rests—each in virtue of its inertia. When writers in general become acquainted with the elements of physics and gain a full appreciation of the principle of inertia, instead of being content, as at present, with the mere recognition of one of its results (which must be quite incomprehensible to them), they will discover that both aspects of inertia may be illustrated from the ways of men as individuals or in society.

Mental Inertia. If it be mental inertia that causes a man to resist a new idea, it is also mental inertia that causes him to persist in following an old idea, long after any rational cause for following it has ceased to exist. Illustrated in daily life everywhere, this kind of mental inertia is conspicuous in children, the aged, and the insane. This is as truly inertia, and as truly due to the same cause—the lack of any spontaneous force within the person in question—as is the inertia that is expressed simply in continuing to do nothing simply because one never has done anything.

We lay emphasis on this analogy, because it is neglected, true, and useful. If we condemn the inertia of the more obvious kind, we should equally condemn the less obvious inertia which expresses itself in human action as the aimless continuance of a course once entered upon. Each is equally due to mental laziness, passivity, or inertia, and each illustrates Newton's first law of motion in the sphere of mind.

We hope we have convinced the reader that the second part of the law really expresses and depends upon the same fact as the first. But the reader may admit this in theory, but deny that, when we come to the test of actual experience, the second part of the law is found to be true. It is, of course, its apparent untruth that has led to the non-recognition, by the public and the writers, of the more subtle expression of the principle of inertia. For, in point of fact, all the moving bodies with which we are familiar show a tendency to stop moving: whereas Newton's law declares that the fixed and universal tendency of all moving bodies is to go on moving. If the law is contradicted by a single fact, it is no law but a lie; and we must ask ourselves whether the thousands of familiar facts that appear to contradict it really do so.

Why Does a Cricket-ball Stop? A cricket-ball, driven with moderate force along the ground, will reach the boundary at Lord's when the ground is hard and dry and the grass cut short. The critics remark that "the outfield is very fast to-day." The same drive, applied to a ball of the same weight, after a night's rain, will send the ball only to a point short of the boundary by many yards. Everyone knows why the ball stops—" the outfield is slow to-day." When the cricketer uses these terms he is virtually recognising the second part of the first law of motion. He admits that the ball stops short of the boundary in the second case, not because of any tendency to stop, but because *something stops it*. He knows very well, too, that the same drive would cause the ball to run for hundreds of yards if the outfield consisted of a very smooth sheet of ice. In such a case the ball would not roll, but would slide, and there would be very little sign of any tendency to stop.

The difference between the firm turf outfield, the wet outfield, and the ice outfield (on which any drive that passed the fielders would be worth a hundred runs, if there were no boundaries), lies in the differing values of the external forces of *friction* in the three cases. In the last case, the force of friction is so slight that the ball does not roll, but glides or slides. It is, of course, friction that makes the ball roll in actual practice. Abolish friction and the ball will glide for ever, if there be no other force to stop it. In point of fact, however, the ball would not roll for ever, even on the smoothest ice, and even if its own surface was as smooth, so that friction was reduced to a minimum. It would not roll for ever, even if the conditions were such (quite unobtainable in our experience, whether of cricket or any other form of practical dynamics) that there was no friction at all. The ball would stop at last. This would not be because of any tendency to stop, but simply because of the resistance of the air.

The Ocean of Air. Remember that the air is really an ocean, at the bottom of which we crawl and play cricket. The hardest drive would not send a ball far through water; the hardest drive will not send it infinitely far through air; but, in virtue of the fact of inertia, the feeblest drive would send the ball moving at undiminished speed—it matters not how slowly—for all eternity, if there were no friction and no resisting medium.

The apparent tendency to stop must thus be recognised as consisting in the interference of friction and the resistance of the medium with the real tendency—the tendency to go on. But we may note one or two further facts concerning the resistance of the medium.

It has this character, that it increases with the velocity of the moving body. This is a physical fact which is unalterable, and as

such it enables us to make certain predictions as to mechanical possibilities. For it follows from this fact that there must be limits to the velocity attainable by a ship moving through the ocean of air, or a ship moving partly through an ocean of air and partly through an ocean of water. The two cases are exactly parallel. In each the difficulty of maintaining a velocity increases as the velocity increases. If a given "horse-power" or strength of engine will yield a given velocity, twice that strength of engine will *not* yield twice that velocity. The same principle applies to the speed of projectiles.

The Spinning Top. The second fact to be noted is that the resistance of the medium—however invisible the medium may happen to be—and however unimportant, as compared with friction, it may be in the case of the cricket-ball, is yet easily demonstrable by a simple experiment, and is found to be very considerable. A heavy metal top will spin in water for only a very short time. In air it will spin for perhaps twenty minutes. Here friction is slight, since the point of contact between the top and the surface is so small. (Try spinning the top on india-rubber—or cheese.) If now the top be spun in a "vacuum"—that is, in a vessel from which the greater part of the air has been removed—it will spin for an hour. Abolish all friction and all resistance from air, and the top would spin *for ever*. Plainly, then, the reader will say, perpetual motion is theoretically possible, though men of science declare that it is not.

There is here an apparent contradiction, but it depends upon a misuse of language. Newton's first law of motion positively declares not merely that perpetual motion is possible, but that it is inevitable and necessary. Every moving thing, it declares, will exhibit perpetual motion if only it be left alone.

Perpetual Motion. But a special meaning has been attached to the phrase perpetual motion, and we must explain that meaning here, since it bears directly upon Newton's laws of motion, and since Newton recognised indirectly, in virtue of his study of motion, that law of the conservation of energy which contains a denial of the possibility of so-called perpetual motion. We have seen that perpetual motion is as natural and necessary—so far as the laws of nature are concerned—as perpetual rest. Each implies the basic principle of inertia. But by so-called "perpetual motion" is meant not perpetual motion at all, but the production of perpetual work by motion, *without any loss or disappearance of that motion*—a very different thing.

As long as motion remains motion it will be perpetual; and, indeed, it may be shown that motion is perpetual, since even when the motion of a body *ceases* it is not *annihilated*, but is really transformed into other forms of motion. Otherwise it would not cease, declares Newton's first law.

The cricket-ball stops rolling, but its motion has been communicated to innumerable particles of air which it has displaced, and has also expressed itself as heat (which is a mode of motion) engendered by the friction between the rotating ball and the ground, and the rotating ball and the air.

Motion Cannot be Destroyed. It would be a case of what is so badly named perpetual motion if the cricket-ball caused all these motions in its path—did all this work—and yet lost none of its own motion. If it were prevented from doing any of this work, it would display perpetual motion in its own body; but in doing work, that is, in imparting motion to its surroundings, it loses its own motion. What is meant, then, by the "impossibility of perpetual motion" is really no such thing: nothing but perpetual motion is possible to any moving thing, unless it bestows its motion to something else. It simply cannot stop save by giving up its motion to something. It cannot destroy its motion. By the *impossibility of perpetual motion* is meant the fact that the cricket-ball cannot *both give up its motion and retain it*. One cannot both eat his cake and have it. One cannot make something out of nothing, nor destroy anything—not even motion. Motion may be got rid of, but it remains somewhere. This is what is meant, as we shall see later, by the law of the conservation of energy.

The Conservation of Energy. Energy—including the kinetic energy we call motion—cannot be created or destroyed. When the ball left the bat, *something was put into it*. The bat lost part of its motion, which the ball gained. If the ball had a tendency to stop, this would mean that the something put into it had a tendency to be annihilated. But there is no such thing as annihilation. The something imparted to the ball remains with it after one yard, and will remain with it throughout an eternal passage through infinity, unless it is transferred to something else.

It must continue to exist somewhere. But if it be imparted to something else—*e.g.* the air or the turf—it necessarily leaves the ball; and so the ball stops. It follows that the ball can do no work without giving up something it possesses. It can do no work without *doing* it. That is what the perpetual motion machines are designed to do: their makers expect them to do work without doing it; to create power out of nothing; to give their motion to a lever or a wheel, and yet to keep it.

We have insisted upon these considerations at length, first because the phrase *impossibility of perpetual motion* is the very worst conceivable way of expressing what it is meant to designate, whilst the utter impropriety of the phrase is let pass by writers in general; and because it is very important, and not sufficiently insisted upon in the text-books, that we recognise the necessary connection and interdependence of Newton's First Law of Motion and the law of the Conservation of Energy. The former is now to be regarded as none other than an expression of a special case of the latter. The law of the conservation of energy includes the fact of inertia.

SHORTHAND

Third Instalment of the Special Course taught on Pitman's Twentieth Century Plan, dealing with Circles, Loops and Grammalogues

By SIR ISAAC PITMAN AND SONS

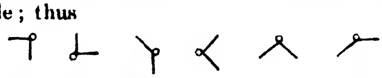
THERE are in the English language a number of frequently recurring combinations of consonants which are represented in Pitman's Shorthand by large circles, loops, and hooks, attached to the consonant stems. After the student has learned the use of the additional sign for *s* (a small circle) in the following section, he will begin to master the series of abbreviations above mentioned. The systematic and general employment of hooks, etc., for doubling and trebling the power of consonant characters forms a distinguishing feature of this shorthand method. The signs can be mastered with comparative ease, and their uniform employment under simple rules, and the readiness with which they can be written, render them an important addition to the speed resources of the system.

Circle S and Z. *S* (together with its heavy sound *z*, for which *s* is generally written) is one of the most frequently occurring consonants in the English language. The consonant *s* is represented, not only by the stroke), but also by a small circle (○), which forms an easy means of joining one consonant to another.

When the circle stands alone, or is joined to straight consonants not forming an angle, it is written with the backward or LEFT motion, thus 

sp, *sk*, *ps*, *ks*.

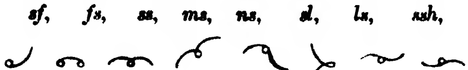
Between two straight lines forming an angle, the circle *s* is written on the OUTSIDE of the angle; thus



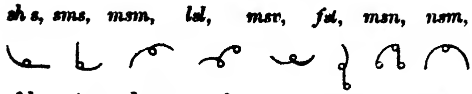
kst, *tsk*, *pst*, *chsp*, *rsp*, *rsk*.

When the circle *s* is joined to curves, it is written inside the curve, and when it occurs between two curves, it is usually written inside the first; as

sf, *fs*, *ss*, *ms*, *ns*, *sl*, *ls*, *ssh*,

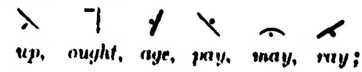


sh s, *sms*, *msm*, *lsl*, *msv*, *fsl*, *msn*, *nsm*,



fsk, *tsn*, *lsm*, *msls*, *nsng*, *ssts*, *slsts*, *lsr*.

The circle *s* is always read *first* at the beginning of a word, and *last* at the end, the vowel or vowels being read according to their positions with regard to the stroke consonant, and not with reference to the circle, as



up, *ought*, *age*, *pay*, *may*, *ray*;

sup, *sought*, *sage*, *pace*, *mace*, *race*.

The succeeding Exercises when in shorthand are to be transcribed in longhand; when in ordinary print they are to be written in shorthand.

EXERCISE.

1. 
2. 
1. Soup, snow, cars, keys, psalm, seed, bees, alms, thaws.
2. Upset, musk, deceit, opossum, tears, beseech, oxide.

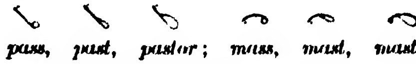
Loops ST and STR. The frequently occurring combination *st* at the beginning of a word, as *stem*, and *st* and *zd* at the end of a word, as in *mist*, *mused*, are represented by a loop made half the length of the stroke to which it is attached. This *st* (stee) loop follows the same rule as the circle *s*, that is, it is always read *first* at the beginning of a word, and *last* at the end; like the circle *s* it is written *backward* to straight letters and inside curves; thus

ache, *sake*, *stake*; *Kay*, *case*, *cased*.

When convenient the *st* loop may be employed medially, thus

vestry, *testing*.

A large loop, extending two-thirds of the length of the stroke to which it is attached, represents *str*. This *str* loop *is not written at the beginning of a word*. At the end of a word it is invariably read *last*. The same rules for writing apply to it as to the circle *s* and the loop *st*, and it is written *backward* to straight letters and inside curves, thus



pass, *past*, *pastor*; *mass*, *mast*, *master*.

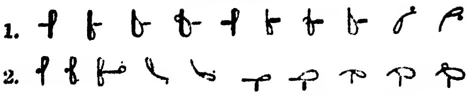
This loop may be used medially, as in

masterpiece.

The circle *s* is added to a final loop, as in the following examples,

taste, *tastes*, *lustre*, *lustres*.

Exercise.



1. Steep, post, stick, kissed, stuff, foist, statue, statute.
2. Jest, jester, jesters, elastic, pastor, foster, Chester.

Large circles SW and SS or SZ. A large INITIAL circle written in the same manner as the circle *s*, represents the double consonant *sw*, thus

seat, sweet, sum, swum. but *sway, swaying.*

A large MEDIAL or FINAL circle, written in the same way as circle *s*, represents *ss* or *sz*. This large circle may be supposed to contain the second-place short vowel *e*, and thus to represent *ses, sez, zes*, or *zez*; thus

necessity; passes; possessive; causes.

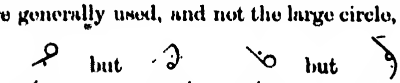
Other vowels may be expressed by placing the vowel-sign within the circle; thus

exist (ek*zist*), *exhaust, exercise.*

Final *s* is added by continuing the circle; thus

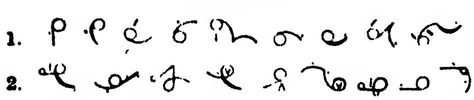
exercises.

When a word has a final accent, the stroke *s* and small circle or the small circle and stroke *s* are generally used, and not the large circle, thus



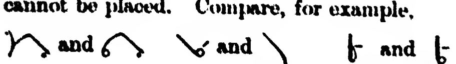
ra'ces, but *recess'; pa'ces,* but *possess'.*

Exercise.



1. Switch, Swedish (*sh* up), swing, swill, swiftest, swivEL.
2. PossessoR, accessory, unsuccessfuL; roses, anaLysis.

Vowels and S and T. As an initial circle or loop must always be read *first*, and a final circle or loop must always be read *last*, it is necessary, when a word begins or ends with a vowel, that stroke consonants be employed, and not circle *s* or loop *st*, to which vowels cannot be placed. Compare, for example,



asleep, sleep; puss, pussy; dust, dusty.

Therefore,

The STROKE consonant must be used—

(*a*) When *s* or *z* is the only consonant in a word, as

saw, sigh, easy.

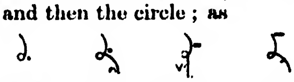
The stroke is also employed in derivatives from such words, as

sawmill, sighing, easiness.

(*b*) When a word begins with a vowel immediately followed by *s* or *z*, as

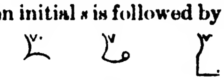
ask, espy, assume, Isaac.

(*c*) When a word begins with *s*, followed by a vowel and another *s* or *z*, the stroke *s* is written and then the circle; as



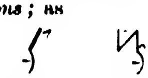
cease, seizure, society, saucer.

(*d*) When initial *s* is followed by two vowels, as



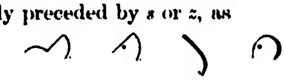
Siam, science, sciatica;

or when final *s* is preceded by two vowels *in different positions*; as



joyous, tortuous.

(*e*) When a word ends with a vowel immediately preceded by *s* or *z*, as

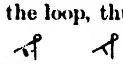


mercy, racy, busy, lazy.

(*f*) When a word begins with *z*, the stroke) is written, thus

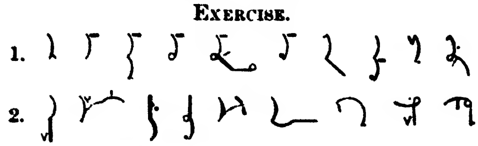
zero, zeal, zigzag.

When the last consonants in a word are *s t* with a vowel between them, and when a vowel follows *s t*, the circle *s* and the consonant *t* must be used, and not the loop, thus



rosette, rusty.

Exercise.



1. Ace, essay, says, espouse, schism, assize, assignee.
2. Dizzy, cosy, rosy, russet. suicide, scissoRS, easel, zenith.

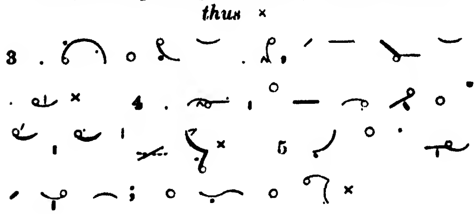
Grammalogues. Frequently occurring words are expressed in shorthand by one of their letters, as ╲ for ╲ *be*. These words are called grammalogues or letter-words, and the shorthand characters that represent them are called logograms or word-letters. Below is given a list of grammalogues which should be committed to memory. These characters are generally written on the line, but often above or through it. The position in which they should be written is indicated thus: (1) *above* the line; (3) *through* the line; all others rest *on* the line.

GRAMMALOGUES.

a, an (1)	*he*	*shall*
all (1)	*him, may*	*should*
and (1up)	*how*	*the*
any, in (1)	*I, eye* (1)	*them*
are	*is, his*	*these* (3)
as, has (1)	*it*	*this*
be	*me, my* (1)	*those* (1)
but	*of* (1)	*to*
can (1)	*on* (1)	*who* (down)
first	*our, hour* (3)	*was*
give	*put* (3)	*why* (1)
have		*you*

EXERCISE.

The full stop is represented by a small cross; thus ×



Grammalogues are printed in italic.

3. CULTIVATION OF THE SOIL

Ploughing, Harrowing, Cultivating, Rolling, Pressing, Sowing. Drainage of Soils. The Value and Composition of Manures

By Professor JAMES LONG

The Ideal Form of Cultivation. The soil is tilled either by hand, horse, or steam power. The chief object in view is the formation of a seed-bed, the mould composing which should be reduced by weathering and the aid of farm implements to as fine a condition or tilth as possible. Owing to their extreme fineness and delicacy, the roots of plants are unable to penetrate as they should in all directions unless the mechanical condition of the soil approaches perfection.

The cultivation of soil has the effect of bringing most of its constituents into contact with the air and the sun, by which means it is better adapted to the feeding of plants, while its texture is improved. The ideal form of cultivation is spade labour, but this is impossible on the farm owing to its great cost. With the spade or the fork the surface of the soil is completely turned, broken up, or laid up in loose clods for pulverisation by sun and rain, or frost, whereas the subsoil may be also dug or loosened without being brought to the surface.

It is owing to the influence of the elements that trenching or double-digging proves so valuable in nursery and garden work. The oftener the subsoil is moved, while kept in its place, and the more it is in this way exposed to air and sunlight, the more rapidly is it improved, and the greater the extent of the feeding ground of the plants which grow above it. The plant food present in the subsoil, practically the second nine inches below the surface, is chiefly present in an unavailable form, but as its future availability depends chiefly upon air, heat and moisture, it is obvious that digging is superior to ploughing, and the subsoil plough, which, unlike the ordinary plough, keeps the subsoil in its place, should be used as often as possible.

Ploughing. Arable land is, in the first place, cultivated solely with the *plough*, which is made in a variety of forms which are described in a succeeding chapter. It is seldom that the farmer ploughs more than nine inches deep or more than a foot in width. As a rule, the greater the depth, the narrower the furrow, for both width and depth increase the draught. It is, too, in most cases, especially where the surface soil is shallow, dangerous to plough too deep in practice, inasmuch as the inferior subsoil would be brought to the surface.

Plants which, like wheat, oats, roots, potatoes, lucerne, and the clovers, are deep-rooted, travelling both laterally and below in search of food and water, prefer deep soils. Barley and other shallow-rooted plants are successfully grown on thin soils where deep ploughing is impossible, but where deep stirring is sometimes essential. The area covered with the plough in a day varies from half an acre on the heaviest clays to one acre on the lighter soils, but this is ruled by the depth to which the plough penetrates, the horses travelling more or less rapidly in accordance with the draught. The form or shape of the furrow to be ploughed should be studied. The object in turning a furrow is to provide space for air beneath, to prevent the further growth of the plant life still growing on the surface, and to present a crest on each furrow, which, in response to the harrows, will work down into a fine seed-bed.

Furrow-slicing. Where land is ploughed in summer for cleaning, or in winter for frosting, high-crested furrow slices are important, as they weather better, and consequently pulverise more completely. It is important, where the soil ploughed is covered with vegetation, that the skim coulter should be attached to the plough, that it may pare the edge of the slice on the land side, and thus remove and bury those plants which, after the furrow has been laid, would otherwise remain partially exposed and in contact with the atmosphere, and thus be induced to continue their growth. The bottom of the furrow should be left flat, and here the horses walk when harnessed in single file.

In Canada and other Colonies gang ploughs are used, so that three furrows may be taken at one working, the driver riding behind his team. This practice is most economical and rapid, but adapted only to large fields. Three-breasted ploughs are seldom used in this country, while double-breasted or double-furrow ploughs are more common for work on hillsides; where the *one-way* or turn-wrest plough is also found most useful. Soil under the plough, unless where it is exceptionally light, is laid up in "lands," or ridges, with open furrows between them for carrying off the water. These lands vary in breadth from the width of a 13-coulter drill upwards, this width depending upon the soil texture. Thus, the heaviest clays are ploughed in lands of 11 or 12 feet, and being crested, or laid up, much higher than the furrows, they remain more or less dry during the winter season. It is essential that all such soils should be underdrained.

The Steam Plough. The steam plough has not proved a very successful aid to British farming; apart from its cost and the damage which follows the movement of the engine on the headlands of the fields, the implements are too clumsy as well as too risky; their work is therefore imperfect and sometimes more or less destructive. There are, however, occasions when fields which have been abandoned

to nature, or which are crowded with weeds, may be steam-ploughed with advantage. Where land has been ploughed with horse power, the steam cultivator may sometimes be used with great success. There is little risk of the subsoil being brought to the surface, while the rapidity and power with which the implement is drawn through the field assists in the reduction of the tilth and the destruction of weeds. The mould-

LINCOLN RED BULL

ing, ridging, or double-breasted plough is employed in forming ridges on which mangels and swedes are grown, and also for covering potatoes, which, planted in the furrow, are subsequently ridged over.

The soil, first ploughed deep, is brought to a fine tilth, especially necessary for the potato, and subsequently ridged throughout with the ridging plough. Manure is placed in the furrows, the potato sets are laid in their places, and the ridges between each furrow are split in two, and the furrows covered, forming in turn fresh ridges or *bouts*. The steam digger, which for some time promised success, has not yet taken hold of the farm. The latest invention, however, in which horizontal discs are introduced into the soil, stirring and pulverising it to considerable depth without turning it over, is suggestive of a marked advance, and possibly when the cost of the implement comes within the range of the farmer's pocket, it may be employed with advantage.

Harrowing and Cultivating. The cultivation of the soil by the aid of the horse *Cultivator*, *Scuffler*, *Grubber*, *Scarifier*, or *Horse Hoe*, is intended to improve the tilth by reducing it to fineness, and removing the weeds. These implements, some of which are large and powerful, are provided with bent pointed tines, which are sometimes shod with arrow-pointed heads or hoes, the horse-hoe in its turn being shod with L-shaped heads or shares. In this way coarse cloddy land is broken down and partially cleaned, but no implement, indeed, no form of labour, produces the same result as sun, rain, and frost, when the land is taken at the right moment. The horse-hoe is especially employed in hoeing between rows of beans, potatoes, mangels, swedes, and cabbages. It not only improves the surface tilth, but cuts down all weeds before it.

Land is harrowed after the plough to produce fine tilth in the seed-bed, and, whether sowing with the drill or the seed-harrow or by hand, with the object of covering the seed. Seed-harrows are lighter and smaller than harrows intended to follow the plough, but the weight depends upon the nature of the soil, for the heavier the soil the heavier the harrow required. In early spring the harrow is frequently drawn across a field of growing corn to kill young weed seedlings, as well as to break the crust which has formed, and to admit air. Similarly, harrows are drawn across meadows before the spring grass commences to grow, for the destruction of moss, the breaking of the soil cap, and the admission of air. Some farmers harrow their turnips as well to improve the tilth as to remove a number of the growing plants which, sown thickly in rows, are subsequently singled with a hand hoe, leaving spaces of 15 to 20 inches between each turnip. In autumn the stubbles are harrowed to kill weeds, and on those farms where *Trifolium incarnatum* (crimson clover) is grown, in order to cover the seed which has been broadcasted.

Rolling, Pressing and Sowing. Rollers are made in two forms—flat, and with a series of loose rings. Both are intended to give compactness to seed beds. After harrowing in the seed, whether corn, clover, or grass, the roller is passed over the land, moisture is preserved, the seed is induced to germinate better, and

GUERNSEY COW

the plant to grow more quickly, while the soil surface remains level and consequently more suitable for ulterior forms of labour. Grass land is rolled after harrowing to give the compactness which has been disturbed by the harrows, as well as to crush excrescences or loose materials, such as stones, which had not been picked up, in order that they may not be in the way of the knives of the mow-

ing machine, and possibly become a cause of accident.

The *Presser*, which is now employed in few parts of England, is drawn after the plough over land intended for wheat. The heavy rings of which it is composed produce deep, if narrow, furrows or impressions, into which broadcasted seed falls, and where it is subsequently covered by the harrows and roller. Although the seed of corn

ABERDEEN-ANGUS BULL

is frequently sown by hand, the prevailing method is now to deposit it in the soil by the aid of a *drill*. The two leading types of drill are those which are known as cup and force feeding drills respectively. The quantity of corn to be sown is regulated, and dropped into the furrows made by the tines of the cylinders, which are known as coulters. The average drill will not only sow corn, but clover, lucerne, peas, and in some cases beans and grass seeds. Grass and clover seeds when mixed are commonly broadcasted by the aid of a seed-harrow, which takes a wide sweep. Sometimes, however, a broadcaster is attached to an ordinary drill, so that grass seeds may be sown with the corn, and, therefore, at one operation. Drills are sometimes made with interchangeable bodies, so that turnip, mangels, and cabbage seed, together with artificial manures, may also be sown with the one machine. The

RED-POLLED BULL

HIGHLAND BULL

typical English drill is much inferior to the Canadian, which is lighter, requiring less horse power, and only one man and a boy—sometimes a man will suffice—instead of two men and a boy. The work is more quickly performed, the wearing parts are simpler, and easily replaced, while the ground covered in a day is measured.

Drainage of Soils. Unless drained effectively, many soils, especially the clays and marshy lands, would be useless for the production of crops. Land needs draining when it is boggy, when rain collects on the surface, or when the water table is so near the surface that the roots of plants penetrate it. A wet soil is often recognised by the weeds which grow upon it, as the sedge and the rush. Draining has the effect of removing surplus water, and of introducing air, consequently it promotes warmth, the soil becomes porous, is healthier for stock, and is followed by the disappearance of water-loving weeds, and the vigorous growth of

WELSH BULL

cultivated plants. The natural growth of crops is earlier, manures act more effectively, the soil is worked more easily, and a more perfect seed-bed preparable. Land may be drained on the surface by making grips or furrows—a common practice on very heavy clay where each "land" is ploughed to the width of the drill; by opening furrows with the spade, and filling with hard bushes, or—and this is the most approved practice—by laying pipes. The common drain pipe, 2¼ inches in diameter or bore, is made of

well-baked clay. It must be laid on a level bed, carry its water into the main drain, which conveys it to a carefully-selected outfall.

The depth at which the pipes are laid depends upon the character of the soil; it varies from 2½ feet in heavy clay to 4 feet in loam. The distance from drain to drain also varies with the soil from 12 to 40 feet. The main drains are laid lower than the collecting drains that the water may be perfectly collected and carried away. The main object of draining is not to remove water from above, but from below, and thus to reduce the height of the water table. It was found at Rothamsted that when the rainfall reached 25 inches some 2,500 tons of water were deposited per acre, of which less than 50 per cent. was evaporated, the balance passing through the soil; it follows, therefore, that on a soil which is not sufficiently porous or well-drained successful cropping is impossible.

The farm student, having learned the principles of draining, should make a point of studying it in actual practice. Especially should he also make a point of examining land which is undrained but which needs draining, and of heavy clay land with crops upon it which has been successfully drained.

MANURES

In order to understand the principles upon which farm production is based, it is necessary to realise that plants feed, and that just as the bodies of animals, including man, are built of materials found in the soil, the atmosphere, and in water, so are the bodies of plants. The plant, either directly or indirectly, feeds the animal, hence the dependence of the one kingdom upon the other, for the waste or excreta of the animal returns to the soil, and after undergoing certain chemical and other changes, becomes food for plants. Manure may be broadly divided into two kinds, farmyard dung, *i.e.*, the solid and liquid excreta of animals, and artificial manures, some of which are bye-products, while others are obtained direct from the soil itself. Farmyard manure is a mixture of the excreta of the livestock of the farm and straw and other litter provided for their comfort. It is the most perfect manure, because it contains all that is necessary for plant life, and because of the mechanical, or physical, action which it exerts, especially on the extremely light and heavy soils. In the consumption of food by stock, whether corn or cake, hay, straw, or roots, only a portion of the nutritious material is utilised, the remainder is evacuated, and as this refuse contains the larger proportion of the fertilising matter present in the ration, it follows that by its return to the soil something is provided for the enrichment of future crops, although not all that was taken from it.

Comparative Values of Food. An animal which is productive, as the cow in milk or in calf, or the steer in process of fattening, utilises more of the valuable properties of food than an animal maintained in merely store condition, hence the manure produced by either is of less value, but in practice the productive animal is usually fed upon rich rations imported on to the farm, so that the manure produced may not only maintain the fertility of the soil, but actually increase it. Where no such food is imported, and where the livestock of the farm are fed solely upon its produce, the soil is gradually impoverished, especially as regards its most valuable constituent, nitrogen. Soil exhaustion, however, may be largely prevented in most cases by deeper and more thorough cultivation. The minerals below, when stirred, are submitted to the influence of air, and the insoluble foods they contain are gradually rendered available.

By the application of nitrogen in some artificial form to soil well supplied with potash, phosphoric acid, and lime, crops may be grown without exhausting it, but no farm practice is generally justified or economical where the employment of dung is ignored. As a soil is infertile where either nitrogen, potash, or phosphoric acid are absent, it follows that care must be taken that it is supplied with each, and in sufficient abundance. The systematic use of dung ensures this; but again, in practice where dung is the product of ill-fed stock, it must be supplemented by artificials containing one or more of these materials if the results are to be successful.

Value of Dung. Still, further, as dung possesses a mechanical value which artificial fertilisers do not, it is essential on both heavy and light soils owing to the importance of improving their texture. Vegetable and animal matter of all kinds contain some fertilising property, hence the compost heap of the gardener and the dung heap of the farmer. Even weeds are convertible into useful manure, but their life must first be destroyed, or the soil may be again infected by their presence, or by the germination of their seeds.

THE COMPOSITION OF MANURE: ANALYSIS OF ITS PROPERTIES.

[The figures given are per cent.]

	Water	Organic Matter	Nitrogen	Phosphoric Acid	Potash	Lime
Farm manure, mixed and fresh	75	21	·40	·18	·45	·49
Do. do. and rotten	75	19	·50	·26	·63	·70
Urine: Cow	92	6	0·8	0·70	0·60	0·07
Horse	89	8	1·2	1·20	0·90	0·04
Pig	97	1½	0·3	1·25	0·08	0·02
Sheep	86	10	1·4	0·50	0·60	0·30

Where dung is built into a heap, the sides should be perpendicular and compact, and the dung from each class of stock thoroughly mixed. As dung ferments or oxidizes, oxygen uniting with certain of its constituents in the presence of air, it should be kept as compact and cool as possible. In the uncovered farmyard, which is usually littered with straw, the manure is subjected to rain and fermentation prevented, but such practice is followed by great reduction in its value, owing to the washing away of a large proportion of its most valuable properties, while the labour of cartage to the land is increased.

Liquid Manure. Unless manure, the urine being absorbed by the litter, whether straw or peat moss, is daily carted to the fields, it should be heaped under cover, and above a tank intended for the salvage of the liquid. If a pump is erected above the tank, and in the centre of the heap, the liquid may be daily distributed over the solid manure, and while being absorbed, thus keep the heap cool. As we shall see later, the liquid excreta, weight for weight, is of greater value than the solid excreta of stock, although it is extensively wasted in farm practice. If this liquid, *i.e.*, urine, is drained into a tank, as already suggested, it must be diluted with about twice its volume of water in order to prevent the loss of its nitrogen, which will otherwise escape in the form of carbonate of ammonia. It follows that, from what has been said, a dung heap should be covered with a simple roof to prevent its damage by rain. Where a manure heap heats—and heating is more rapid in the case of the excreta of the horse than of the heavier excreta of cattle and pigs—nitrogen in the form of ammonia is quickly lost, while if washed by rain, the drainings will remove a large proportion of the two chief mineral fertilisers, potash and phosphoric acid. The loss of nitrogen may be prevented by the employment of gypsum (plaster of Paris) or the potassic fertiliser kainite, or even by the liberal distribution of dry earth.

Effect of Covered Yards. In farm practice of the best kind cattle and pigs are largely kept, as, indeed, are sheep in France, in covered yards or sheds, with the result that less straw is employed as litter, and the manure produced is not damaged by rain. Upon the condition of farming manure much depends. In rotten or fermented dung fertilising materials are more readily available to plants, although largely diminished in weight, this loss being due to oxidation and consequently to combustion. Fermented dung, however, is mechanically more useful than fresh or light dung containing abundance of straw, for the lighter soils, which it renders more compact, a remark which equally applies to heavy cow and pig dung; moreover, as these soils are not retentive, some of the fertilising constituents of raw or unfermented dung are quickly washed into the subsoil or the drains before they have been taken up by plants. On the other hand, unfermented dung, in which the litter is whole, improves the texture of the heavier soils, which it heats as it decomposes, while its fertilising properties are not wasted owing to the retentive power of soils of this character. Bearing these remarks in mind, it should nevertheless be understood by the student of farming that, while there is always loss as between the production of dung, solid and liquid, by stock, and its being covered by the plough, the loss is immensely smaller where it is taken into the field in quite fresh condition, the urine being absorbed by the solids and the litter, and still further that the results are inferior where the solid manure is used without the liquid.

There are many opinions as to the quantity of manure produced by animals. Much depends upon their weight, the food and water they consume, and, where litter is employed, upon the quantity supplied to them, but observations which have been made point to the production of from 8 to 10 tons, including litter under cover during the winter season of six to seven months.

Fertilising Materials. This may be estimated in the following way, it being first understood that the weight of the chief fertilising materials—nitrogen, phosphoric acid, and potash—present in a ton depends altogether upon the quality of the food consumed by the stock producing it, upon its condition, whether fresh or rotten, and the manner in which it has been preserved. Thus there may be from 9 to 15 lb. each of nitrogen and potash, and from 4 to 10 lb. of phosphoric acid. If, therefore, we take a sample containing 0·4 per cent. of nitrogen, 0·2 per cent of phosphoric acid, and 0·45 per cent. of potash, and value the nitrogen at 6*d.* a pound, the phosphoric acid at 2½*d.*, and the potash at 1½*d.*, we arrive at a total value of about 7*s.* 1*d.*

To this, however, something should be added to represent the value of the mechanical action of dung, which we believe has never yet been estimated; but if we place this as low as 2*s.* 6*d.*, we get a total of 9*s.* 7*d.*, which represents a ton of farm manure of quite moderate quality, although it is commonly sold by villagers and others to farmers at as little as 5*s.* A first-rate sample of dung valued in the same way would be worth some shiliings more; hence our desire to impress upon the reader the immense importance of care in the management of what, after all, is one of the most valuable properties of the farm. In daily practice a student will find that this value is largely ignored, that dung on the majority of homesteads is exposed to the rain, and consequently to partial destruction.

THE ARCHITECTURE OF THE BODY

Various Tissues described. Chemical Composition of the Body. Repair and Decay. Uses of Food. How Temperature is regulated

By Dr. A. T. SCHOFIELD

The Tissues of the Body. We shall not here enter into a minute description of all the eight tissues, of which, as we have seen, the body is made up, because three of them, the *muscular, nervous, epithelial*, or *skin*, will be treated later. Of the remaining five, we shall examine the two most important, the *cartilaginous* and *bony*, first, and then briefly notice the *adipose*, or fat, the *fibrous*, and *connective* tissues.

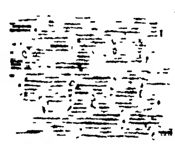
Cartilage forms the models of all the bones in the fœtus, or infant before birth (except the flat bones, which are made from thick membrane), and is the precursor of bone. It also persists through life in some parts to supply a smooth surface in joints to form tubes and to provide a yielding framework when required, as in the front of the chest. Cartilage is composed of cells, imbedded in a large amount of intercellular substance, that multiply by fission within the cell-wall, or capsule, which eventually forms the intercellular substance. It is generally covered with a membrane called *perichondrium*. It contains *no nerves*, and is of three varieties—*hyaline, white fibrous*, and *yellow elastic cartilage*.

Hyaline cartilage [16] has an intercellular substance or *matrix* like ground glass, which really consists of layers of *laminæ*, like those of an onion, round the cells. It contains no blood-vessels, and is principally found in joints, and in the ribs and nasal cartilages.

White fibrous cartilage has an intercellular substance or matrix of white fibres arranged in layers. It is found in a cartilage in the knee-joint, between the vertebra in the back, and in a few other places.

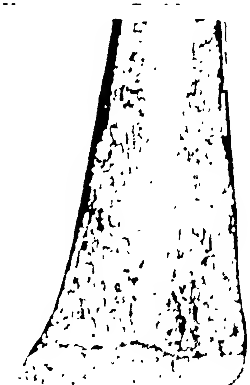
Yellow elastic cartilage has a matrix of yellow elastic fibres, and is found in the external ear, the epiglottis at the back of the tongue, and in the eustachian tubes, that lead from the throat to the ear [17].

Bones. Bones [18] form the framework of the body, and are hard, tough, and elastic. They are twice as strong as oak; one inch of compact bone will support 5000 lb. weight. They are a compound of two-thirds earthy material, principally phosphate of lime, and one-third animal, principally gelatine. They contain also a little carbonate and fluoride of lime, and phosphate of magnesium. These are so intimately blended that all the lime can be dissolved out by weak hydrochloric acid, and yet leave the bone the same shape, but flexible; or the gelatine can be removed by boiling with the same result as to shape, only the bone becomes brittle.



16. CARTILAGE CORPUSCLES

17. FROM A SECTION THROUGH THE EPIGLOTTIS
a. Perichondrium
b. Network of elastic fibrils surrounding the cartilage cells

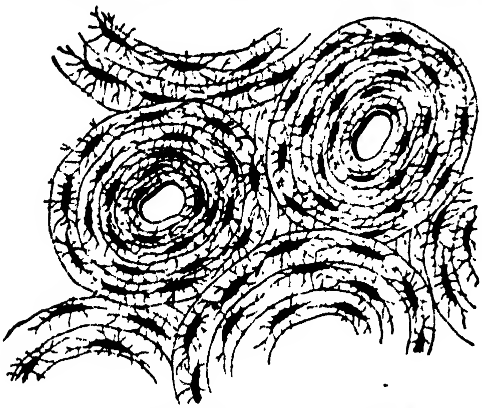


18. SECTION OF BONE
Natural size

The animal matter is in excess in the bones of the young, making them tougher; and the mineral in those of the old, making them more brittle. One cannot really break a baby's bones, which are like leather; whereas an old person's thigh-bone may snap right in two, from a fall on a carpet. Bone is of different qualities—*ivory*, or *dentine, compact tissue*, and *cancellous tissue*, or *spongy bone*. We get dentine in the teeth, compact bone in the shafts of the long bones, and cancellous tissue in their ends. Cancellous tissue is like pumice-stone, only the lattice work is beautifully arranged in regular Gothic arches, so as to support the greatest pressure with the smallest weight. One cubic inch, weighing a drachm, can support 500 lb. Flat bones have an exterior of compact tissue, and a layer of cancellous tissue inside.

Construction of Bone. Under the microscope [20] bone is found to consist of vertical bundles of scaly plates, with spaces between called *lacunæ*, connected together by tiny canals called *canaliculi*, $\frac{1}{20000}$ inch in diameter, and surrounding central ducts called *Haversian canals*, which branch and are connected with each other. In the lacunæ are large branched cells called *bone corpuscles*, the only really active living parts. They

never move, but spend their lives in nourishing the bone surrounding them. Round the bundles [19] of bony scales surrounding each Haversian canal



19. TRANSVERSE SECTION OF BONE
Showing laminæ, lacunæ, and canal

are other layers, binding, as it were, all together into the complete bone. These scales are all impregnated with lime salts. Bone is a substance formed out of cartilage in the following way: In the child before birth there is at first no bone, but models of every bone are formed in cartilage, which changes into osseous tissue. In the cartilage of the limbs, for instance, lime salts begin to form in the shaft, and at each end, until each of these three parts is changed into bone, the only cartilage left being a disc between the shaft and each end [21].

20. LONGITUDINAL SECTION OF BONE
a. Haversian or bone canals
b. Bone corpuscles

Let us notice the reason for this arrangement in the growing child and look at the difference between the shin-bone of a child and an adult [22]. While this bone is growing it is actively used all the time at the joints, as the child moves about. The part here must necessarily be hard, and the bone cannot therefore grow at the ends. It is consequently made in three pieces, and continues to grow just where the cartilage rings are till eighteen or twenty; then the cartilage disappears, and all three parts unite in one, and the length of the bone is finally fixed. Many bones are in *more* than three pieces in childhood. Take the bones of the spine, for instance [23]. Here we see that no fewer than six pieces are fused into one at manhood. This will explain how carefully a growing child should be handled, and how straight the spinal column should be kept, when it is built up of over 200 pieces instead of 26 solid bones.

Flat bones like the shoulder-blades and the bones of the skull are formed of tough membrane instead of cartilage, and in it the lime salts grow in the same way.

Shape and Size of Bones. Bones are hollow to make them lighter and stronger. In birds they are filled with warm air, which in the swift swallow enters even the small bones of the toes. The tubular construction, with its resultant strength, is common throughout nature. When Galileo, the great astronomer, was a prisoner in the Spanish Inquisition, accused of infidelity, he picked up a hollow straw from his dungeon floor and said, "If there were nothing else in Nature to show me the existence of a God, this would suffice." The interior of the bones in man is filled with *marrow*, except in the air-cells of the frontal bone and some bones of the face. *Red marrow* is found in cancellous tissue, and contains large numbers of lymph corpuscles and blood corpuscles. This marrow is probably one of the sources of the blood corpuscles. *Yellow marrow* (mostly fat) fills the shafts of long bones.

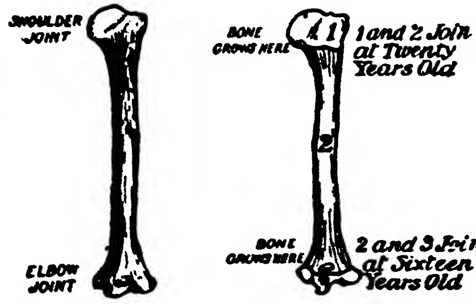
Bones are of many sizes and shapes, but may roughly be divided into four varieties:

1. LONG BONES. These are chiefly found in the limbs and ribs. They form long levers by which the arms and legs are moved. They consist of a middle part or shaft and ends or extremities, covered with cartilage, the bones themselves being covered with fibrous tissue, which forms a tough skin (*periosteum*) over them. The shaft is generally hollow, and contains the blood-vessels, and some fat called marrow.

2. SHORT BONES. These are found in the wrist and ankle, and wherever great strength is wanted in a joint.

3. FLAT BONES. These are like plates, flat or rounded, and are used to protect parts. They are formed of two hard outer layers, with light spongy tissue between. The skull and the shoulder-blades are made of flat bones.

4. IRREGULAR BONES. These include all



21. DIAGRAM OF ADULT AND GROWING BONE

the bones of no particular shape, such as the vertebræ of the backbone, and some others.

Other Kinds of Tissue. Adipose or fat tissue exists all over the body between the muscles and the skin, as a protective covering, and a retainer of heat, fat being, like the felt covering a boiler, a non-conductor of heat. It is also used internally as packing round various organs. It is formed of loose fibrous tissue full of cells, containing globules of oil. No tissue in the body varies so much in quantity at different times.

Fibrous tissue is made up of strong fibres with a few cells, and forms the tendons and ligaments, and all the strong bands of the body; whether attached to muscles, surrounding joints, or binding the various bones together [24].

Connective tissue is absolutely everywhere, and connects all the other structures and tissues together by masses of loose fibres with scattered cells.

As the intercellular substance is the cement between cells that form each tissue (cartilage, bone, etc.), so the connective tissue is the mortar for the whole body, that forms all the structures and tissues into a solid building.

Chemical Construction of the Body. Let us emphasise, even at the risk of going over old ground, the great fact that life consists of *Metabolism*, in other words of *incessant change*; and trace roughly the process by which the change is effected. Then we shall *analyse the body* and resolve it into its several constituents, noticing the remarkable fact that the food of the body, which is considered in its proper place in the section on HEALTH, exactly corresponds with the analysis of the materials of the body, showing thereby how entirely it meets its needs.

We shall then discuss the means by which the *body heat* is manufactured and maintained; and so grasp the fact of the enormous force required to warm a man of some 150 lb. weight to a constant heat of nearly 100° F., whatever the external temperature may be: a force that runs to nearly 3000 foot-tons (or tons raised a foot high) per day. Lastly, we shall consider the daily *gain and loss of the body*, and thus be prepared to commence the study of Physiology proper, to which these first two sections form an introduction, and which consists of a detailed description of the vital processes of the various systems of the body.

a. A capillary blood-vessel. *b.* Bundles of fibrous tissue. *c* The connective tissue corpuscles. *d.* Plasma cells

Repair and Decay. Let us then glance first at the great question of METABOLISM. Life has been shown to be a condition of incessant change, dependent on the two opposite principles of *repair* and *decay*.

One twenty-fourth part of the body (more or less) wastes every day, and this has to be made good. To effect this, we have to take in fresh material at the rate of about *a ton a year*. Life has been happily said to be a condition of *dynamic equilibrium*, never absolutely balanced, however, but ever oscillating to one side or the other. We are never exactly the same weight for two minutes together.

If a person could be placed upon a scale, accurately balanced with his weight, at 6 a.m., and carry on his day's routine in that position he would find while lying in bed the scale was very slowly rising, as he got very gradually lighter, from the slow wasting of the tissues. When he began to dress he would find himself ascending in the air more quickly, presuming, of course, that his clothes are not weighed, the destruction of the body being much more rapid with any exertion. At breakfast the scale would suddenly descend from the food taken, to far below its level at 6 a.m. Then, till lunch, if in active business with brain or manual work, he would rise steadily from the loss of weight. At lunch the descending movement would be repeated, and thus the daily round would go on.

The whole of these changes that take place in the living body are included in the one word, *Metabolism*; which includes not only the wear and tear of life, the destruction or *Katabolism*, and repair or *Anabolism*, of all living tissue, but also the processes producing the manifestation of living force and energy necessary to its storage and expenditure. Animal force and energy are

evolved by the reduction of *complex* substances to *simple*.

A complex substance, such as meat, is built up of large numbers of molecules like a tower of bricks. Of course, force or energy has been required to do this. As this substance is reduced to simple bodies, containing fewer molecules, such as *urea*, *carbonic acid*, and *water*, the force stored up in the meat as *potential* energy becomes manifested and used as *kinetic* energy, or active life force.

Life a Twofold Process. The whole process of life is, therefore, twofold; the one consisting in the reception, assimilation, metabolism, and excretion of matter, or the *vegetative function*; the other in the *animal functions*, or the direction of the energy thus set free by means of the will, nerves, and muscles to the purposes of life.

Food is, therefore, required for two great purposes: (1) to repair the tissues of the body, and (2) to be stored as potential force for future use. In regard to food, we have to consider both quality and quantity. It must be suitable and it must be sufficient. To be suitable for repair, it must be homologous, *i.e.* of the same nature as that which has to be made good. If of a different nature it is heterologous, and is a poison or medicine, not a food. We will, therefore proceed first to examine the composition of the human body.

The Composition of the Human Body. The human body contains one fourth of all the known elements (17 out of 67). Chief among them in importance and quantity are the four non-metallic elements: *oxygen*, *carbon*, *hydrogen*, and *nitrogen*; and the three metals, *calcium*, *sodium*, and *potassium*. The following is a rough analysis of the body:

Oxygen [O]	72·0
Carbon [C]	13·5
Hydrogen [H]	9·0
Nitrogen [N]	2·5
Calcium [Ca]	1·3
Phosphorus [P] and Sulphur [S]	1·2
Sodium [Na], Potassium [K], Chlorine [Cl], Iron [Fe], Magnesium [Mg], Silicon [Si]. Traces only of Lead [Pb], Copper [Cu], and Aluminium [Al]	·5
	100·0

It will thus be seen that the metals form less than 2 per cent. of the whole body.

In round numbers we may say the body is $\frac{3}{4}$ O, $\frac{1}{8}$ C, $\frac{1}{10}$ H, $\frac{1}{40}$ N. Its average weight is 150 lb., of which 113 lb. are water, and 37 lb. solids, made up as follows: Muscles, 17 lb.; fat, 6 lb.; food in blood, 4 lb.; bones, 10 lb.

A more graphic way of considering the composition of the body is to compare its contents and their quantities to well-known articles of food, or commerce. This has been done in many ways. For instance, it is computed that a woman's body is equal in composition and amount to 1000 eggs.

She is composed of gases, liquids, and solids. Of oxygen there is enough to fill 200 36-gallon barrels; of nitrogen 4½ lb.; of hydrogen, enough to fill a balloon capable of lifting the woman over 2000 feet; of carbon 21½ lb., or enough to make 9000 lead pencils; of iron there are 48 grains, enough to make five tacks; of salt enough to fill six saltcellars; of phosphorus, 3½ lb., enough to make 8000 boxes of matches; of water there is enough to fill a 9 gallon barrel.

Substances of the Body. Leaving these fantastic ideas, we must remember that the various substances of the body do not occur often as elements, but chiefly as compounds, which are generally of great complexity. The following are the chief of these:

1. INORGANIC LIQUIDS. WATER. This forms two-thirds by weight of the whole body. The fluids of the body contain from 80 to 99 per cent. The solids vary from the enamel with 2 per cent. to the kidneys with 82 per cent. Skin, hair, muscle, are all three-fourths water; bone and cartilage, one-half; and fat about a quarter.

ACID. Hydrochloric in the gastric juice.

2. INORGANIC GASES. These include chiefly O, H N, and CO_2.

OXYGEN [O]. This gas is essential to all vegetable and animal life. It is the only element directly used in the body—to the extent of 7000 grains daily, which represents also, of course, the daily loss.

HYDROGEN [H]. This gas, by its combination in the body with O, forms water. It also enters into nearly every organic compound.

NITROGEN [N]. This gas is found in the body in its free state, merely as a diluent of oxygen; though in combination it is an integral part of every tissue. The daily quantity lost by the body is 300 grains.

CARBONIC DIOXIDE, or CARBONIC ACID GAS [CO_2]. This is formed in the body by the combination of O with carbon.

CARBON itself is also a most important part of organic compounds; 5000 grains a day are used, and it enters into nearly every part of the body.

3. INORGANIC SOLIDS. SALTS. Chiefly chlorides of sodium, and potassium, and phosphates of calcium, and sodium. Sodium chloride (common salt) is the most important of these. It occurs everywhere, and is absolutely necessary for existence.

CALCIUM PHOSPHATE is the most abundant salt, and forms half of the bones.

Organic Bodies. These may be divided into two great classes, *nitrogenous* and *non-nitrogenous*. The first consists mainly of albumen (proteid), the latter of starches, sugars, and fats.

1. NITROGENOUS COMPOUNDS. These all contain C, O, H, N, and S (sulphur). They include *albumen* of all sorts (like the white of egg) found in all cells, forming the bases of protoplasm; in the blood and lymph, in muscle and nerve, in cartilage and bone, and in the skin.

SECRETIONS. These include the constituents of bile (glycocholic and taurocholic acids), bile pigments, and all the ferments, and digestive fluids of the body that contain nitrogen.

Excretions. These are the effete products of the body, and include urea. uric acid, leucin, tyrosin, etc., passed by kidneys and bowels.

2. NON-NITROGENOUS COMPOUNDS. These are divided into the two great classes of *Carbohydrates* and fats and oils, or *Hydrocarbons*.

Carbohydrates. These bodies all contain carbon, also hydrogen and oxygen in the proportion to form water, and include animal starches, such as *glycogen* in the liver and *dextrin* in muscle; also *sugars* found in the liver, blood, muscles, etc.

Hydrocarbons, or fats and oils. These contain carbon, and hydrogen and oxygen, but not in the proportion to form water. They are found in all body fat, in bile, etc.

A close comparison of this list of the constituents of the body with that of foodstuffs in the section on Health will show how surprisingly they resemble each other. The food taken is exactly adapted in detail to the waste of the body, and that so largely by instinct, that few have any idea why certain articles are food and others are not, and why they are eaten in certain proportions. A comparison of these two sections will give the key.

The Heat of the Body. The heat of the body is maintained by chemical reactions; mainly by the combustion of O with the production of CO_2 and water. It is a form of energy, and is produced by the vibration of the molecules. The ultimate source of it is the food, and oxygen taken into the body; and the cause of it is the metabolism or vital changes of the body. The amount of it depends upon the amount of these changes. The repair, building up, or *anabolism* of the tissue is, however, believed rather to absorb heat than to evolve it. It is in the decay, oxidation, or *katabolism* of the tissue that heat is principally evolved. It is found, indeed, by direct experiments that the amount of C and H that unite in the body in twenty-four hours with O is sufficient to maintain the body temperature for a day. The energy stored in the food of the body could be truly described as latent heat, were all of it used in the production of heat. Nevertheless, though some of it produces mechanical and electrical energy, it is convenient to measure its potential forces under the head of *heat units*.

Heat Units. A heat unit is the force that raises one pound of water 1° F., and corresponds in mechanical energy with 772 work units (a work unit being 1 lb. raised one foot high). In other words, it requires 772 times as much force to raise 1 lb. water 1° F. as it does to raise 1 lb. one foot high. The amount of heat units in any food is found by burning it in a closed chamber, surrounded with a fixed quantity of water; which in its turn is in a chamber, isolated by non-conducting substances and cold water, from any external heat. The heat evolved passes by means of a coiled lead tube through the water, and the increase of its temperature, ascertained by delicate thermometers, multiplied by the volume of water, readily gives the number of heat units. A living animal can be placed inside the chamber instead of food, and the heat it gives off, passed through the water in like manner, shows the number of heat units it evolves.

It is thus found that 52 parts of fat contain as many heat units as 100 of albumen, or proteid, 114 of starch, or 130 of sugar. The reason that fat gives so much more heat than starch or sugar, is, as I have said, that in the latter the H and O are in the proportions to form water, so that the C alone is burnt; whereas in fat there is always a great excess of H, so that both C and H oxidise, and are sources of heat. Some heat, no doubt, enters the body through hot drinks.

The places where most heat is produced are the muscles, the secreting glands and organs and the brain. The muscles form about one half of the body, and the bones nearly the other half. The latter produce but little heat, whereas the former are the greatest *thermogenic* (*i.e.* heat-producing) centres in the body. Muscle-work forms about one-fifth of all the work done in the body, and nine-tenths of it is produced in the form of heat units, and only one-tenth in mechanical energy. The heart must be included with the muscles as a thermogenic centre.

The secreting glands, such as the liver, produce heat. With salivary glands, the blood leaving them is a degree hotter when they act than when they are passive. In the liver of the dog the temperature is often 105°.

The brain, by its active *metabolism*, is also a source of heat.

Other small sources of heat are the concussion of joints, the friction of muscles, blood, the formation of salts, and other chemical changes.

Warm and Cold-blooded Animals. Warm and cold-blooded animals have lately been called *homoiothermal*, or of uniform heat, and *poikilothermal*, or of varying heat; because the real difference between them is that the blood in a warm-blooded animal remains the same, notwithstanding variations in surrounding temperature; while the blood in the cold-blooded animal varies with the surrounding medium.

Of warm-blooded animals (mammals and birds), man has a temperature of 99° F. (98·6 in the armpit); the average temperature of the mammalia being 101° F. In birds the average temperature is 107° F. Amongst cold-blooded animals many vary but slightly with the surrounding temperature. Snakes average 82° F.; in cold weather they are hotter, and in hot, colder than the air. Fish are often one or two degrees warmer than the water. The frog is generally about half a degree warmer than the water.

In warm-blooded animals the metabolism and the consumption of oxygen increase in cold weather and decrease in hot; whereas in cold-blooded animals the metabolism and the consumption of oxygen decrease in cold weather and increase in hot.

This shows that there is some regulating centre that governs the production of heat. That this centre is *nervous* is shown by the fact that after poisoning with curari—a nerve poison—this regulating power is lost, and the

warm-blooded animal behaves like a cold-blooded one. Though the blood can complete the circuit of the body in twenty-three seconds, the temperature varies as follows:

On the skin from 72·6 F. at the tip of nose and ear to 98·6° F. in closed axilla; the average being about 92 to 94° F. The skin is observed to be warmer over muscles than over bone.

In the rectum the temperature is 100°. In the blood it is 102° F., in the brain 104° F., in the liver and heart 106° F.

Muscles and glands increase in heat one degree during action, and the brain about half a degree.

Conditions Governing Heat. The principal conditions affecting the mean temperature of the body are age, sex, period of day, exercise, season, food, poisons and disease.

AGE. In the newly-born the temperature is one degree above normal, also in the very aged; but in these, the governing centres being feeble, exposure soon lowers it to a dangerous degree.

Infants and children are much subject to feverish attacks, owing to the activity of their metabolism, and the imperfect development of the regulating centre. From 28 to 65, this centre being fully developed, the temperature of the body is kept more uniform; while in old age variation from slight causes again occurs readily.

SEX. In woman the temperature is higher than in man.

PERIOD. The temperature rises during the day and falls during the night, being highest at 6 p.m. (99·8° F.) and lowest at 2 a.m. (97·6° F.), at which hour most deaths occur.

EXERCISE. Active exercise will increase the temperature from one degree to two degrees Fahrenheit.

SEASON. In summer the temperature sometimes temporarily rises to three degrees higher than in winter. Climates varying 100° F. have no permanent effect on body temperature.

FOOD. There is a very slight rise after food; a fall of one degree after taking cold alcohol; and a temporary rise of five degrees after taking hot alcohol, with a subsequent fall.

POISONS. Alcohol, quinine, aconite, etc., decrease temperature; strychnine raises it.

DISEASES. In diseases the temperature varies from 77° F. in Asiatic cholera to 107° F. in pneumonia. After death the temperature rises for a short time, especially at the onset of *rigor mortis*.

Nature's Economy. The heat of the body may be regulated by altering the amount lost or produced. In the body this is done in various ways, the process being governed by a nervous centre. Body heat is *diminished* by the skin, lungs, urine, cold food, cold alcohol, and air. By the skin about 75 per cent. is lost; by the lungs 20 per cent.; by urine, etc., 3 per cent.; and about 2 per cent. in other ways.

Heat is lost from the skin by *conduction*, *radiation*, and *evaporation*. Besides the central regulating power, the skin has a power by reflex action. A hot atmosphere acts on the sensory nerves, and by the vaso-motor nerves *dilates* the surface capillaries and reduces the heat by evaporation. A cold atmosphere, on the other hand, *closes* the capillaries and retains the heat in the body. Thus external heat and cold, through the wondrous economy of Nature, defeat their own ends.

There appears to be in the action of the skin a balance between *radiation* and *evaporation* that tends to assimilate the loss in winter and summer. In cold weather much heat is lost by radiation, little by evaporation, the capillaries being contracted. In hot weather much is lost by evaporation and little by radiation, the temperature being so high.

The loss of heat from the skin can be largely regulated by clothing; wool, being a bad conductor, is obviously the best covering for the skin. A naked man is said to be unable to maintain his normal heat when the temperature is below 81° F.

The loss of heat by the lungs is fairly constant, as, unlike the skin, they have no power of reflex action. The loss does not, moreover, vary with the surrounding temperature, and but little with exercise.

Regulation of Heat-production. The production of heat can be regulated by *food*, *exercise*, and *nervous influence*. Amongst foods, fat, as we have seen, gives the most heat. In paralysis, the affected part loses heat. In nervous excitement heat is increased, in nervous depression it is diminished. In exercise the increased heat is largely counterbalanced by the increased loss. The shivering from cold helps to warm the body. It is calculated that a man produces nearly two heat units per minute; that is a force able to lift nearly three-quarters of a ton one foot high. I have already spoken of a heat-governing centre. This probably controls the heat-producing and heat-losing centres. Nothing is known of the details of the action of these centres. Great extremes of dry heat can be borne for a short time owing to the power of evaporation possessed by the skin; thus 260° has been borne for eight minutes, while Chabot, the fire king, entered an oven at 500° F. At the same time, if the heat is moist evaporation is prevented, the air being already saturated, and 112° F. cannot be endured.

Death from too great heat appears to arise from too rapid and exhaustive metabolism; that from cold from too slow and diminished metabolism; death in the latter coming with torpor and sleep.

The Balance-sheet of the Body. Now turn to consider the interesting question of the daily GAIN AND LOSS of the body; in other words, to present its balance-sheet.

The body loses daily 2¼ lb. of solids and gases and 6 lb. of water.

This loss is made up as follows:

The lungs contribute 5,000 grains of H_2O and 15,000 of CO_2. The skin contributes 11,500 H_2O and 250 of solids and gases. The kidneys contribute 23,000 H_2O, and 1,100 solids. The intestines contribute 2,000 H_2O and 800 solids.

The body receives daily nearly 1¼ lb. (8,000 grains) dry food, 5½ lb. water (as liquid or combined with food), and 1¾ lb. of oxygen gas.

It will be observed that half a pound less

water is taken in daily than is given out. The difference is made up by combustion in the body. Nearly the same amount of nitrogen that is taken in is excreted as urea.

This daily amount of gain and loss may be regarded as income and expenditure; while the weight of the body partly represents the capital.

Observe that the body receives a *solid* (food), a *liquid* (water), and a *gas* (oxygen). It excretes a *solid* (urea and excreta) by intestines and kidneys, a *liquid* (water) by intestines and kidneys, a *liquid* (water) by kidneys and skin, and a *gas* (carbonic acid) by the lungs.

The amount of food taken represents about 3400 foot-tons (tons raised one foot high) of force, and of this nine-tenths, or 3060 foot-tons (a force equal to lifting a man 8¼ miles high), are used in maintaining the heat of the body, and the remaining 340 foot-tons in the active functions of life, whether in storing force by its physiological processes or spending it by its nervous or mechanical energy.

Now let us consider the chemical analysis of the 8½ lb. that are lost daily. This amount may be divided into 1 lb. solid, 1½ lb. gas, and 6 lb. water. The water and gas need no analysis. The solids contain 4500 grains of C, 300 grains of N, or the general proportion of 15 parts of C to 1 of N. The quantities of hydrogen and oxygen in the solids are of no moment, as they can be supplied by air and water to any amount free of all cost.

If these two elements, C and N, could, therefore, in their uncombined state, be used as food, the problem of diet would be solved; but, unfortunately, animals cannot feed on C or N as elements, and we have, therefore, to find that food that will supply the right quantity of these elements with the least waste. This problem is solved in the section on HEALTH.

The Body a Steam Engine. It may be profitable in various ways to compare the vital action of the body with a steam engine.

Three pounds of coal, costing one penny, will, properly burnt, raise one ton half a mile high and boil 22 quarts of water.

Three pounds of food, costing one shilling, will raise one ton half a mile high, or carry the body, with a weight of 85 lb. on it, 20 miles in seven hours, besides warming and repairing the body. Or,

Three pounds of food, costing one shilling, will repair the body, boil 22 quarts of water, and raise one ton half a mile high.

The outcome of all this is that the body is about twelve times as expensive to work as a locomotive. Of course, food varies in the amount of force it gives out. Theoretically, 100 lb. of fat gives the same force as 213 of proteids, or 202 of starch or sugar.

We must remember, moreover, that for every foot-ton (one ton raised one foot) done in mechanical work (motion, locomotion, etc.), nine foot-tons are used in maintaining the body heat, and other processes.

The amount of air food required varies, of course, enormously. For instance, in a state of rest 480 cubic inches of air are breathed per minute; if walking three miles an hour, 1550; if running six miles an hour, 3260. So delicate is the automatic supply of air food, that there is a difference in the rate of respiration between travelling third and first class, and between sitting up and lying down.

The average man requires, to replace the waste of the body, 307 grains of nitrogen and 4700 of carbon daily, besides oxygen and hydrogen (unlimited)—*i.e.* about the same that we have seen is lost. The following are actual amounts used daily in four different sorts of work:

	Nitrogen Grains	Carbon Grains
London needlewoman ..	135 ..	3270
„ navvy	350 ..	6200
Prisoner, light work ..	226 ..	4356
„ hard labour ..	263 ..	5013

Weston, the pedestrian, used 545 grains of nitrogen and 7880 of carbon to produce 790 mechanical foot-tons of force which he spent in walking 50 miles a day.

NOTE. On page 96 the figure 96¼ on fourth line from bottom of the right-hand column should be 98¼. In the Short Dictionary of Physiological Terms on page 102 (which was compiled independently of Dr. Schofield's course) the word "inner" in the definition of *Fibula* should be "outer."

Section I. GRAMMAR.

Nouns: Third Declension. The Third Declension has two divisions: (*a*) Consonant stems; (*b*) -*i* stems.

Roughly speaking, the nouns in the first division have more syllables in their genitive singular than in the nominative singular (Imparisyllabic), while those in the second have the same number of syllables in the genitive singular as in the nominative singular (Parisyllabic).

Consonant Stems: Masculine and Feminine.

Singular.

	Judge, m.	*Man*, m.	*Age*, f.	*Lion*, m.	*Foot*, m.	
N.V.	judex	homo	aetas	leo	pes	—
Acc.	judic-	homin-	aetat-	leon-	ped-	EM
Gen.	judic-	homin-	aetat-	leon-	ped-	IS
Dat.	judic-	homin-	aetat-	leon-	ped-	I
Abl.	judic-	homin-	aetat-	leon-	ped-	E

Plural.

N.V.A.	judic-	homin-	aetat-	leon-	ped-	ES
Gen.	judic-	homin-	aetat-	leon-	ped-	UM
D. Abl.	judic-	homin-	aetat-	leon-	ped-	IBUS

Singular.

	Father, m.	*Law*, f.	*Honour*, m.	*Cinder*, m.	*Swine*, com.	
N. V.	pater	lex	honos	cinis	sus	—
Acc.	patr-	leg-	honor-	ciner-	su-	EM
Gen.	patr-	leg-	honor-	ciner-	su-	IS
Dat.	patr-	leg-	honor-	ciner-	su-	I
Abl.	patr-	leg-	honor-	ciner-	su-	E

Plural.

N.V.A.	patr-	leg-	honor-	ciner-	su-	ES
Gen.	patr-	leg-	honor-	ciner-	su-	UM
D. Abl.	patr-	leg-	honor-	ciner-	su-	IBUS

Consonant Stems: Neuter.

Singular.

	Grass.	*Work.*	*Time.*	*Hard wood.*	
N. V. A.	gramen	opus	tempus	robur	—
Gen.	gramin-	oper-	tempor-	robor-	IS
Dat.	gramin-	oper-	tempor-	robor-	I
Abl.	gramin-	oper-	tempor-	robor-	E

Plural.

N. V. A.	gramin-	oper-	tempor-	robor-	A
Gen.	gramin-	oper-	tempor-	robor-	UM
D. Abl.	gramin-	oper-	tempor-	robor-	IBUS

Similarly with other neuter nouns: *caput, capitis* (head); *crus, cruris* (leg); *fulgur, fulguris* (lightning); *cadaver, cadaveris* (corpse), etc.

-*i* Stems.

Singular.

	Raft, f.	*Temple*, f.	*Art*, f.	*Tooth*, m.	*Shower*, m.
N. V.	ratis	aedes	ars	dens	imber
Acc.	ratem	aedem	artem	dentem	imbrem
Gen.	ratis	aedis	artis	den is	imbris
Dat.	rati	aedi	arti	den i	imbri
Abl.	rate	aede	arte	dente	imbre

Plural.

N.V.A.	rates	aedes	artes	dentes	imbres
Gen.	ratium	aedium	artium	dentium	imbrium
D. Abl.	ratibus	aedibus	artibus	dentibus	imbribus

(Note the -*i* in the genitive plural.)

Singular.

	Fire, m.	*Animal*, n.	*Bone*, n.	*Sea*, n.
N. V.	ignis	animal	os	mare
Acc.	ignem	animal	os	mare
Gen.	ignis	animalis	ossis	maris
Dat.	igni	animali	ossi	mari
Abl.	igne *or* i	animali	osse	mari

Plural.

N. V. A.	ignes	animalia	ossa	maria
Gen.	ignium	animalium	ossium	marium
D. Abl.	ignibus	animalibus	ossibus	maribus

Note. -*i* nouns in -*ans* and -*ens* often drop -*i* in genitive plural, *e.g. parens, parentum.* The accusative plural of -*i* nouns (mas. and fem.) is often spelt as ending in -*is*, *e.g. dentis* for *dentes*.

Adjectives: Third Declension. All adjectives, except those in -*us*, -*a*, -*um*; and in -*er*, -*a*, -*um*, follow the third declension. Thus, melior (*better*), similis (*like*), ingens (*vast*), audax (*bold*).

Singular.

	M. F.	*N.*	*M. F.*	*N.*
N V.	melior	melius	similis	simile
Acc.	meliorem	melius	similem	simile
Gen.	melioris		similis	
Dat.	meliori		simili	
Abl.	meliore *or* i		simili	

Plural.

N. V. A.	meliores	meliora	similes	similia
Gen.	meliorum		similium	
D. Abl.	melioribus		similibus	

Note. All adjectives ending in -*is* make their ablative singular in -*i*.

Singular.

	M. F.	*N.*	*M. F.*	*N.*
N. V.	ingens		audax	
Acc.	ingentem	ingens	audacem	audax
Gen.	ingentis		audacis	
Dat.	ingenti		audaci	
Abl.	ingente *or* i		audaci (rarely *e*)	

Plural.

	M. F.	N.	M. F.	N.
N. V. A.	ingentes	ingentia	audaces	audacia
Gen.	ingentium		audacium	
D. Abl.	ingentibus		audacibus	

N.B. Decline all present participles like *ingens*.

Adjectives in *-er* of the third declension have three endings in nominative singular: *e.g.* celer, celeris, celere (*swift*); acer, acris, acre (*keen*). No other adjective is declined like *celer*.

Singular.

	M.	F.	N.	M.	F.	N.
N. V.	celer	celeris	celere	acer	acris	acre
Acc.	celerem		celere	acrem		acre
Gen.	celeris			acris		
D. Abl.	celeri			acri		

Plural.

	M. F.	N.	M. F.	N.
N. V. A.	celeres	celeria	acres	acria
Gen.	celerium		acrium	
D. Abl.	celeribus		acribus	

Comparison of Adjectives. The adjective has three degrees of comparison: the positive, the comparative, and the superlative, *e.g.*, *longus*, long; *longior*, longer *or* too long; *longissimus*, longest *or* very long.

The comparative is formed by changing the *-i* or *-is* of the genitive of the positive into *-ior*; and the superlative into *-issimus*. Thus:

durus (*hard*)	gen. *duri*	durior	durissimus
tristis (*sad*)	gen. *tristis*	tristior	tristissimus
audax (*bold*)	gen. *audacis*	audacior	audacissimus

EXCEPTIONS.

1. Adjectives in *-er* form the superlative by adding *-rimus* to the nominative (*i.e.* they double the *-r* and add *-imus*). *e.g.*:

asper (*rough*) asperior asperrimus
(So celer, miser, liber, pauper, tener, etc.)
pulcher (*beautiful*) pulchrior pulcherrimus
(So niger, piger, acer, ruber, vafer, etc.)
vetus (*ancient*) has superlative veterrimus (no comparative).

2. Six adjectives in *-ilis* double the *-l* and add *-imus*:

similis (*like*) similior simillimus

So dissimilis (*unlike*), facilis (*easy*), difficilis (*difficult*), gracilis (*slender*), humilis (*lowly*).

All the others in *-ilis* are regular: thus
utilis (*useful*) utilior utilissimus

3. The following are irregular:

bonus (*good*)	melior	optimus
malus (*bad*)	pejor	pessimus
magnus (*great*)	major	maximus
parvus (*small*)	minor	minimus
multus (*much*)	*plus (neuter)	plurimus
nequam (*wicked*)	nequior	nequissimus
dives (*rich*)	divitior / ditior	divitissimus / ditissimus
senex (*old*)	senior	natu maximus (*by birth the greatest*)
juvenis (*young*)	junior	natu minimus
potis (*able*)	potior (*better*)	potissimus (*best*)
(no positive)	ocior (*swifter*)	ocissimus
frugi (*frugal*)	frugalior	frugalissimus
egens (*needy*)	egentior	egentissimus

* There is no masculine or feminine singular of *Plus*, but full plural: Nom. Acc. *plures, plura*: Gen. *plurium*: D. Abl. *pluribus*.

4. Adjectives in *-dicus*, *-ficus*, and *-volus* change *us* into *-entior*, *-entissimus*.

maledicus	maledicentior	maledicentissimus
beneficus	beneficentior	beneficentissimus
malevolus	malevolentior	malevolentissimus

5. Adjectives ending in *-us*, preceded by a vowel, have no comparative or superlative: to form one, use *magis* and *maxime* (adverbs) = more and most. Thus:

idoneus (*useful*) magis idoneus (*more useful*) maxime idoneus (*most useful*)

But *antiquus*, *pinguis*, and *tenuis* are regular, because the *-u* is really consonantal.

6. The following spring from prepositions:

citra (*on this side*)	citerior	citimus
de (*down from*)	deterior (*worse*)	deterrimus
extra (*outside*)	exterior	extremus / extimus
infra (*below*)	inferior	infimus / imus
intra (*within*)	interior	intimus
post (*after*)	posterior (*later*)	postremus (*last*) / postumus (*last-born*)
prae (*before*)	prior	primus (*first*)
prope (*near*)	propior	proximus
super (*above*)	superior	supremus (*last* or *highest*) / summus
ultra (*beyond*)	ulterior	ultimus (*last*)

Adverbs: Comparison. Adverbs derived from adjectives with *-i* stems usually end in *-ter*; from other adjectives, usually in *-e*. Thus: audax (*bold*), audacter (*boldly*); brevis (*short*), breviter (*shortly*); dignus (*worthy*), digne (*worthily*).

In comparison they imitate their corresponding adjective, but make comparative *-us*, superlative *-e*:

graviter (*weightily*)	gravius	gravissime
digne	dignius	dignissime
audacter	audacius	audacissime

So: saepe (*often*) saepius saepissime
diu (*long*) diutius diutissime

Irregular:

multum (*much*)	plus	plurimum
magnopere (*greatly*)	magis (*most*)	maxime

Pronouns: Relative.

Qui, who or which.

	Singular. M.	F.	N.	*Plural.* M.	F.	N.
N.	qui	quae	quod	qui	quae	quae
A.	quem	quam	quod	quos	quas	quae
G.	cujus			quorum	quarum	quorum
D.	cui			quibus *or* quis		
A.	quo	qua	quo	quibus *or* quis		

Interrogative. *Quis, who or what? (only in questions).*

Declined like qui, except the nominative and accusative singular:

	M.	F.	N.	
Nom.	quis	(quis)	quid	*
	qui	quae	quod	
Acc.	quem	quam	quid	*
	quem	quam	quod	

Also the *Indefinite* pronoun *quis* (anyone) is declined like the interrogative, except that the nominative singular is *quis, qua, quid.*

Compounds of *qui* and *quis:*

1. *Quisnam, quidnam?* (also *quinam*) = who?
2. *Ecquis, ecqua, ecquid?* = anyone? (rare).
3. *Aliquis, aliqua, aliquid* = someone.
4. *Quispiam, quaepiam, quodpiam* = some.
5. *Quisquam, quicquam* = any at all (generally used with negatives, *e.g. nec quisquam* = nor anyone, *i.e.* "and no one").
6. *Quidam, quaedam, quiddam* = certain, a certain person (very definite).
7. *Quicumque, quaecumque,* etc. = whosoever.
8. *Quisquis* = whosoever; *quidquid* = whatsoever.
9. *Quivis, quaevis, quodvis* = which you will (very indefinite: *vis* means "thou wishest," from *volo* = I wish).
10. *Quilibet* = which you like (*libet* is an impersonal verb = it pleases).
11. *Quisque, quaeque, quicque* = each (also *unusquisque* = each one).

Section II. SYNTAX.

Rule 1. The relative agrees with its antecedent (*i.e.* the word to which it *relates*) in number, gender, and person, but takes its case from its own clause: *e.g., Carus est amicus quem cras videbo* = dear is the friend whom I shall see to-morrow.

Rule 2. "Than" after a comparative is expressed by "*quam.*" But if the comparison is being made between two *nouns,* the second noun may be put in the ablative, "*quam*" being omitted. In the former construction, the two things compared are in the same case, as "*Luna minor est quam sol*" = the moon is smaller than the sun (or we could say, *Luna minor est sole*). The latter construction is only used when the comparative adjective is nominative or accusative.

The Accusative Case. The accusative is the case of the direct or nearer object of the transitive verb: *e.g. Brutus Cæsarem interfecit* = Brutus killed Cæsar.

a. Some verbs, especially those of *concealing, asking,* and *teaching,* may take two accusatives, one of the person, the other of the thing, *e.g. nihil matrem celat* = he conceals nothing from his mother; *nunquam divitias deos rogavi* = never asked I riches from the gods.

b. Intransitive verbs may take a cognate accusative, *i.e.* an accusative of kindred meaning to the verb, *e.g. cursum currere* = to run a race; *duram servitutem servit* = he serves a hard slavery.

* Note. The forms *quis, quid* are substantival, *e.g. quis adest?* = who is present? But *qui, quod* are adjectival, *i.e.* used with nouns; *e.g. qui miles?* = what soldier?

c. Factitive verbs (*i.e.* verbs of *making, calling, thinking,* etc.) have two accusatives, one of the object, the other of the complement, *e.g. Ciceronem consulem creant* = they make Cicero Consul; *patriam Britanniam vocamus* = we call our country Britain.

d. Duration of time and measure of space are put in the accusative, *e.g.* '*Victoria multos annos regnavit* = Victoria reigned for many years (here, "for" = "during"); *muri erant ducenos pedes alti* = the walls were 200 feet high. ["Point of time at which" is put in the ablative.]

e. The place whither one goes is put in the accusative, and without a preposition if it is the name of a town or small island, or domum (*home*), rus (*country*), *e.g. Romam redivit* = he returned to Rome; *rus eo* = I am going into the country (*rus* is neuter). But "*in* Italiam eo," because Italy is not a town or small island.

Note. (*d*) and (*e*) are really extensions of (*b*).

f. The accusative of respect is joined to verbs and adjectives (rare in prose, common in poetry), *e.g. nudae sunt lacertos* = they are bare as to their arms; *deo similis humeros* = like unto a god in his shoulders.

g. The accusative is often used in exclamations: really object to some verb understood, *e.g. me miserum!* = wretched me! *O te ferreum!* = man of iron that thou art!

Easy Passage to be turned into Latin.

[Note on the order of words in a Latin sentence.—The verb, or if not the verb, some important part of the predicate, usually comes last of all. The verb *sum,* however, seldom concludes a sentence, *e.g. amicus est mihi carissimus.* Adjectives, when used as attributes ("a good man"), usually *follow* their noun (*vir bonus*). Adverbs usually *precede* their verbs (*graviter dixit* = he spoke weightily).]

"Little Boy Blue."

[Use the dictionary for new words.]

"Once upon a time there was a boy whose name was 'Blue' (say, to whom the name was 'Blue'). When his father had given him a horn to blow (which he might blow), he ordered his son to watch the sheep. But because this boy was very lazy, he often *used to go to sleep* (imperfect) for many hours in the fields, thinking to himself (say, with himself): 'To sleep is more pleasant than to work.' At last his father found him out: for the oxen which he was watching had entered into the meadow, and the sheep had settled in the cornfield. 'Where is Little Boy Blue?' all the men shouted. And by-and-by they found him under a haycock in the middle of a field—fast asleep! What did his father give him?"

"Little Boy Blue" in Latin.

Olim erat puer cui nomen erat Caeruleo (dat. in apposition to *cui*). Ubi pater cornu ei dederat quod inflaret, filium oves servare jussit (perf. of *jubeo*). Quia autem (*autem* is never first word in a sentence) hic puer erat pigerrimus,

multas horas in agris saepe dormiebat, secum reputans "Dormire est jucundius (neuter) quam laborare." Tandem pater illum deprehendit: nam boves quos servabat in pratum intraverant, atque oves in agro frumentario consederant (plupf. of *consido*). "Ubi est Caeruleus?" omnes conclamaverunt. Denique illum* repperertunt (perf. of *reperio*) sub foeni meta in medio agro (note that the Romans said "in the middle field") dormientem. Quid illi pater dedit? (perf. of *do, dare*).

SECTION III. TRANSLATION.

Put the following into English, using a dictionary for unknown words.

THE BEATITUDES.

Beati (sunt) pauperes spiritu: quoniam ipsorum est regnum coelorum. Beati *qui* (*a*) lugent: quoniam ipsi solamen recipient. Beati qui sunt mites: quoniam ipsi terram *hereditario jure* (*b*) obtinebunt. Beati qui esuriunt et sitiunt justitiam: quoniam ipsi *saturabuntur* (*c*). Beati qui sunt misericordes: quoniam ipsis misericordia *tribuetur* (*d*). Beati qui sunt *mundo corde* (*e*): quoniam ipsi Deum videbunt. Beati qui sunt pacifici: quoniam filii Dei *vocabuntur* (*f*).

* Better Latin to say 'quem denique repperertunt,' = "whom at length they found": use the relative often where English uses the demonstrative.

THE LORD'S PRAYER.

Pater noster qui es in cœlis, *sanctificetur* (*g*) nomen tuum. Veniat regnum tuum: fiat voluntas tua, sicut in caelo, ita etiam in terra. Panem nostrum quotidianum da nobis hodie. Et remitte nobis debita nostra, sicut *et* (*h*) nos remittimus debitoribus nostris. Et *ne* (*i*) nos inducas in tentationem, sed libera nos ab illo malo. Quia tuum est regnum, et potentia, et gloria, in secula.

NOTES.

(*a*) In full, it would be *Beati sunt ii qui*.

(*b*) Literally "they shall occupy by hereditary right."

(*c*) Future passive, third plural, of *saturo*.

(*d*) Future passive, third singular, of *tribuo*.

(*e*) Ablative of quality, = of a pure heart.

(*f*) Future passive, third plural, of *voco*.

(*g*) Present subjunctive passive, third singular.

(*h*) *Et* here = also. *Et* can mean (1) both, (2) and, (3) also, (4) even.

(*i*) *Ne* is the negative particle used with imperative and subjunctive: *non* or *haud* with indicative and infinitive. Here *ne inducas* = do not lead us. (This is not a good Latin construction: it should be perfect subjunctive, not present).

[For key to above, see Matthew v. 3–9, and vi. 9–13.]

Continued from page 348

By Gerald K. Hibbert, M.A.

Adjectives. An adjective is a word "added to" a noun to qualify it, or limit it by reference to quality, quantity, or position. There are, therefore, three main classes of adjectives:

1. Of Quality;
2. Of Quantity;
3. Of Position or Relation.

1. Qualitative, or Descriptive, Adjectives, denoting some quality or attribute: *e.g., white, ugly, thick, French, such.*
2. Quantitative Adjectives, denoting *how much* or *how many*. These include:
   a. Cardinal Numerals: *one, two, three*, etc.;
   b. The Indefinite Numerals: *many, few, some, all, enough, any, much, more, most several, sundry, certain, none* or *no* (= *not any*), *less, least, both.*
3. Adjectives of Relation, or Demonstrative Adjectives. These include:
   a. Ordinal numerals: *first, second*, etc.;
   b. The Pronominal Adjectives (adjectives which are also used as pronouns): *a, an, the, this, that, these, those, other, yon; my, thy, his*, etc.; *which, what, whether; each, every, either, neither.*

Remarks on the Above. The words *hundred, thousand, million* are nouns; we can say "a hundred," though we cannot say, "a twenty." "One hundred men" is therefore "one hundred *of* men," and in Anglo-Saxon "men" was put in the genitive case.

When *many* is used with *a* or *an* to denote a number of persons or things looked at individually, it takes a singular verb: "Full many a flower is born to blush unseen" (Gray's "Elegy"). The phrase "a many" is no longer used in good grammar (except "a good many," "a great many"), although Tennyson writes "shed a many tears."

No is a shortened form of *none*, which equals "not one." The use of *none* as an adjective is confined to Old English: "There is none other name under heaven" (Acts).

Just as many adjectives are used as pronouns (*e.g.*, "the *other* day," adjective; "hate the one and love the *other*," pronoun), so also many adjectives are used as nouns: "the merciful," "the ridiculous," "*all* is lost," "*enough* is as good as a feast." This applies sometimes to numerals: "I will not destroy it for *twenty's* sake"; "we count by *tens*."

In Anglo-Saxon adjectives were inflected for Number, Gender, and Case; but in Modern English they are indeclinable (except *this* and *that*, which have as plurals *these* and *those*).

Comparison of Adjectives. There are three degrees of Comparison: the *Positive*, the *Comparative*, the *Superlative*.

The Positive is the simple adjective, as "a *bright* light."

The Comparative compares one thing with another, and asserts that the one possesses a certain quality in a higher degree than the other: as, "a *brighter* light."

The Superlative compares one thing with many, and asserts that it possesses a certain quality in a higher degree than any of the others: as "the *brightest* light."

NOTES.

1. The Superlative is not used in comparing two objects only (except by some of the poets). It is wrong to say, "Which is the tallest of the two sisters?"
2. Certain adjectives, from their meaning, are incapable of comparison: *e.g.*, *one*, *two*, *first*, *second*, *this*, *that*, *square*, *triangular*, *perfect*, etc. We do, of course, say, "This is more perfect than that," but we are not then using "perfect" in its strict sense. Compare "The chiefest among ten thousand."

HOW TO FORM THE COMPARATIVE.

1. By adding *-er* to the positive (or *-r*, if the positive end in *e* mute): *e.g.*, *long*, *longer*; *scarce*, *scarcer*. If the positive ends in *y* preceded by a consonant, the *y* becomes *i*: *lofty*, *loftier*. If the positive ends in a single consonant preceded by a single vowel, the consonant is doubled: *fit*, *fitter*.
2. By prefixing *more* to the positive, in all cases where the positive has more than two syllables (*alarming*, *more alarming*), and in most cases where the positive is disyllabic (*decent*, *more decent*). The disyllabic adjectives that form their comparatives in *-er* are those ending in *y*, *ble*, *er*, *ow*, and those that have the accent on the last syllable (*prettier*, *nobler*, *tenderer*, *narrower*, *politer*). It is very much a matter of taste in these cases: what sounds best is oftenest used.

HOW TO FORM THE SUPERLATIVE.

1. By adding *-est* to the positive: *e.g.*, *longest*;
2. By prefixing *most* to the positive: *e.g.*, *most alarming*. The remarks on the formation of the comparative apply equally here.

The Superlative is sometimes used, not to compare one thing with many others, but to denote that a thing possesses a certain quality in a high degree: this is usually expressed by prefixing "a most" or "a very" to the positive: as, "a most extraordinary thing."

Double comparatives and superlatives are found in old writers: *e.g.*, "worser," "the most unkindest cut of all," "the most straitest sect," and (even in Modern English) "lesser."

IRREGULAR COMPARISON.

Positive.	*Comparative.*	*Superlative.*
good	better (1)	best (betest)
bad	worse (2)	worst
little	less	least
much *or* many	more	most
old	older *or* elder (3)	oldest *or* eldest
far	farther (4)	farthest
[forth, *adverb*]	further	furthest
fore	former	foremost, first
nigh	nigher, nearer (5)	nighest, nearest, next.
late	later, latter	latest, last.

NOTES.

(1) From old word *bat* = good.
(2) From Anglo-Saxon *weor* = bad.
(3) *Elder* is not used when two persons are definitely compared in point of age. We may say "an elder brother," but not "elder than."
(4) Probably formed from *far* by false analogy with *further* (which is probably from *forth*).
(5) *Nearer* is a double comparative; *near* itself is a comparative form (positive, *neah*).

Words like *foremost*, *hindmost*, *innermost*, *utmost*, etc., are probably double superlatives, as they seem to contain the two old superlative endings: *-m* (for *-ema*) and *-ost*.

Position of Adjectives. An adjective is said to be used *attributively* when it immediately precedes or follows a noun; but when the verb "to be," or some similar verb, comes between it and the noun, it is said to be used *predicatively*. Thus: "The *wise* men of Gotham" (attributive); "Heap on more wood, the wind is *chill*" (predicative).

The Articles. *A*, *an*, and *the* are sometimes called articles (Latin, *articulus* = a joint), but they are really adjectives (see above).

The is called the Definite Article, because it points out or defines: as, "The pied piper of Hamelin"; "The Maccabees." It is a weak form of the demonstrative "that." In such phrases as "The more the merrier"; "The nearer the bone, the sweeter the meat," *the* is not the article, but the old instrumental case of the demonstrative adjective *se*, *seo*, *that* (the, that), and means "by how much . . . by so much" (literally, "by how much the more, by so much the merrier").

A, *an*, are called Indefinite Articles; they are weakened forms of the numeral *one*. They show that it is *one* thing of the class which is meant, but do not specify *which*; *e.g.* "As a man thinketh in his heart, so is he." *An* is used before words beginning with a vowel or *h* mute; *a* before words beginning with a consonant or *h* aspirated, or *u* when sounded *yu*; *e.g.*, *an army*, *an heir*, *a cat*, *a horse*, *a unicorn* (but *an umbrella*). But *an* may stand before a word beginning with *h* aspirated when the accent is not on the first syllable of the word: *an historical parallel*, *an hypothesis*. Writers differ very much on this point. In the Psalms we find "an host," "an unicorn," and Macaulay has "an European."

In such sentences as "He kneeled upon his knees *three times a day*," *a* is not the indefinite article, but represents the old preposition *on* (= in).

The article should be repeated before each noun in a series of enumerations, when the nouns denote distinct things: as, "the butler and the baker of the King of Egypt." To say "the butler and baker" would imply that one man was both butler and baker. When the nouns denote things closely connected, the article need not be repeated: as "The beauty and worth of every human soul."

EXERCISE. Pick out all the adjectives in the following passage, classify them, and give comparative and superlative; say whether used attributively or predicatively:

"All the earth and air
With thy voice is loud,
As, when night is bare,
From one lonely cloud
The moon rains out her beams, and heaven is overflowed.

Chorus hymeneal
Or triumphal chant,
Matched with thine, would be all
But an empty vaunt—
A thing wherein we feel there is some hidden want."

(*Shelley*, "Ode to a Skylark.")

Correct the following sentences:

1. He is the tallest man of all the rest.
2. Which of these two do you like best ?
3. He wore a large and a very shabby hat.
4. The King sent for the Chancellor and Treasurer.
5. Milton is greater than any poet.
6. I can see two different flags, a white and green.

KEY TO SENTENCES ON PAGE 248.

1. *He* should be *him*, as *but* is here a preposition, meaning *except*.

2. *Whom* should be *who*.

3. *He* should be *him*, to be in apposition to *friend*, which is in the objective case.

4. *Cherubim* should be *cherub*.

5. *I* should be *me*, for the same reason as in the first sentence.

Pronouns. A Pronoun is exactly what its name implies, a word used "for a noun": *e.g.*, "Love took up the glass of Time, and turned *it* in his glowing hands." *It* is here used to avoid repeating "the glass of Time."

As a pronoun is a substitute for a noun, it has number, gender, and case, just as would the noun for which it stands.

Pronouns are often confused with adjectives. To test a pronoun, ask the question, "Does this word stand instead of a noun ?" If so, it is a pronoun ; if not, it is something else, probably an adjective. Thus: In "Give John that book," *that* does not stand for a noun, and is therefore not a pronoun ; it is a demonstrative adjective. But in "Give John his book and that of his brother," *that* stands for "the book," and is therefore a pronoun.

CLASSIFICATION OF PRONOUNS.

1. Personal ;	4. Relative ;
2. Demonstrative ;	5. Indefinite* ;
3. Interrogative ;	6. Distributive.*

[* Some include these two under Partitive.]

1. PERSONAL PRONOUNS. *I*, *we*, *thou*, *ye* or *you*, *he*, *she*, *it*, *they* ; and all their cases.

I and *we* are personal pronouns of the First Person (the person speaking) ; *thou*, *ye*, and *you* of the Second Person (the person spoken to) ; *he*, *she*, *it*, and *they* of the Third Person (the person spoken of).

He, *she*, *it*, and *they* are sometimes classed as Demonstrative Pronouns.

The Personal Pronouns are thus declined:

	FIRST PERSON.		SECOND PERSON.	
	Singular.	*Plural.*	*Singular.*	*Plural.*
Nom.	I	we	thou	ye, you
Obj.	me	us	thee	you
Pos.	my *or* mine	our *or* ours	thy *or* thine	your *or* yours.

THIRD PERSON.

	Singular.			*Plural.*
	Masc.	*Fem.*	*Neuter.*	*All genders.*
Nom.	he	she	it	they
Obj.	him	her	it	them
Pos.	his	her *or* hers	its	their *or* theirs

The possessive cases of these pronouns are always adjectival, and are best classed as adjectives (see under Adjectives of Relation at commencement of this lesson). The forms *mine*, *thine*, *ours*, *yours*, *hers*, *theirs* are used only predicatively: *e.g.*, "the loss is ours." Sometimes, however, in poetry and stately diction we find *mine* and *thine* used attributively, but only before a noun beginning with a vowel: "Give every man thine ear, but few thy voice" (Hamlet). The forms *my*, *thy*, *our*, *your*, *her*, *their*, are used only attributively: "my fault."

Ye was once nominative, and *you* objective, though occasionally we meet an exception, as "Lest confidence . . . deceive ye to persuasion over-sure" ("Paradise Regained"). *You* is now both nominative and objective.

Thou is now rarely used, except in poetry or addressing the Divine Being, and among the Quakers. The plural *you* gradually supplanted it, as a mark of special respect, the person addressed as *you* being supposed to be as good as many "thous." We now, of course, use *you* and *your*, whether we are addressing one person or more than one.

It is the Anglo-Saxon *hit*, the *t* being a neuter suffix (as in *what*, *that*). Its original possessive was *his*, and *its* is a modern form: *e.g.*, "The iron gate . . . opened to them of his own accord" (Acts).

The following are sometimes called *Reflexive* Pronouns, but are really Personal:

Singular.	*Plural.*
myself (ourself)	ourselves
thyself (yourself)	yourselves
himself, herself, itself.	themselves.

Also the modern form *oneself*, which has no plural ; it was originally written "one's self."

Self (which means *same*), though originally an adjective, came to be regarded as a noun ; hence *myself*, etc. In the forms *himself*, *themselves*, we see "self" used in its original adjectival sense, and *themselves* should therefore be "themself."

The form "ourself" is used by royalty. "It was ourself thou didst abuse" ("King Henry V.")

They are called *reflexive* because they are used when the action "bends back" and affects the doer: as, "He saved others, *Himself* He cannot save" (*himself* being here *objective*).

Sometimes they have no reflexive force, but are used for emphasis: as, "God Himself is with us"; "Myself am hell." Here *himself* and *myself* are in the *nominative* case.

NOTE. The objective cases of the Personal Pronouns can be used reflexively, without the addition of *self* ; as, "Get thee gone," "I'll disrobe me."

FRENCH

Continued from page 327

By Louis A. Barbé, B.A.

Capitals and Small Letters. There are some differences between the French and the English uses of capital and small letters. We shall note chiefly the points of difference.

1. After a colon a capital is used to introduce a quotation, thus: *Aristote disait à ses disciples : Mes amis, il n'y a point d'amis* (Aristotle used to say to his disciples: "My friends, there are no friends").

2. The name of God and all words synonymous with it are written with an initial capital as in English, thus: *Dieu* (pronounced *Dee-ĕ*), God; *le Seigneur* (*lĕ Seyn-yer*), the Lord; *le Créateur* (*lĕ Crey-ah-tër*), the Creator; *l'Être Suprême* (*laytr Sü-prame*), the Supreme Being. But when the word is a compound substantive of which the component parts are joined by a hyphen, they each take a capital: *le Tout-Puissant* (*lĕ Too-Püee-sawn*), the Almighty. It is not customary to use capitals, as is done in English, in the case of *pronouns* referring to God.

3. The names of the signs of the zodiac, of the constellations, of the planets, when they are referred to as parts of the planetary system, and *le Soleil* (*Sŏ-ley-ye*), the Sun, when it is considered as its centre, are looked upon as proper names and take capitals.

4. When moral qualities and abstract ideas are personified the nouns indicating them are written with capitals, as *la Fortune* (*la for-tün*), fortune; *la Vérité* (*la vey-ree-tey*), truth.

5. No adjectives, and sometimes not even the nouns (unless they naturally have capitals) occurring in the titles of literary works, take capitals. Thus Pascal's "Thoughts on Religion" is written *Pensées sur la religion*, and Sainte-Beuve's "Literary Portraits" is in French *Portraits littéraires*.

6. The adjectives *saint* and *grand* take capitals when they are integral parts of a proper noun, as *la rue Saint-Honoré*, *la Saint-Jean* (the feast of St. John—*i.e.* Midsummer Day), *Henri le Grand*. Otherwise they are written with small initials, as *saint Jean*, *saint Honoré*, *le grand Henri*.

7. Adjectives used as substantives, to indicate a language, take no capital, thus, *le français* (*lĕ frawn-sey*), the French language; *le latin et le grec* (*lĕ la-tan ey lĕ grek*), Latin and Greek.

8. Small initials only are used:

(*a*) For the names of the months, of the days of the week, and of the points of the compass, as *janvier* (*jawn-vee-ey*), January; *février* (*fey-vree-ey*), February; *lundi* (*lun-dee*), Monday; *mardi* (*mahr-dee*), Tuesday; *le nord* (*lĕ nŏr*), north; *le sud* (*lĕ süd*), south. But when these last are used to designate a division of the globe, or a number of countries, they take capitals, as *mer du Nord* (North Sea), *empire d'Occident* (*awn-peer dŏk-see-dawn*), Empire of the West.

(*b*) For the names of the various religions and sects, and of their adherents, as *christianisme* (*cree-stee-ah-neesm*), Christianity.

(*c*) For the names of members of religious orders, as *bénédictins*, *dominicains* (*bey-ney-dik-tan*, *dŏ-mee-nee-kan*).

(*d*) For titles, as *l'empereur de Russie*, *le roi Édouard*, *le duc de Guise*; pronounced *l'awn-pĕ-rër dĕ Rüs-see*, *lĕ rwa Ed-warr*, *le dük dĕ Gweez*.

9. The abbreviations of *monsieur*, *madame*, *mademoiselle*, pronounced respectively *mĕ-see-ĕ*, *ma-dahm*, and *ma-dé-mwa-zel* (Mr., Mrs. and Miss), are *M.*, *Mme*, *Mlle*. Their plurals are written *MM.*, *Mmes*, *Mlles*. Of the forms sometimes used in England instead of these, *Mons.* is to be avoided, because it is considered uncomplimentary; *Mde.*, because it means *marchande*; and *Mdlle.*, because it is not French at all. Other abbreviations of frequent occurrence are: *Mgr*, for *monseigneur* (*mon-seyn-yër*), my lord; *Me*, for *maître*, pronounced *mey-tr*, the title given to lawyers; and *Ve*, for *veuve* (*vëv*), widow. B.C. and A.D. are respectively *avant J.C.* and *après J.C.*

10. The pronoun *je* (I) is not written with a capital.

EXERCISE I.

Indicate phonetically the pronunciation and give the meaning of the following words:

femme, *tête*, *histoire*, *aiguille*, *faubourg*, *doigt*, *péril*, *mauvais*, *Dieu*, *Espagnol*, *vérité*, *soleil*, *février*, *mardi*, *monsieur*, *maître*, *Noël*, *mademoiselle*, *nord*, *beaucoup*, *quoi*, *hiver*, *damner*, *sculpter*, *prompt*, *cuiller*, *maison*, *sous*, *misère*, *poison*, *poids*, *paix*, *sept*, *huit*, *neuf*, *dixième*, *signe*, *amer*, *prix*, *Guise*, *cri*, *babil*, *ville*, *œuf*, *sœur*, *plomb*, *mais*, *chef-d'œuvre*, *citoyen*, *gloire*.

Syllables. In dividing words into syllables, the following rules should be observed:

1. A single consonant between two vowels always belongs to the second of the two syllables, thus: *généralement* is composed of the syllables *gé'né'ra'le'ment*, generally.

2. When two separable consonants occur in the body of a word, the first of them belongs to the preceding, and the second to the following syllable, thus: *con'sen'tir*.

3. If the second of the two consonants is *l* or *r*, they are inseparable, and both belong to the second syllable, as in *trou'bler*, to trouble; *mon'trer*, to show; *é'criture*, writing.

4. If *r* and *l* themselves come together, they are separable, thus: *par'ler*, to speak; *mer'lan*, whiting; *hor'loge*, clock.

5. The consonants *nr* and *nl* are to be separated, as in *den'rée*, provisions; *s'en'rhumer*, to catch a cold; *en'lever*, to carry off; *en'lacer*, to entwine.

6. *Ll* and *rr* are also to be divided, as in *al'ler*, *ar'river*, *der'rière*, *il'lustre*.

7. The consonants *ch*, *ph*, and, except in a very few words, *gn*, are inseparable, as *four'chette*, fork; *so'phiste*, sophist; *a'gneau* (*an-yŏ*) lamb, *poi'gnard* (*pwahn-yarr*), dagger.

Liaison. By *liaison*, pronounced *lee-ey-son*, or linking, is understood the carrying

on of the final consonant of one word to the initial vowel of the next, providing the two are intimately connected in sense. In the case of a word ending in *mute e*, this applies to the consonant immediately preceding it. When carried over in this way some of the consonants change their sound. D becomes T, *un grand homme* = *un gran'-tom* (a great man), G becomes K, *un long espoir* = *un lon' kespoir* (a long hope), S and X become Z, *les amis, six enfants* = *ley-zahmee* (the friends), *see-zawn'-fawn'* (six children). In the numeral *neuf* (nine), F becomes V, *neuf ans* = *nĕ-vawn'* (nine years); P is carried on only in *trop*, pronounced *trŏ* (too much), and *beaucoup*, pronounced *bŏ-kōō* (much), *il va trop avant* = *trŏ-pa-vawn'* (he goes too far forward), *beaucoup en parlent* = *bŏ-cōō-pawn'-parl* (many speak of it). The *t* of *et* (*ey*), and, is never sounded, and therefore never carried on.

Punctuation. The punctuation marks are as follow:

1. *La virgule* (,), (*la veer-gül*).
   Le point et virgule (;), (*lĕ pwan'-tey-veer-gül*).
   Les deux points (:), (*ley dĕh pwan'*).
   Le point (.), (*lĕ pwan'*).
   Le point d'interrogation (?), (*lĕ pwan' d'an'-ter-rŏ-ga-see-on'*).
   Le point d'exclamation (!), (*lĕ pwan' d'eks-cla-ma-see-on'*).

To these may be added:

2. *Les points de suspension* (. . . .), (*ley pwan' dĕ süs-pawn'-see-on'*).
   La parenthèse (( )), (*la pa-rawn'-taze*).
   Les crochets ([ ]), (*ley crŏ-shey*).
   Les guillemets (" "), (*ley gheeyĕmey*).
   Le tiret (—), (*lĕ tee-rey*).
   L'accolade (f.), (⏜) (*l'ac-cŏ-lad*).
   L'astérisque (m.) (*), (*l'asteyreesk*).

3. In dictation the directions for opening and closing a parenthesis and inverted commas are: *Ouvrez la parenthèse* (open the parenthesis); *Fermez les guillemets*, pronounced *ferrmey ley gheeyĕmey* (close the quotation).

ORTHOGRAPHIC SIGNS

Accents. There are three accents, the acute accent (´), *accent aigu*, the grave accent (`), *accent grave*, and the circumflex accent (^), *accent circonflexe*.

The *accent aigu* is placed only over the vowel *e* to give it the closed sound, as in *témérité* (*tey-mey-ree-tey*), temerity.

The *accent grave* is placed chiefly on the letter *e*, but also on *a* and on *u*. It is placed on the letter *e* to give it the open sound, as in *après* (*aprey*), after; *succès* (*süksey*), success; *prophète* (*prŏfate*), prophet.

It is also used to distinguish one word from another, thus:

(*a*) On the preposition *dès* (from), to distinguish it from *des* (of the), and from *dés* (dice, thimbles), all pronounced *dey*;

(*b*) On the preposition *à* (to), to distinguish it from *a* (has);

(*c*) On the adverb *là* (there), to distinguish it from the feminine article *la* (the);

(*d*) On the adverb *où* (where), to distinguish it from the conjunction *ou* (or);

(*e*) On the adverb *çà* (here), and its compound *deçà* (on this side); and also on the adverb *déjà* (already).

The *accent circonflexe* occurs on all the vowels except *y*. It usually indicates the omission of a letter (*a*, *e*, or *s*), and the vowel on which it is placed is almost invariably long, thus: *âge* (*āhj*), age; *fête* (*fāte*), feast, holiday; *flûte* (*flühl*), flute; *apôtre* (*apohtr*), apostle; *maître* (*meytr*), master.

It is always placed on the vowel immediately preceding the terminations *mes* and *tes* of the first and second persons plural of the past definite, and on that immediately preceding the final *t* of the third person singular imperfect subjunctive in all verbs. Thus: *nous aimâmes* (*noo-zeymāhm*), we loved; *vous reçûtes* (*rĕsüht*), you received; *il finît* (*fee-nee*), he might finish; *il fût* (*fü*), he might be.

It is also required on the *i* of verbs in *aître* wherever that *i* retains a *t* after it throughout the conjugation, thus: *paraître* (to appear) has *paraît* in third person singular present indicative, but *parais* in the second person. When the letter *i* takes a circumflex accent it is not dotted. The *accent circonflexe* is also placed:

(*a*) On *dû*, the masculine singular form of the past participle of *devoir* (to owe), to distinguish it from *du* (of the), both pronounced *dü*;

(*b*) On the *u* of *mûr* (ripe), to distinguish it from *mur* (wall), both pronounced *mür*;

(*c*) On the adjective *sûr* (sure), to distinguish it from *sur* (on), both pronounced *sür*.

Exercise II.

A. Indicate the silent letters in those of the following words that have any:

automne, histoire, sang, août, doigt, septembre, porte, champ, sud, portent, plomb, danger, lac, vingt, mer, faubourg, paix, outil, blanc, prix, Jésus, nez, cerf, beaucoup, baril, péril, monsieur, amer, chez, clef, sculpter, baptême, hier, coup, porc, corps, dans, damner, homme, hache, serf, drap, sous, mais, neuf, bord, gentil, gosier, et, thé.

B. Divide the following words into syllables, and give their meanings:

laurier, chaloupe, sourcil, plaisir, mardi, vérité, après, fourchette, agneau, poignard, généralement, ami, écriture, parler, merlan, montrer, troubler, denrée, virgule, consentir, enlacer, beaucoup, devoir, déjà.

The Apostrophe. The apostrophe is like a comma, placed a little above the line ('), to indicate the elision or omission of the final vowel of one word, before the initial vowel or mute *h* of another, as *l'objet*, for *le objet*, *l'homme* for *le homme*, *j'ai* (I have) for *je ai*.

Elision takes place, and is indicated by an apostrophe:

1. In the masculine and feminine singular forms of the definite article, *le, la*; thus, *l'oiseau* (*lwa-zŏ*), the bird, for *le oiseau*, *l'aiguille* (the needle) for *la aiguille*. *Yeuse* (evergreen oak) is the only word beginning with *y* that requires elision in the article preceding it, *l'yeuse*, pronounced *lee-ĕz*; elision does not take place before

onze (eleven) and its derivatives, or before *oui* (*wēē*), yes, when used as a noun.

2. In the pronouns *je* (I), *me* (me), *te* (thee), *le* and *la* (him, her or it), *se* (himself), *ce* (this), both pronounced *sĕ*, *que* (which), in the preposition *de* (of or from), the conjunction *que* (that), and in *ne*, the negative particle, thus: *j'aime* (I love), *il s'amuse* (he amuses himself).

There is, however, no elision in *le* and *la* when they come after a verb—*e.g.*, *donnez-le à l'homme*, pronounced *don-nēy-lë à l'öm* (give it to the man).

3. In *lorsque* (when), *puisque* (since), and *quoique* (although), but only before *il* (he), *elle* (she), *on* (one), *ils* (they), *elles* (they), and *un*, *une*, the indefinite article.

4. In *quelque* (*kel-kë*), some, but only in the expressions *quelqu'un* (m.), *quelqu'une* (f.), (some one), pronounced *kelkun'* and *kel-kün*.

5. In *presque* (almost), but only in the word *presqu'île* (peninsula).

6. In *jusque* (as far as, until), *e.g.*, *jusqu'à Paris* (*jüska Parē*), as far as Paris; *jusqu'alors* (*jüskalorr*), till then.

7. In *entre* (between), when it is the first component of a compound noun, as *entr'acte* (interlude), or of a compound verb, as *s'entr'aider* (*saun'tr-ēy-dēy*), to help one another.

8. In *aujourd'hui* (*ō-joor-düē*), to-day.

9. There is an apostrophe in *grand'mère* (*graun'-merr*), grandmother, and a few similar words, although there is really no elision.

10. The vowel *i* is elided only in the one word *si* (if), and only when it precedes *il* (he), or *ils* (they).

11. When the pronouns *moi* (me, to me), *toi* (thee, to thee), come after a verb, and before *en* (some, of it), the two vowels *oi* are elided, thus: *donnez-m'en* (*dön-ney-maun'*), give me some.

The Cedilla. The cedilla (*la cédille*) is placed under the letter *c* (ç), when the letter, though occurring before one of the vowels *a*, *o* or *u*, requires to be pronounced with the hissing *s*-sound which it naturally has before the other vowels. Thus, there is a cedilla under the *c* of *façade* (*fasahd*), facade; *garçon* (*garrson'*), boy; *reçu* (*rèsü*), received.

In words which are not written with a cedilla the *c* retains its hard sound, as *calcul* (*kalkül*), calculation; *cocarde* (*kokard*), cockade; *écu* (*ēykü*), shield.

The Diaeresis. The diæresis is two dots (¨) placed on the second of two vowels, to indicate that it ought to be pronounced independently, and that the sounds of both vowels are not to be merged into one diphthong, thus: *haïr* (to hate), *naïf* (simple), *Ésaü*, to show that the words are to be sounded *ha-ēēr*, *nah-ēēf*, *Esah-ü*, and not *hèr*, *nèf*, *Eso*.

Exercise III.

A. Name the accents in the following words: *même*, *bergère* (shepherdess), *blé* (corn), *mûr dès*, *mère* (mother), *déjà*, *paraît*, *côté* (side), *près* (near), *prés* (meadows), *tête*, *été* (summer), *fâché* (sorry, angry), *fenêtre* (window), *lèvre* (lip), *être* (to be), *à*, *où*, *dû*, *général*, *maître*, *succès*, *témérité*, *île* (island).

B. Elide the vowel and put an apostrophe wherever it is required in the following sets of words:

Je ne ai de autre ambition (I have no other ambition); *ce est moi* (it is I); *la oreille* (the ear); *le homme*; *le oiseau*; *il faut que il parte* (he must go away); *la crainte que elle me a causée* (the fear which she has caused me); *lorsque un enfant ne obéit pas* (when a child does not obey); *si il vient* (if he comes); *le héros*; *la héroïne*; *presque en même temps* (almost at the same time); *quelque autre* (some other); *le onze juillet* (the 11th July); *jusque à Londres* (as far as London).

The Hyphen. The hyphen is a stroke (-) placed between words to indicate that they are intimately connected, and form a single word or expression as regards meaning. Thus: *chef-d'œuvre* (masterpiece) and *moi-même*, pronounced *mwah-māme* (myself).

1. In compound substantives, usage is not consistent with regard to the hyphen. Thus, whilst *chef-d'œuvre* takes it, *trait d'union* (*trey-dün-yon'*), itself the French word for hyphen though quite as much a compound word, is written without it. In other words, it is arbitrary.

2. In proper names, both of persons and of place, component words are joined by a hyphen, thus: *Gay-Lussac*, *Clermont-Ferrand*. It is also customary to join the several Christian names of an individual by hyphens, as *Jean-Jacques Rousseau*.

3. Pronouns coming immediately after a verb, and standing to it in the relation of subject or object, are joined to it by a hyphen. If there are two such pronouns two hyphens are used. Thus: *Donnez-le-moi* (give it to me).

4. Hyphens are required both before and after the euphonic T, used in certain tenses after the third person singular, when followed by *il*, *elle*, *on*, as *parle-t-il?* (does he speak?)

5. When *ci* and *là* are joined as enclitics to a noun or pronoun, a hyphen is required, thus: *celui-ci* (this one), *celui-là* (that one), pronounced *së-lü-ēē-sēē* and *së-lü-ēē-la*, *cet homme-ci* (this man) *cette femme-là* (that woman). When prefixed to certain words they are joined to them by a hyphen, as in *ci-après* (hereafter).

6. The tens and units of a number are joined by a hyphen, except where the conjunction *et* (and) comes between them, thus: *dix-neuf* (19), but *vingt et un* (21). There is also a hyphen between *quatre* and *vingt* in the numbers from 80 to 99, thus, *quatre-vingts* (80), *quatre-vingt-dix* (90). *Cent* (100) is not joined by a hyphen to any number whether coming before or after it; thus 210 must be written *deux cent dix*, pronounced *dēh sawn' dēēss*.

7. *Même* (*māme*), self, is joined by a hyphen to the personal pronouns—*e.g.* *moi-même* (myself), *eux-mêmes* (themselves).

To be continued

MUNICIPAL ENGINEERS & SURVEYORS

Engineers and the Public Service. Qualifications, Salaries and Duties of Engineers, Surveyors and their Assistants

By ERNEST A. CARR

Expert Views and Advice. A valuable introduction to our detailed survey of the various departments of local government work is afforded by some practical advice to candidates as to the Municipal Service generally, and the best methods of qualifying for it, for which we are indebted to the courtesy of the Town Clerk of Manchester, the Solicitor and Clerk to the Wallasey District Council, a leading official of the Borough of Croydon, and other experts. These views have been furnished for our exclusive benefit, and are specially useful from the fact that they are no text-book theories, but the utterances of practical men of wide experience.

All are agreed that, although for certain scientific posts previous municipal experience is not essential, it is very important that candidates generally should enter the Service as early as possible.

"In the municipal, as well as in any other service," says the Wallasey authority already mentioned, "there is no royal road to success, but only the beaten track of hard work and strenuous endeavour.

"To become a good municipal servant it is desirable that a person should either be articled or apprenticed to the Chief of one of the various staffs of a Corporation. A parent who is well enough off to do so should article his son in preference to apprenticing him, as, although in the former case he will generally receive no salary for a term of years, he obtains more quickly such qualifications as will enable him to compete for the responsible positions of the Service. One great advantage of a youth passing through the drudgery of an apprenticeship is that, if he has brains to enable him to qualify for a professional position, his practical knowledge will give him a far better—because more intimate—command over his staff."

The Value of the Specialist. A further point emphasised is the importance of specialising from the first. The men who succeed are they who early determine which branch of the Service best suits their tastes and capacity, and who steadfastly pursue their training with that special object in view. "As to the course of instruction for municipal posts," writes the same expert, "first a good general education and then a practical training in the department to which the candidate wishes to attach himself, constitute as good a course as I know.

"The principal Departments of a Corporation are those of the Town Clerk, Borough Surveyor, Gas Engineer, Water Engineer, Electrical Engineer, Accountant or Treasurer, Police, Tramways and Education. Other Departments are the Public Libraries, Parks, Markets, Baths, etc."

On the question of diplomas and similar qualifications another official states: "The various professions are now so well filled with capable men that it is necessary for a candidate for any municipal position of value to be able to pass a very stiff examination, or to possess high qualifications as to his knowledge of the work of the department he seeks to enter."

Seeking Posts. Students in doubt as to their fitness for local government duties will be interested to learn, on the authority of an official of twenty-one years' service, that the most successful officers are not necessarily the book-worms and "intellectuals." "Even amongst 'brainy people,'" he writes, "there is often a truly woeful lack of initiative. In the Municipal Service there is room for the individual of ability, and still more of originality, courage and administrative capacity. Such an officer will be always able to command and retain a position of great responsibility at a good salary."

How is a qualified candidate to obtain an appointment? On this question the replies of the experts may be summarised as follows: He should forward a list of his qualifications to the clerk of each public authority in the district, stating the class of post he seeks and asking that he may be informed of any vacancy arising. He should scan the advertisements headed "Municipal" in the daily press, and the "Official Announcements" of trade and professional journals. But his best chance is to study every week the advertisements of the newspapers devoted wholly to Local Government affairs. These contain all requisite particulars of any appointment vacant, and specify the method of applying for it. It is a frequent practice of the authorities to require a successful candidate to undergo a medical examination before he is appointed.

The Demand for Municipal Experts. Year by year Science has played an increasingly prominent part in the conduct of local affairs. In the palmy days of the vestries, it was considered beneath the notice of practical men. Then came the beginnings of modern sanitation and engineering; the despised subject was found to possess more than a theoretic value, and to be capable of solving problems too complex for the old "rule of thumb" methods. Electricity developed with incredible speed from a schoolroom study to a mighty yet tractable monster, capable of unheard-of feats in the public service. Chemistry was employed to expose the fraudulent trader,

bacteriology shed new light on the mysteries of infectious disease, the local authorities forsook their prejudices, and to-day Science stands acknowledged as the most beneficent handmaid of the common weal.

The natural consequence has been a rapidly growing demand throughout the Municipal Service for trained scientific experts, able to apply their special knowledge to the wants of local government. A distinct class of officials has thus sprung up, with positions well in advance of the ordinary clerical and administrative staff; and among the most responsible and best-paid scientific posts are those connected with municipal engineering and surveying.

Salaries. To illustrate the salaries paid by municipal bodies to their leading engineers, we may turn to the pay lists of the Manchester Corporation. This energetic body, which employs a large technical staff for its gas, water and electrical undertakings, remunerates the leading officers as follows. Surveyor, £1100 a year; Gas Engineer, £1000; Superintendent, £700; Electrical Engineer and Tramway Manager, £900 each; Water Engineer, and Surveyor of Mains, £600.

It would be easy to multiply instances like this. Newcastle's engineer receives £800 a year, rising to £1000; a similar post at Leeds is remunerated with £600, while the engineers in charge of the waterworks and sewage works of the latter city each receive £1000 a year. The general question of salaries, however, will be discussed a little later. These examples are intended merely to show how attractive is this branch of the Service.

It is but fair and just that responsible posts of this class should be handsomely remunerated. To provide a large town with a proper water supply from remote sources, to devise satisfactory sewerage systems, or establish generating stations and supply services for electric lighting and traction—these are among the vast practical problems referred to the engineer's judgment. Such undertakings involve an outlay of many thousand pounds—perhaps even several millions; and their cost is largely determined by the way in which they are planned and carried out under his supervision. With issues so grave dependent on his work, it must be admitted that the municipal engineer is worthy of his hire.

The Scope of the Service. Many engineering works undertaken by local authorities are not compulsory, and the engineer is not always, therefore, an indispensable member of the staff. There is, however, a rapidly deepening conviction among persons interested in local government, that public services such as tramways or gas supply, instead of resting in the hands of trading companies, should be carried on by the authority itself. The effect of this has naturally been to widen the field of activities for municipal engineers of every grade. Nowadays many urban districts boast a small engineering staff of their own, whilst the larger and more enterprising boroughs have each a strong force. There is every prospect that for many years to come the scope of the engineer in municipal work will continue to expand.

Candidates for municipal employment should spare no effort to attain professional standing, or at least to establish proof of their competency, through one of the recognised examining bodies of the engineering calling. In the present course, however, we need not discuss the technical training or the examinations to be undergone before such diplomas can be gained. These questions are fully dealt with in the sections devoted to engineering itself [see CIVIL, ELECTRICAL and MECHANICAL ENGINEERING]. We are concerned simply with the practical considerations affecting municipal engineering as such. Briefly, these resolve themselves thus: What are the duties and salaries of municipal engineers and their assistants? What qualifications, and especially what practical experience, are most in demand in connection with such posts?

The Chief Posts. The field of inquiry is so wide that it must be mapped out into separate tracts corresponding with the special needs of local authorities rather than with the professional boundaries. For practical purposes we may classify municipal engineers as follows:

Borough Engineer.
Surveyor.
Electrical Engineer: General, Lighting, Tramways, or Consulting.
Waterworks Engineer.
Gas Engineer.

We shall now discuss only the chief and assistant posts of the first two classes. The remaining sections will be dealt with in due course.

The duties of a Borough or City Engineer vary with the special needs of each district. In a river port he may be mainly concerned with docks and sluices, and the clearing of fairways. A coast area involves such tasks as the construction of breakwaters and shore defence works. Hilly country has also its own problems—notably, road engineering and storm-water drainage.

The Borough Engineer. The borough engineer is required to have a thorough practical knowledge of civil, sanitary and electrical engineering, and of building construction. He must be familiar with the principles of mechanical construction and design, an expert in taking levels and drawing plans, and in preparing specifications, estimates, and bills of quantity. He may be called upon to design main drainage and water supply systems—or any other engineering work a local authority may lawfully undertake—and to supervise the execution of all such works. He is placed in control of all bridges and tunnels, and also of the engines, pumps, lighting appliances, tramway tracks, generating stations, dust destructors, and other mechanism belonging to the council; and must advise that authority as to their repair and renewal. And not least important among the duties entrusted to him is the scrutiny of all engineering contracts in order to safeguard municipal interests.

In many towns the offices of engineer and surveyor are united. The additional duties need not, however, detain us now. They will

be considered in discussing the surveyor's position.

The Engineering Societies. The professional qualifications expected of candidates for the post of borough engineer depend on the views of the authority concerned. The larger boroughs regard with greatest favour the Membership and Associate Membership of that most ancient and distinguished of engineering societies, the Institution of Civil Engineers [see page 160]. The "M.I.M.E." is also held in high esteem; and, among additional qualifications, the diplomas of the following bodies are most frequently met with: the Electrical Engineers', Sanitary Engineers' and Surveyors' Institutions, and the Sanitary Institute.

Many competent engineers, whose training would fit them for municipal duties, and who are conspicuous in the career of every successful candidate for valuable public appointments, and is so important that a few instances of such careers may be found helpful.

One municipal prize-winner, after serving four years' articles to a civil engineer engaged in water, sewage and railway practice, spent two years in acquiring architectural experience, and three more as engineer and agent for a contractor for large public works, including the construction of roads, bridges and main sewerage systems. A term of municipal surveying added valuable practice in innumerable duties relating to streets, parks, tramway systems, etc.; and the experience thus acquired has secured for its possessor the engineership of a leading northern city.

The record of another engineer who, at the age of thirty-two, has lately won a municipal

EXAMINATIONS FOR MUNICIPAL AND COUNTY ENGINEERS

Examining Body, Time and Place of Examination.	Subjects of Examination. No exemption from any part of the examination is granted to candidates, but certain certificates of general knowledge in English and Mathematics are required.	Fees and Age Limit.
INCORPORATED ASSOCIATION OF MUNICIPAL AND COUNTY ENGINEERS. London: April. In one Provincial Town: October. In Scotland: As required. In Ireland: As required.	**1. Engineering as applied to Municipal Work:** 1st Paper: A. Sewage Disposal. B. Tramways Construction. C. Bridge Construction. D. Water Supply. 2nd Paper: A. Geodesy. B. Hydraulics. C. Sewerage. D. Road Construction and Maintenance. **2. Building Construction; Strength of Materials:** A. Materials. B. The Construction of Public and Private Buildings. C. Building By-laws. D. Public Baths and Hospitals. **3. Sanitary Science as Applied to Towns and Buildings:** A. Heating and Ventilation. B. Scavenging and Disposal of Refuse. C. Water Supply and Drainage of Buildings. D. Disinfection. **4. Municipal and Local Government Law as Relating to the work of Municipal Engineers and Surveyors.**	£4 4s. for first examination. On re-examination after failure £2 2s. Candidates must have attained their 22nd birthday.

Note.—The Examiners do not recommend any particular text-books, as it is desired to make the examinations rather a test of the candidate's practical knowledge of the subjects generally than to find his acquaintance with any particular book or books.

Fifty per cent. of the total number of marks given are required to constitute a pass.

Further particulars, with specimen question papers, may be obtained from the Secretary to the Association at 11, Victoria Street, London, S.W.

attracted to the Service, have been unable to follow the course of studies prescribed for membership of the Institute of Civil Engineers, or for any similar professional diploma. Practical experts of this class should avail themselves of the examinations of a body devoted solely to the municipal aspects of their calling—the Incorporated Association of Municipal and County Engineers. This is a powerful organisation, restricted in membership to trained engineers and surveyors to public authorities. A table of its examinations is given on this page.

The Supreme Essential. It will be readily understood that no certificates, and no amount of theoretic training, will supply the place of that foremost essential, viz. responsible experience in engineering works of a varied and comprehensive nature. This fact stands out post with a beginning salary of £800 a year, is mainly associated with giant railway works and contracts all over the country. These undertakings involved such varied duties as the alteration of street levels, the construction of bridges, viaducts, canals and wharves; and the making and sewering of new roads. In most of these works he was the responsible engineer in charge of the contract. It is noteworthy that, unlike the majority of his rivals, this officer had had no previous service under a local authority.

First Steps. A more typical career, perhaps, is that of the present Southend borough engineer, who has much brilliant municipal service to his credit. His articles were served in a borough engineer's office, and since that time as assistant, and later as principal, he has been engaged on public works, including ordnance

map surveys, extensive main drainage and storm-water schemes, the designing of public baths, schools, pumping stations and other borough buildings, and sundry street and tramway works. Solid achievement and variety of experience being so essential, it follows that candidates whose years do not reach the middle thirties are seldom regarded as ripe enough for chief appointments. On the other hand, those over fifty are often considered past their best.

Enough has been said to indicate that there is no royal road to a borough or county engineership. But with such a goal in view, a student cannot begin more favourably than as articled pupil to an official of that standing—preferably a member or associate member of the Institution of Civil Engineers—in a busy provincial town. In this way valuable insight into municipal work will be gained, as well as a good opportunity of securing a footing in the Service.

Instances of the salaries paid by the larger corporations have already been given. Speaking generally, they vary between £500 and £1200 a year. Minor authorities pay less—from £350 to £550 a year. But these bodies rarely appoint a chief engineer. Their practice is to employ gas, electrical and other specialists as required, whilst the place of the borough engineer is occupied by the municipal surveyor.

The Municipal Surveyor. Many educational works classify appointments of this character among the posts available to men who have undergone the training of a general surveyor. This is true to so limited an extent as to be really misleading. Property or estate, as well as building, surveyors are occasionally included in the staff of a public authority, and are the municipal representatives of professional valuation or quantity surveying, usually holding the Fellowship or Professional Associateship of the Surveyors' Institution [see SURVEYING]. But where the post is that of "borough surveyor" the training expected of that officer, and the duties entrusted to him, are substantially those of an engineer.

In order to explain clearly the surveyor's duties, and the way in which they differ from those of a borough engineer, it is necessary to note that there is a broad distinction to be drawn between surveyors to a *county* or *district council* and those in the service of a *city* or *borough*. Whatever the character of the public authority he serves, a surveyor is not called upon to undertake such grave and costly mechanical schemes as may occupy the attention of the municipal engineer. Elaborate water services, for instance, with reservoirs and lengthy conduits, the formation of docks and harbour defences, or the devising of an important main drainage scheme, would lie outside the scope of his duties; though many borough surveyors gladly undertake responsible work of this nature for the sake of an enhanced reputation. On the other hand, the expert surveyor carries out minor engineering works equally with the engineer; and, in addition, is burdened with a mass of miscellaneous duties in connection with roads and the land surface generally, from which his brother official is wholly or partly free.

County and District Surveyors. Under a public authority for a county, urban, or rural district, the duties involved are practically those of a Surveyor of Highways. The officer is responsible for surveying, levelling, maintaining and repairing all roads and bridges in his charge. In an urban or rural district he supervises generally the work of road cleansing, watering, paving and lighting, and of laying out and sewering all new thoroughfares in his area. Street lamps, hydrants and trees are under his care, and occasionally the maintenance of tramway tracks. He acts also as expert adviser to his authority in matters of contract. He must be, in brief, a sound road engineer and a capable draughtsman.

The smallest responsible posts are naturally in the rural districts, where traffic is least and new streets work is unimportant. The salaries paid are correspondingly small—£100, £120 or £150 a year, rising to £180 or £200. But there is ample leisure for private work or study, and these appointments afford good openings into the Municipal Service for young men who must earn a livelihood while qualifying for higher positions.

In urban districts the duties are heavier and more responsible, including inspection of buildings in course of construction; and salaries range from £150 to £250 a year—occasionally over £300. County authorities require their surveyors to be expert engineers, for the work involved may include the reconstruction of important county bridges. The officers appointed are usually members either of the Surveyors' Institution, the Institution of Civil Engineers, or the Association of Municipal and County Engineers. If private practice is prohibited, the salary paid varies from £400 to £800 or £1000, according to the area and importance of the county. In a recent and typical instance, a stipend of £500 was offered, rising by £50 annually to £700. Some of the smaller county councils, by imposing no restrictions as to private work, secure the services of competent prac'ising surveyors and engineers for £250 or £300 a year.

Borough Surveyors. The busiest and best-paid section of municipal surveying is that of the leading cities and boroughs, including the metropolitan divisions.

The Borough Surveyor is a great deal more than a surveyor of highways. To the duties of that office, magnified as they are by the importance and business of his district, must be added multifarious other tasks in engineering, land surveying and architecture. The most important of these are the construction and repair of tramway tracks, the carrying out of street widening and improvement schemes, the clearance of "condemned areas," the formation of public gardens and recreation grounds, and the inspection of houses and sewers in course of construction. It is only in the largest towns, as we have seen, that a borough engineer is employed; and where this

is not the case, the surveyor has general charge of municipal machinery and apparatus. Further, he is often called upon to act as architect for his council in the designing of public baths, libraries, schools and other buildings, and to superintend their erection.

For such responsible work one must be experienced in far more than land surveying. The borough surveyor's practical training should be as diverse as the engineer's, and of the same general character. Except for the increased importance of architectural knowledge, all that has been said of the experience and diplomas best suited to the equipment of a borough engineer applies equally to surveyorships. Indeed, a highly qualified officer of either class is fully competent for the other, and such transfers are not infrequent. The best degree for surveyors is the A.M.Inst.C.E.; or, failing that, the Associateship of the Surveyors' Institution [see page 160].

The remuneration is similar to that of the borough engineer, and the proportion of liberally paid posts is high. Minor boroughs pay their surveyors from £200 to £500 a year; the larger towns from £400 to £800, £1,000, and even higher. Manchester pays its chief surveyor £1,100, and its district officials £340—in one instance £400. The City Corporation, small as its area is, pays its surveyor £1,000 a year. In the London boroughs the stipend varies from £500 to £900, with travelling allowances.

Assistant Engineers and Surveyors. To the young student of engineering and sanitary service, with his experience still to come, and his way in the world yet to make, the principal appointments of the class we have been considering are as yet beyond reach. Such a student, if the question of a living wage be important and an articled pupilship out of the question, would be well advised not to seek municipal employment directly he leaves his technical college or school of engineering. Without practical experience, the only posts in the Service available to him would be office positions—perhaps as plan-copier or draughtsman. As we shall notice when considering municipal clerkships, such appointments are not ill-paid, but they lead further and further from actual engineering; and the student, remembering the supreme importance of practical knowledge in the career he seeks, should resolutely turn his back on the Municipal Service for a time.

A year or two spent on the outdoor staff of a public contractor or civil engineer will put such a youth in a very different position. He will now be competent to take a post as Assistant in a municipal surveyor's or engineer's office. His training thereafter will be of the most practical and useful nature: he will learn exactly the scope of municipal work, and, if he has ability, and does not neglect the science and theory of his subject, will be well on the way to his goal of a principal appointment

It is worth noticing, by the way, that a distinction is often drawn between a Surveyors' Assistant and an Assistant Surveyor, the latter being the senior and more responsible post.

Candidates for assistantships are required to be capable draughtsmen, practically acquainted with drainage and street work, and experienced in the preparation of specifications, quantities and estimates. For the best appointments competence to superintend outdoor works is usually stipulated; and if the vacancy is in a borough surveyor's office, some knowledge of architectural work is commonly demanded.

The Duties of an Assistant Surveyor. The work expected of an Assistant is of precisely the same character, whether he is employed in an engineer's or surveyor's office; but vacancies of the latter class are by far the more frequent. The following typical "List of Duties," recently prescribed by an urban district council, will be of practical service to students preparing for such posts.

The Assistant Surveyor must reside in the district, and devote his whole time to the duties of the office. He will act under the control and superintendence of the Surveyor to the Council. The undermentioned duties appertain to the office:

1. To make surveys, take levels, and prepare drawings, tracings, specifications and estimates for private street works; for construction of all sewers and drains, and for works of street improvement.

2. To assist in the preparation of drawings, tracings, specifications, and estimates of all other works of every description required by the Council from time to time.

3. To assist in the checking of accounts, the inspection of all new buildings, streets and sewers, and in the supervision of the various branches of the Council's work, and all works the Council may have in hand from time to time.

4. To be in attendance at the meetings of the Council and the various Committees.

5. Generally to assist the Surveyor in the discharge of his duties, and to perform any other duties appertaining to the Surveyor's Department that the Surveyor may direct.

Salaries of Assistant Surveyors. Assistants' salaries vary like those of their chiefs. For the appointment to which the above list relates, £120 was offered, with annual increments of from £10 to £150. In provincial towns and the London boroughs the surveying staff is classified into juniors and seniors; the former receiving from £80 to £175, the latter not less than £150, rising to £200 or £225, and more generally an initial salary of £180 or £200, with a maximum of £300. If the staff is large, the chief assistant's stipend begins at £250 and may rise to £400. The usual limits of age are—for juniors, 19 to 25; for seniors, 25 to 35 or 40.

It will be seen that a moderate income is attainable even as an assistant surveyor or engineer. But in the Municipal Service no hardworking and able officer of good general education should allow himself to remain in that status all his life. The fatal mistake which renders such stagnation possible is to neglect one's opportunities of qualifying professionally at the earliest possible moment. To work hard at one's duties and studies at the same time is admittedly trying; but it is essential for the man who means to succeed.

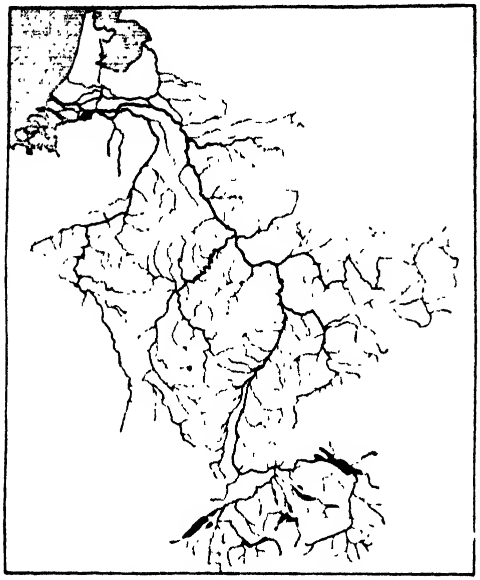
THE SHAPING OF THE EARTH

Rain, Rivers, Oceans, Lakes, Mountains. The Streams and Rivers as Nature's Sculptors. Glaciers and Volcanoes and their Work

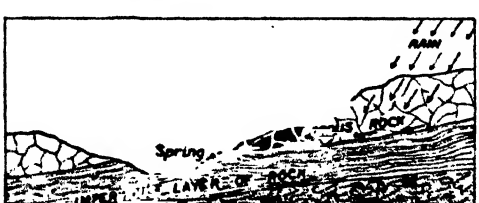
By Dr. A. J. HERBERTSON and F. D. HERBERTSON, B.A.

WATER, which plays its part, as we have seen, in determining the shape of the earth, does more than help to make new soil out of the waste of the rocks. It carries the new soil down to the lower lands, and spreads it out over them. Everyone who has built a sand castle by the sea knows that next day the sand is perfectly smooth again. The waves have moved the grains of sand, and spread them out level. The same thing happens in every flood. The swollen river overflows the lowlands, its waters discoloured with the soil it whirls along with it. As it subsides it drops over the flooded area the particles of soil which it has no longer the force to carry. The same process goes on imperceptibly after every shower. Wherever there is the slightest slope there is a downward movement of particles of soil and water towards the lowest level. Thus all over the earth a levelling movement is going on, wearing down mountains, and building up the plains with new soil made from their broken-down rock waste.



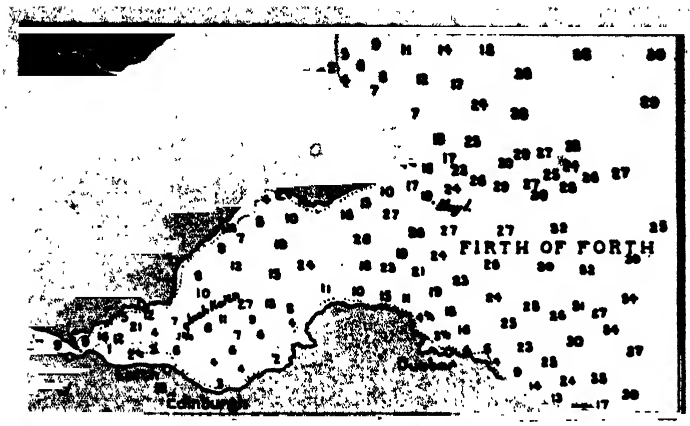
26. BASIN OF THE RHINE
Showing the course of the river and its tributaries

Trees as Protectors of the Earth. These processes that go on eternally are evidently as much creative as destructive, though man may desire to check them so far as possible, because they interfere with his requirements. In many mountain lands the hillsides are so stripped of soil that the inhabitants have to collect it from far below to replenish their little plots. This destruction of the soil, or denudation, as it is called, is greatly checked by trees, which not only break the force of wind and rain, but also bind the soil together with their roots, so that it is less easily washed away. What is true of forests is true of all vegetation, and men are now turning this knowledge to account. In the hot desert, for example, the sands are slowly but steadily driven before the wind in long sand dunes, which advance so many inches or feet in a year. Whole cities have been buried by them in the deserts of Asia, and the railways which now cross many deserts are menaced by the same fate. To protect them, coarse grasses and desert trees are planted alongside the tracks to bind the sands together and arrest their movement. In lands of the temperate zones the forests on the hill slopes have been so recklessly cut down that the lower slopes are unfit for cultivation. Most civilised governments are now paying great attention to reforesting, in order to arrest this disappearance of the soil.



27. SECTION OF A SURFACE SPRING

The Making of a River. A river is a body of water, holding rock waste in suspension, and moving along a defined channel, or bed, from higher to lower levels. Every drop of rain which does not sink into the ground moves downwards, following the slope of the surface, seeking the lowest attainable level, and carrying more or less of the surface soil with it. Trickles of water collect into rivulets, and these into larger and larger ones, always seeking lower levels, and gradually joining up to form a main stream. The whole of the area thus drained is called a river basin. The higher ground separating one basin from another is called a *water-parting*, or a *divide*. The streams which unite to form a main stream are called the *head waters*, or *sources*. Branches which enter well-defined



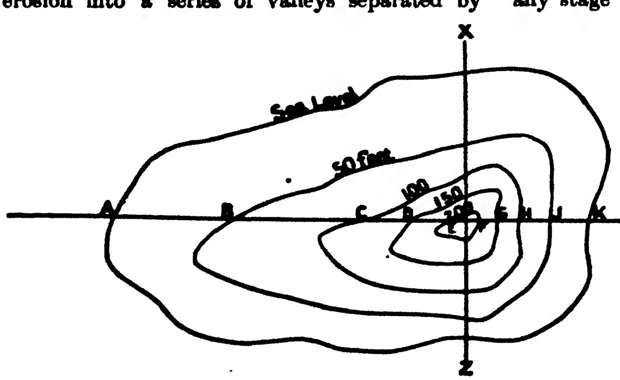
28. THE FIRTH OF FORTH, SHOWING DEPTHS IN FATHOMS AT LOW WATER. THE DOTTED LINE ROUND THE COAST IS THE 3-FATHOM LINE

streams are called *tributaries*. Where a tributary enters there is a *confluence*. The bank of a river which is on the right hand of a traveller going towards the sea is the right bank. The other is the *left bank* [26].

Character of a River's Course. The upper course of a river rising at any height is usually very steep, with great falls in its bed. Every river, however, by perpetually grinding rock waste over these obstructions, is gradually removing these inequalities, or grading its bed, as it is called. It is also deepening it, and gradually cutting out, or eroding, a valley, with more or less steep sides, according to its age and the nature of the rocks. Each of its tributaries, and the streamlets which feed them, is doing the same, and thus in the course of ages a highland region is cut up by stream-erosion into a series of valleys separated by higher ground, forming the hilly or mountainous regions we know. It is in its upper course, where it is too swift and steep for navigation, that a river does most work in wearing down the rock waste it carries. As the slope lessens its speed slackens, and it begins to drop more and more of the sediment it is carrying, thus further levelling its bed. In the plains it frequently overflows its banks, forming stretches of flat land on both sides, called its *flood plain*. Here it is probably navigable, or can be made so artificially. This process is called *canalisation*. Most of the rivers of Europe are canalised, and connected by canals, which may, perhaps, be called artificial rivers. Across the

29. THE FIRTH OF FORTH, SHOWING DEPTH OF WATER BY CONTOURS AND SHADING AT INTERVALS OF 10 FATHOMS

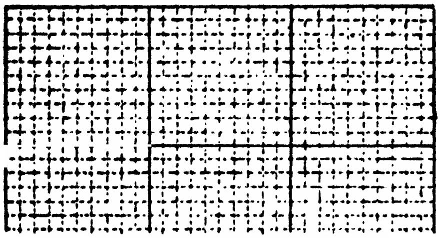
lowlands the river, now much slower, continues to seek the lowest level—that is the sea. At any stage of its course it may have found its way thither blocked by a range of mountains or hills. One of two things then must happen. Either the river has been turned in a new direction, and flows round the base, or, if the rocks are of a kind easily acted on by water, it may have cut a passage or gorge through them. The steepness of the walls of this gorge, like that of the walls of its upper valley, will depend partly on the length of time during which weathering has been proceeding, and partly on the character of the rocks and the rate at which they weather. The Thames, which rises in the Cotswolds, in which it has cut its upper valley, has to cut through



30. MAP OF CONTOUR LINES

two other barriers—the Oxford Heights and the Chiltern Hills—before it reaches the sea.

The River's Entry to the Sea. A river enters the sea by its mouth, the character of which depends on the nature of the sea into which it flows. If this has strong tides and currents, the sediment, or fine rock waste, which



31. DIAGRAM OF SECTIONAL PAPER

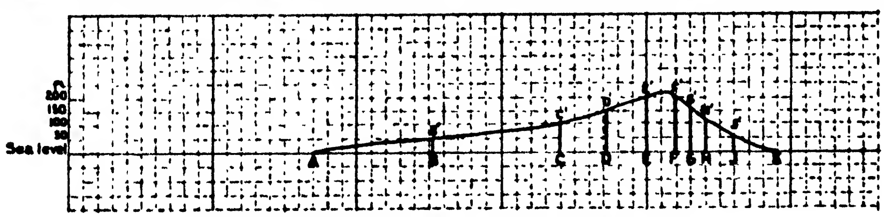
the river has brought down with it, and which it drops when its motion is checked by the sea, is rapidly carried away, and the channel is kept deep and unobstructed. This forms an estuary, up which the tides penetrate twice daily, enabling shipping to pass easily up and down. In a sea with feeble tides and currents the dropped sediment accumulates on the bottom at the river's mouth, gradually silting it up. In the course of ages the new land thus formed rises above the surface, forming mud flats of alluvial land. Across this sodden new land the river has to find its way, and, having no banks to confine it, it breaks up into a network of branches, or distributaries. At the mouth of each of these the same land-making process is going on, and the new land is steadily pushed out to sea, forming a fan-shaped delta, so called from its resemblance in shape to the Greek letter Δ of that name.

Underground Stores of Water. A certain amount of rain percolates through the ground, until it is stopped by rock of a kind through which it cannot pass. Along this layer of impervious rock it makes its way underground until the layer comes again to the surface of the land at a lower level. Here it bursts out as a spring [27]. Where the arrangement of the rocks makes this impossible, it forms a sort of underground reservoir. Coal mines are often flooded by miners accidentally breaking into such subterranean rivers or reservoirs. This underground store of water helps man in his attempts to make use of the drier regions of the world, as we shall see.

Lakes and Rivers. A lake is a body of water surrounded by land. Lakes are of all sizes. They are usually drained by a river, and are then fresh. Lakes with no outlet become salt or brackish.

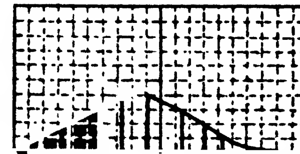
Where a river enters a lake its motion is checked, and it deposits much of the sediment it carries. All lakes thus tend to be filled up. A shallow lake is often divided into two by the formation of an intersecting belt of new land, where the river enters. A lake in a river's course thus acts as a filter, and the river which entered it as a muddy stream may emerge bright and clear at the other end.

Highlands and Lowlands. Next to the distinction between sea and land, perhaps the most important to man is that between highland and lowland, mountain and plain. Mountains, we saw, have a colder climate than lowlands, and consequently different vegetation, occupations, and mode of life. They interfere with communication, often cutting off for many months all intercourse between villages on opposite slopes, which are only a few miles distant as the crow flies. In a highland region the question of routes becomes very important. These are generally supplied by the river valleys, by following which it is possible to reach a pass or col, the lowest part of the ridge or range. In text-books of geography the highest points are generally given, whereas it is the passes, or lowest accessible points, on which communication depends, that we want to know.



32. PROFILE OF CONTOUR OF LINE A TO K ON 30

Old and Young Mountains. We have seen that the greater part of the sculpturing out of a highland region into mountains and hills has been the work of streams, which in cutting out their own beds, and carrying away loose material, have gradually shaped the present feature of the landscape. These processes have been going on for varying periods in different parts of the world. In older mountain regions, where they have been longest at work, the peaks are less sharp, the slopes less steep, the valleys broader, and more or less graded, forming good routes. In young mountain regions, uplifted in



33. PROFILE OF CONTOUR OF LINE X TO Z ON 30

comparatively recent times, where erosion has gone on for a much shorter period, the peaks are sharp, the valleys narrow, and very imperfectly graded. The upper valleys are often mere precipitous gorges, useless as routes. Such regions are almost inaccessible till man cuts or carries roads along the steep walls of the valleys. In the Himalayas, which are young mountains, the roads are often carried on frail supports along the face of precipices of the most terrifying description.

Glaciers and their Work. Where mountains rise above the snow line, the height of which varies in different parts of the world, their summits have, so far as temperature is concerned, a polar climate. Snow cannot lie to any depth on their steeper slopes, and the bulk of it accumulates in the higher valleys, where it is pressed by its own weight into solid ice. Glaciers erode valleys precisely as rivers do. Often hundreds of feet thick, and many miles long, they have an imperceptible but steady movement downwards, carrying with them the rock waste which falls from the peaks and precipices above. Some of this forms moraines on both sides of the glacier, but much falls through the crevasses, or splits in the glacier, which does not yield so easily to the inequalities of its bed as a river. The friction of the moving glacier and of the rock waste below it gives a curious U-shape to the bottom of the valley. Where we find such valleys we know glaciers formerly filled them, and ice-scratchings can often be seen on their rock walls. When a glacier reaches a certain level, its lower end, or snout, begins to melt and flow away as a river, often hollowing out a beautiful glittering blue ice cave. The rock waste, brought down in the moraines, is deposited at the lowest level reached by the glacier, often forming what look like chains of hills across the valley. Glaciers advance and recede at different periods, and several chains of these terminal moraines can often be traced where glaciers are steadily retreating or have wholly disappeared.

Volcanoes: "Chimneys" of the Earth's Interior. Volcanoes serve as outlets for the molten rock of which some part of the earth's interior consists. They communicate by a sort of pipe, or vent, with lower depths than any reached by man in his deepest mines. From the crater, or upper end of this vent, eruptions take place from time to time. They frequently begin with subterranean eruptions, which blow great clouds of steam and ashes into the air. The falling ashes gradually build up a conical mountain round the vent. In severe eruptions lava, or molten rock, may rise up the vent, flow over the rim of the crater, down the mountain sides, and over the neighbouring country. When cooled it forms a hard rock, on which nothing grows. This is gradually reduced to fine soil by the processes described, and the soil is extremely fertile, probably owing to the presence of chemical fertilisers.

Volcanoes are very irregularly distributed, but are usually near the sea. They occur in the polar regions, on the equator, and under the sea. They vary in height from 20,000 feet to mere hillocks. *Geysers* somewhat resemble volcanoes in their action, but emit hot water instead of lava.

Maps not showing the distribution of high and low land, or relief, are useless for many practical purposes. The sailor must know the depth of the sea bottom, or he may run aground. The cyclist wants to know if a given road is flat or has a dangerous hill. A railway engineer, or an army on the march, wants very precise information as to the lie of the country. The geographer can form no opinion about a country till he knows its general relief. The mapping of relief, therefore, is of great practical importance.

High Land and Low Land. A sea-chart is usually covered with figures, which show at what depth the bottom will be found [28]. On some charts lines are drawn through all places where the depth is the same—10, 20, 30, or more fathoms, as the case may be [29]. Every point on one of these lines, which are called *contour lines*, is at the same distance above the sea bottom.

The height of the land above sea-level has been more or less roughly ascertained all over the world. In civilised countries highly-trained surveyors, working under the orders of the government, make very minute and exact surveys by the aid of delicate instruments [see SURVEYING], and these are recorded in official Ordnance Survey maps. The various heights are either inserted on these maps in figures, as in sea-charts, or joined by contour lines drawn at given distances. Every point on the same contour line is at the same height above sea-level. In maps of large areas on a small scale, in which only the broad general features are shown, it is sufficient to put in contour lines for every 500 or 1,000 feet, as the case may be. Such a map would be useless to the cyclist. The more detail we want to show, the more contour lines we must put in, and our map must, therefore, be on a large scale. Wherever contour lines approach each other closely the land falls and rises more rapidly than when they are further apart. Comparing the contour map and section [30, 31], we see that in the one case the slopes are steep, and in the other more gentle. In many modern atlases the variety of relief is made more graphic by colouring the spaces between the contour lines, the intensity of the tint varying with the height, so that the highest parts are the darkest.

Sometimes hill-shading is used instead of contour lines. The steep slopes are shown by dark shading, or closely drawn thick lines running in the direction of the slope, while gentle slopes are indicated by light shading, or by thin lines at wider intervals.

Contour Maps. A student must practise translating contour maps into representations of the actual relief. For this purpose it is useful to make a few sections from contour maps, which is easily done. Figure 30 indicates the relief of a district by contour lines drawn for sea-level—50 feet, 100 feet, 150 feet, and 200 feet. We rule on a sheet of paper five equidistant lines, or, what

is better, take a sheet of fine chequer paper [31]. We number the lines "sea-level," "50 feet," "100 feet," "150 feet," "200 feet" [32]. Now suppose we want to draw a section along the line *A K*. We measure off a line *A K* along the line representing sea-level on the chequer paper, and mark on it the points *B, C, D, E, F, G, H*, and *J*, all measured exactly to correspond with the same distances along the line *A K* in the contour map.

We name them to correspond, and then draw perpendicular lines through *B* and *J*, which are on the 50-feet line in the contour map to the 50-feet line on the chequer paper. Let us call the points where they cut it *B'* and *J'*. In the same way we draw lines through *C* and *H* to cut the 100-feet line in the points *C'* and *H'*. Similar lines through *D* and *G* to cut the 150-feet line at *D'* and *G'*, and finally through *E* and *F* lines to cut the 200-feet line in *E'* and *F'*. Each point on the contour lines is now represented on the corresponding line on the chequer paper, and at the proper distance. We draw a line through the points *A, B', C', D', E', G,' H', J'*, and *K*, and thereby see what the actual surface of the country along the line *A B* is like. Do not forget, however, that the height is probably exaggerated. The lines *E E'* and *F F'* represent only 200 feet, while the line *A K* may represent any distance according to the scale of the map. A map made to show the true height would generally be too small to be clear. Notice that the long gentle slope of the hill corresponds with the less close contour lines, and the short steep slope with the closer contour lines. In 33 is shown a section of the same hill along the line *X Z*. A little practice will enable us to read contour maps right off without first translating them into sections.

The Continents. An island is a mass of land wholly surrounded with water. The greater part of the land on the earth's surface is grouped into two great islands, the Old and the New World. The former and far larger of these consists of Eurasia in the north, separated by ill-defined boundaries into Europe to the west (3,800,000 square miles), and Asia to the east (17,000,000 square miles); and of Africa in the south (11,500,000 square miles), united to Eurasia by the narrow neck or isthmus of Suez. The island of the New World is divided into North America (9,000,000 square miles) and South America (7,000,000 square miles), united by the long narrow isthmus of Central America. The island of Australia (3,000,000 square miles) is also reckoned as a continent. It is believed that an island continent (generally called Antarctica) of vast extent surrounds the South Pole. Of islands not reckoned as continents the largest is the polar island of Greenland (500,000 square miles). Islands which rise on the continental shelf may be regarded as detached portions of the mainland.

Land and Water. By far the greatest proportion of land is in the northern hemisphere, and in temperate latitudes. Only two continents, Africa and South America, are crossed by the equator, and both narrow rapidly south of it. Australia is the only continent lying wholly in the southern hemisphere. Broadly speaking, the northern hemisphere is the hemisphere of land, and the southern hemisphere is the hemisphere of ocean. The earth could be bisected in such a way that one hemisphere contained almost no land, while the other was composed almost equally of land and water. In the latter the mouth of the Loire, in France, would be approximately in the position of the pole.

In comparing the continents we at once notice certain resemblances. The first is the tapering to the south, already mentioned, which is seen in Greenland, North and South America, Africa, and Australia (Tasmania). Another is the southward running peninsulas which characterise Europe and Asia. We may notice, too, that the general lines of the Old World, broad in the north, tapering in the south, resemble those of the New World, especially if we include Australia (Tasmania), and compare its position with that of South America. There is also a certain uniformity in the distribution of relief. Notice the so-called Mid-World and Pacific Mountain systems, which may be traced in the mountains of Central Europe, North Africa, Central Asia, the islands of the Pacific from Japan to New Guinea, and the lofty mountains of North, Central, and South America.

THE OCEANS

Five sevenths of the lithosphere are covered with water, forming the hydrosphere. The oceans and seas of the world form one great ocean, above which the higher parts of the lithosphere rise as islands of varying size.

Area of the Oceans. For convenience, this great world-ocean is known under different names. The Pacific Ocean (70,000,000 sq. miles), the largest, washes the western shores of Asia and Australia and the western shores of the New World. It communicates on the north with the Arctic Ocean, extending towards the North Pole, and on the south with the Antarctic Ocean, extending towards the South Pole. It communicates round the south of South America with the Atlantic Ocean (25,000,000 square miles), connected, like the Pacific, with the Arctic and Antarctic Oceans, which washes the eastern shores of the New World and the western shores of the Old. The Atlantic Ocean communicates round the south of Africa with the Indian Ocean (17,000,000 square miles), which washes the eastern shores of Africa, the southern shores of Asia, and the western shores of Australia, south of which it is connected with the Pacific. Various great gulfs of these oceans are known as seas. We notice the Caribbean Sea with the Gulf of Mexico, sometimes called the American Mediterranean, enclosed between Central America and the West Indies; the North Sea, enclosed between the British Isles and Europe, and the Mediterranean, enclosed between Southern Europe and Northern Africa. All these are gulfs of the Atlantic. In the Indian Ocean we see the long, narrow, almost land-locked Red Sea, between Asia and Africa.

TYPES OF ELECTRIC CELLS

Including Volta's Cell, Leclanché Cells, Daniell's Cell, Dry Cells, with instructions regarding the care and testing of cells

By Professor SILVANUS P. THOMPSON

IN the article "How Electric Currents are Generated," it was pointed out that in order to set electricity flowing as a current, it is needful to provide some contrivance such as a dynamo or a battery which is capable of setting the electricity into movement, or, in other words, can exert an *electromotive-force*, or electric effort. Dynamos are mechanical contrivances for exerting an electromotive-force to drive the current along the circuit. *Batteries* are chemical contrivances to do the same thing. They are sometimes called *galvanic batteries* in honour of the Italian, Galvani, who was a pioneer in the discovery. Sometimes they are called *voltaic batteries*, in honour of Count Alessandro Volta, who was their actual inventor. Both terms refer to the same thing. The electric current itself was at one time called the galvanic current, or the voltaic current, for the same reasons.

The Cell. Every battery is made up of a number of separate cells joined together; and it is in the cells that the chemical operations proceed which propel the electricity around the wires constituting the circuit. The cell is the source of the electromotive-force which drives the current. In accordance with the principle that the production of electric energy requires the consumption or expenditure of an equal amount of energy of some other kind, we have to regard the cell as an apparatus in which energy that has been previously stored is liberated by chemical action and transformed into electric energy.

Every schoolboy knows that every kind of fuel is a store of energy. Coal represents the energy of the sunlight in past ages stored up chemically, every pound of coal containing some ten million foot-pounds of energy. Every other kind of fuel is likewise a store of energy, which, when it is burned, it gives out in the form of heat. In a *cell* the fuel which constitutes the store of energy is the metal *zinc*. Zinc will burn. A bit of zinc foil when lighted burns with a brilliant blue flame, giving out heat and light: so we know that it is a fuel. But as a fuel it is inferior to coal, for one pound of zinc will give out when burned only about 1,800,000 foot-pounds in the form of heat.

The Emission of Energy. In our cells, however, we do not want heat, and we do not set the zinc to blaze. We cause it to burn in a quiet, cool, chemical manner by dissolving it in acid or in some suitable chemical solution. In this case the chemical union of the metal with the oxygen or with the chlorine of the liquid is not called combustion; it is called chemical combination. The point of importance is that when we cause the zinc to consume quietly by chemical combination in the cell, it gives out its energy not as heat and light, but silently in an electrical way, expending the energy in pushing the current around the circuit. If a cell is badly constructed so that it offers within itself a considerable resistance to the flow of the current, it will get hot in operation, which is undesirable. A cell is a sort of little electro-chemical furnace, in which zinc is the fuel, and in which if it be properly designed, the consumption of the fuel is slow, quiet, and cool.

Volta's Cells. To make a Volta's cell, very simple appliances are needed; but to find out by experiment what it will do needs more expensive apparatus. Procure a piece of sheet copper, say 6 inches long and 2 inches wide, and a piece of sheet zinc about the same size. Take also a common jam-pot or a glass vessel of similar style, say 4 inches in diameter and 5 inches high. A glass jar is preferable, because it lets the interior be seen. Some copper wire—common bell wire, for example—not too thick, should be procured. A few feet of No. 24 standard wire-gauge will suffice. Two clamping screws should be procured by which to attach a bit of copper wire to each of the metal plates. As exciting liquid for the cell there should be provided 2 oz. of sulphuric acid, diluted down to one-fifth strength by carefully adding it a little at a time to 8 oz. of water. It will be necessary to provide also a few drops of quicksilver.

Practical Experiments. By way of preliminary experiments, fill the jar to about 4 inches deep with the dilute acid. Then dip the copper plate into it, holding it upright, and watch its surface. Nothing will happen; but the acid will clean the surface of the copper, which when taken out after a few minutes may be dried with a rag. Now try dipping into the acid, in the same way, the zinc plate. If the zinc is ordinary commercial sheet zinc you will see that at once a number of small bubbles form on its surface and come fizzing to the top. The zinc is, in fact, being consumed by the acid; idly, without the production of any useful result in the way of an electric current, and the energy of the portion consumed will turn into heat, as will be discovered if the zinc be left in too long; for the acid in the jar will grow hot as the zinc dissolves.

Now remove the zinc sheet from the acid, lay it down on a common plate, and pour upon it one drop of quicksilver, then with a bit of rag rub the quicksilver over the zinc. Instead of running off it will stick to the zinc, and can be spread all over it, making it shine almost like silver. This operation is called *amalgamating* the zinc, and it makes it beautifully clean. If

you now try the effect of dipping the zinc once more into the dilute acid you will find that if you have cleaned the whole of the surface that is immersed, the acid will not now act on it, and no more bubbles will rise from it. In fact, pure zinc is not consumed when put into dilute acid. The bubbles that arose from the dirty zinc were hydrogen gas, a product of the chemical action upon the dilute acid.

Experiments with Volta's Cell. So far we have been experimenting with the metal plates separately. We must now make up the Volta's cell by putting into the acid in the jar both of the metal plates at once. They should be put in separately, and supported with bits of wood or otherwise held so that they do not touch one another, and so that the upper end of each of the plates stands above the level of the liquid.

A Volta's cell consists of two plates of different metals—in our case zinc and copper—*dipping into dilute acid* (or other corrosive liquid) in a suitable containing vessel. Our cell [4] answers to this description. If we look at it we shall see that as arranged neither of the metals is consumed. There are no bubbles given off, neither is any electric current generated. Now try the effect of letting the top of one of the metal plates touch the top of the other. The moment they touch something happens: there will be seen a rush of minute bubbles which fizz off through the acid. Observation will show that these bubbles are now formed not on the surface of the zinc but on the surface of the copper. Is the copper then being consumed? Not at all. If you will make a special investigation by working with plates that have been carefully weighed on a delicate balance before the experiment and are weighed again after it, you will find that though the hydrogen bubbles fizz off from the copper it is the zinc that will have lost weight, some of it having been consumed.

Try the effect of making the two plates touch one another under the liquid instead of above the surface. You will find that the same effect results as before. Now try whether this effect—the chemical action evidenced by the evolution of bubbles—happens if, while keeping the two plates apart, you bring a third piece of metal into contact with both of them so as to form a bridge between them. To serve as bridge you may try another strip of sheet metal, or a bit of copper wire. You will observe that if there is a metallic bridge joining them, the effect will be just the same as if they were to touch one another—bubbles will rise from the copper plate when contact is completed, and they will stop rising when contact is broken. Try with other kinds of metal; a clean iron nail, a dirty nail, a silver florin, a bit of lead pipe, a brass knob. You will find that *any* metal will answer, provided it is clean, so that it makes a good metallic contact.

A Wire Circuit. Now attach (preferably by clamping screws or *terminals*, or failing these by soldering, or riveting or squeezing on) to each of the plates a piece of copper wire, as shown in 4. Once more observe the cell, and see what happens when the two ends of the wires are made to touch one another. The effect will be just the same as before. When they touch, bubbles will rise, showing that chemical action is going on in the cell. As soon as they are parted, the chemical action will stop.

Now try whether this effect will occur if you use very long wires. Let the wires be long enough to reach into the next room, and get a friend to help you in the experiment. If he, in the next room, brings the ends of the wires into touch, at that moment you will see the rush of bubbles on the surface of the copper plate in the cell. You could readily contrive a secret sort of telegraph this way, by agreement as to signals made by these evolutions of bubbles! Only you must be careful that the two wires do not accidentally touch one another. It would, in fact, in this experiment be better to use *insulated wires* that have been *protected* all along by being overspun with a layer of cotton (better still double-covered with two layers).

In experiments such as these we begin to realise that something really goes on *in the wire* at the time when the chemical action goes on in the cell. We see that the circuit plays an important part in the operation. In fact the chemical action—that useful chemical action which drives the current—does not occur *unless there is a complete circuit* from the zinc surface, where the energy is being given out, through the liquid to the copper, and then round the conducting wires back to the zinc. We have got our first notions of an electric *circuit*.

Simple Experiments with a Bell. For the next experiments we shall need an ordinary electric trembling bell—a well-made one. We shall also want an ordinary electric bell-push to serve as a key or switch to complete the circuit. Let us first find whether our Voltaic cell will generate a strong enough current to ring the bell. Take some copper wire and join up a circuit with a wire from the copper to the bell-push (screwing the end of the wire to one terminal), another wire stretching from the second terminal of the push to one terminal of the bell, a third wire returning from the other terminal of the bell to the zinc of the cell as in 9. When we have joined up our circuit rightly with good, clean metallic joints, then let us press the button of the push to complete the circuit. The bell ought to ring. If it does not one of three things must be amiss: either our Voltaic cell is not powerful enough, or the bell is out of order, or there is something wrong with the circuit.

We can easily test whether the bell is at fault by trying to ring it by substituting for our Voltaic cell some known suitable good cell such as a Leclanché cell (of which we shall learn later). If the Leclanché cell will not ring the bell, we must examine the mechanism of the bell to see if the adjustment is faulty—or else procure a new bell.

Having made sure that the bell will ring when the button is pressed, next take a number of Voltaic cells, two, three, or four of them, joined up in a row, the copper of one to the zinc of

the next as in 10, and so on, so that the current from the first flows on through the second and then through the third, in series. We have thus built up a *battery of cells*, and when we try them on the bell we shall find that it rings more powerfully than with one cell.

Further Experiments. Try the effect of leaving the circuit completed so that the bell goes on ringing. If the cell used has been newly made up, it will begin to ring vigorously, but in a few moments will ring more feebly and then stop. In fact, a Volta's cell of zinc and copper is very inconstant, and *runs down* quickly. It will recover again in a few minutes if allowed to rest *with the circuit open*, but if you leave it *short-circuited* (that is, with its circuit *closed*), it will run down worse than ever.

Try whether lifting either of the metal plates out of the acid will make the cell recover; you will find that lifting out the zinc does no good, but lifting out the copper for a few minutes and then putting it in again has a beneficial effect. It helps the copper to get rid of the adherent film of hydrogen bubbles which is the cause of this falling off in power. Now try some more experiments. Find whether it makes any difference to the bell if the circuit is altered so as to go to the bell before it goes to the push, or if the push is near the bell instead of being near the cell, or if the connections to the cell are reversed.

Next procure a simple table *galvanometer*, or detector galvanometer, such as can be bought for three or four shillings. A galvanometer [see Chapter on ELECTRICAL MEASUREMENT] is an instrument which, when we pass an electric current through it, will indicate on a dial whether there is a current or not, and whether the current is weak or strong.

Take such a galvanometer and join it up [11] in circuit with the Voltaic cell and with a press-button, by copper wires, just as you did before. When you press the button, and so *make the circuit*, you will see the galvanometer needle swing to one side, and if you keep the button pressed down the needle will settle down pointing in an oblique direction at one side of the zero on the dial. When you release the button and so *break the circuit*, the current stops, and the needle flies back to the zero of the dial.

Now try the effect of reversing the sense of the cell; loosen the copper wires from the terminals and join to the zinc the one that was connected to the copper plate, and join to the copper the one that was joined to the zinc [12]. On again pressing the button, the needle of the galvanometer will be deflected—but in the other direction on the scale.

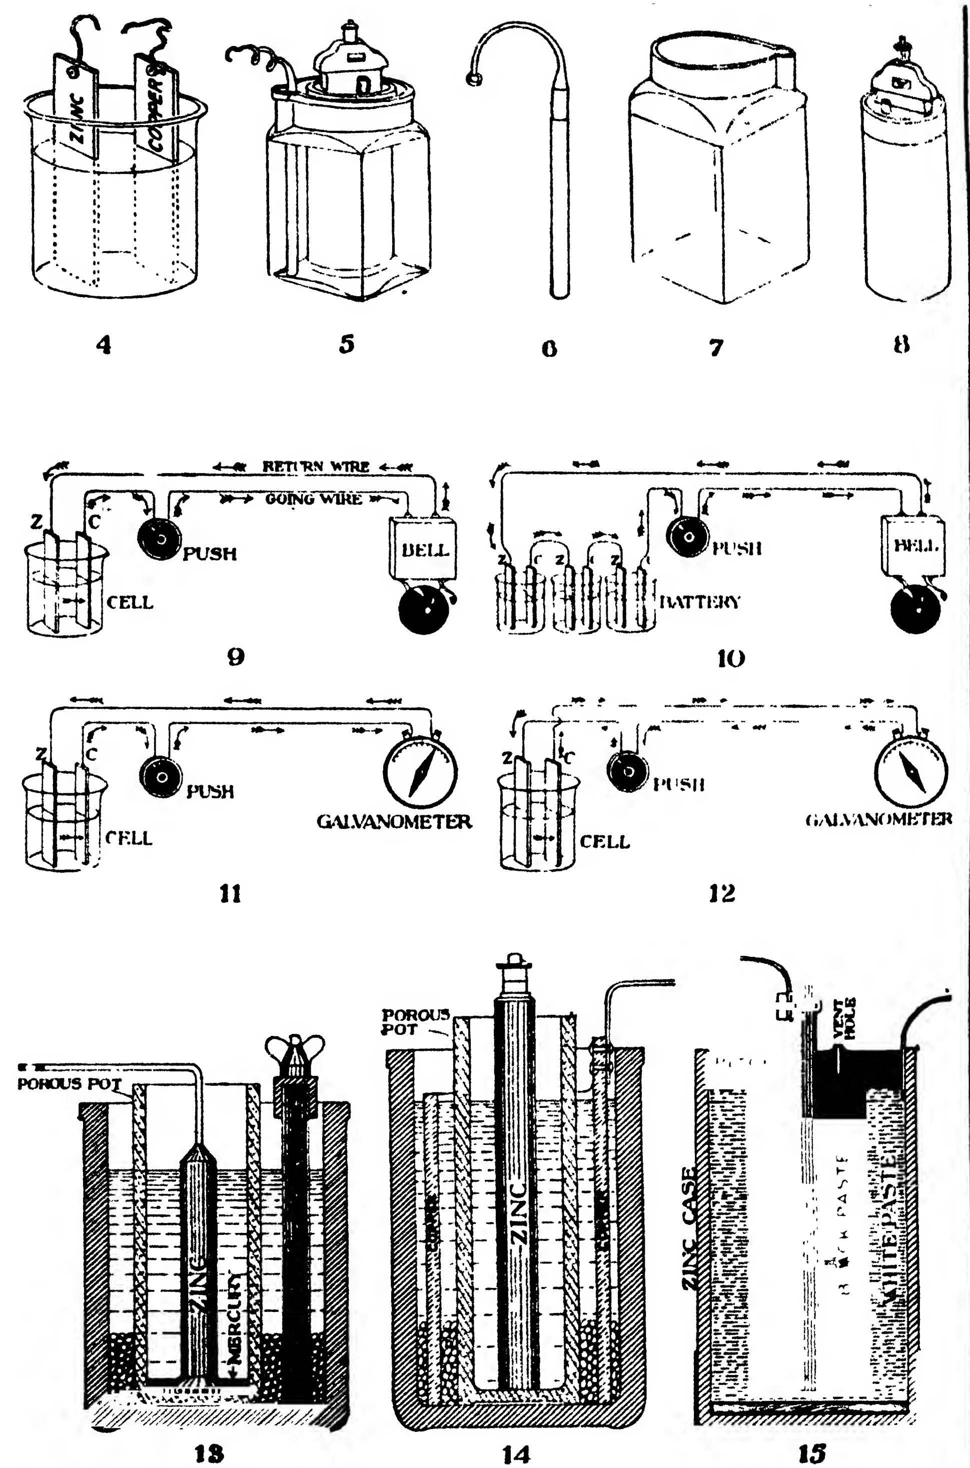
Conductors and Non-conductors. Having a galvanometer and a cell, we can now try a number of substances to see whether they will conduct or not. We should join a wire from one terminal of the cell to one terminal of the galvanometer, and then fasten to each of the unoccupied terminals a piece of wire a foot or two long. If we were to complete the circuit by bringing together the two free ends of these two pieces of wire the galvanometer would at once show the presence of a current.

But if, instead of making them touch one another, we bring them both to touch a third substance, if that substance is a conductor it will complete the circuit by making a conducting bridge between the two wires. Lay down a coin on the table, and bring both the wires to touch it; at once the galvanometer will show a current, because it conducts. Try other coins or pieces of metal. All metals conduct. Try a piece of wood, or glass, or porcelain. None of them conduct: they are called *non-conductors* or *insulators*. Try a piece of leather, a cork, a piece of chalk. Try dipping the two ends of the wires into water or vinegar. Water (unless chemically pure) and all wet things will conduct; but we may not be able to observe the current through them unless we use, instead of one cell, a battery of several cells.

If we use a battery of several cells, it will become more evident that all moist things conduct the current. But it is now time to speak of better cells than the simple Volta cell; for it has already been shown to be unsatisfactory for continued use on account of its inconstancy. In fact, if it be tested with a cell-testing voltmeter [see ELECTRICAL MEASUREMENT], though when newly set up it may show an electromotive-force of over 1 volt, its electromotive-force will have dropped to about 0·62 of a volt, when its copper pole has become covered with a film of hydrogen.

Leclanché Cell. This cell is made in millions for use in electric bell work. Its general form is seen from 5. The fuel consumed in it is zinc—in this case a rod of zinc with a wire cast in at the top [6]. This rod stands in a containing-pot of glass [7], and dips into a liquid made by dissolving in water some crystals of sal ammoniac. This liquid is less corrosive than dilute sulphuric acid, but acts for this purpose equally well as an excitant. No copper plate is used, but instead there is a slab of hard carbon having a terminal screw fastened into its upper part. But this carbon plate does not dip directly into the excitant liquid. If it did, we should have the same old trouble of the hydrogen bubbles interfering with the action of the cell. To avoid this it must be embedded in a substance called a *depolarizer*, which in this case consists of a granular mass of crushed carbon and black oxide of manganese. As this granular mass must not be allowed either to fall to the bottom of the cell or to touch the zinc, it is packed up around the carbon plate inside an inner pot of porous porcelain, as shown in 8. This pot is porous so as to let the excitant soak through, and also to let the current pass; for non-porous porcelain would be a non-conductor.

The *depolarizer* is for the purpose of destroying the hydrogen bubbles formed during the working of the cell; so that during the periods of rest, when no current is being taken from the cell, the carbon plate may become depolarized, that is, freed from the interfering films of hydrogen gas.



DIAGRAMS ILLUSTRATING TYPES OF ELECTRIC CELLS

A good Leclanché cell will have an electromotive-force of 1·45 volts.

Care of Leclanché Cells. The porous-pot form of Leclanché cell is to be obtained in three sizes, known as pint-size, quart-size, and three-pint size. Of these the quart-size is most general; it is about 5¼ inches high, and the glass jar is about 3¾ inches each way. This cell may be purchased complete for 1*s.* 9*d.* It is usual to prepare the cell for use by two preliminary operations. The first is to coat the top rim of the glass jar while hot with paraffin wax, or else with some bituminous preparation, in order to lessen the tendency of the liquid to *creep* and leave, on evaporation, a crust of crystals on the edge. The second process is to clean the rod of zinc by *amalgamating* its surface with quicksilver, as already described. This is advisable, but not absolutely necessary; but a dirty or impure rod is liable to consume away irregularly, owing to local corrosion.

The exciting liquid of the Leclanché cell, a solution in water of sal ammoniac (also called chemically ammonium chloride) is readily made by dissolving in warm water crystals of this substance, which can be bought of any druggist. But it is better to procure the crystals from the firms which supply the cells, as they will furnish sal ammoniac guaranteed to be free from lead salts, which are detrimental to the working of the cell. From three to four ounces of crystals will suffice for a cell of quart-size, and will give a saturated solution. After the liquid has been poured into the cell a few hours will elapse before the cell is in full working order, as it takes times for the liquid to percolate fully through the porous pot.

Cells once set up, and used for intermittent work, such as ringing electric bells, will last for months or years, needing little attention except occasionally pouring in a little water to replace that which has evaporated. It is also well to clear out from the bottom of the outer pot once every six months any sediment that may have settled there, and to add a few crystals of sal ammoniac. The zincs also are benefited by being scraped clean.

In places where a large number of cells are set up in series, as in testing laboratories, great importance must be attached to the insulation of one cell from another. In such a case as this the cells are set up in sets of ten in wooden trays, each tray being separately mounted on glass insulators.

Anode and Kathode. To distinguish between the two plates or *electrodes* of a cell, the name *anode* (which means way-in) is given to that plate or rod by means of which the current enters the liquid; while the name *kathode* (meaning way-out or way-down) is given to that plate or rod by which the current leaves the liquid to go to the circuit. In ordinary cells the anode is always zinc. Anodes dissolve: in fact, it is their solution which furnishes the energy of the current. Kathodes are not attacked: on the contrary, they usually receive a deposit, in some cases of metal, in other cases of hydrogen gas, unless surrounded by a depolarizing material.

As all cells are not equally good it is needful for the student to know how to test them. Tests are needed to ascertain two things: (1) the value of the electromotive-force of the cell, (2) the amount of current it can give. In other words, it is desirable to test the *volts* and the *amperes.*

Testing Cells. To test the electromotive-force of a cell there is needed a low-reading *voltmeter* [see page 292], graduated to read from 0·5 volts to 2·5 volts. It is applied to the cell by two wires when the cell is on *open circuit*, that is, when the cell is disconnected from the circuit and is giving no current. A Leclanché cell should show from 1·45 to 1·4 volts when in good condition as new; but after running for some time and getting spent it may show an electromotive-force as low as 1·2 volts or even lower. A Daniell's cell will show about 1·1 volts; a Fuller cell about 1·8 or 1·9. If no suitable voltmeter is available a good electric bell, if its coils are wound with very fine wire, may be used to test the cells; any cell which has a low electromotive-force will ring the bell feebly compared with a cell of higher voltage.

It is quite possible for two cells that are both alike as to their electromotive-force to give unequal currents, because, though the effort in each of them may be equal, if one of them offers a higher internal resistance to the flow of current than the other one does, it cannot yield as many amperes. If the porous pot in a cell is not porous enough the cell may be found almost incapable of giving a good current, and yet the chemicals in it may be all right and its voltage up to the right value. To test the number of amperes that a cell can give there is needed an *amperemeter* [see 3, page 292].

Fuller's Bichromate Cell. This is a more powerful cell than the Leclanché, but is more costly, and contains corrosive acids. As before, the material which serves as fuel is zinc. A solid rod of zinc stands [13] in an inner porous cell containing dilute sulphuric acid as excitant. Into this inner cell are also poured two ounces of quicksilver to keep the zinc surface bright, and prevent wasteful *local action.* In the outer pot, which is of quart size, stands the plate of carbon, and around it are poured four ounces of crystals of bichromate of potash (a powerful depolarizer), and four ounces of sulphuric acid, and then it is filled up with water. This cell has an electromotive-force of 1·9 volts.

In an earlier and very similar cell invented by Grove the depolarizer was nitric acid, and he used a platinum plate where in modern cells we should use the cheaper carbon.

Daniell's Cell. A cell of very constant properties is that invented by Daniell. It depends on the property that there will be no polarization—that is, no counter electromotive-force due to hydrogen films—if the metal plate is immersed in a suitable solution of a salt of the same metal. To attain this the copper plate is immersed in a solution of the blue

crystals of sulphate of copper, and the zinc dips into a solution of sulphate of zinc.

The sulphate of zinc solution acts as excitant, the sulphate of copper as a depolarizer. To prevent the two liquids from mixing they must be separated by a porous pot. Figure **14** illustrates one of many different forms of Daniell's cells, which are sometimes made narrow, so that a whole battery of them can stand compactly in a row in a tray. The zinc should be amalgamated with quicksilver to keep it bright. It slowly dissolves when the cell is giving out a current, and copper is slowly deposited on the copper plate by the current which decomposes the sulphate of copper in the solution. In **14** are shown a quantity of crystals lying in the bottom of the cell. The reason for putting these there is that they may act as a reserve: they will gradually dissolve as the copper in the blue liquid is deposited on the copper kathode. The electromotive-force of a Daniell's cell is usually about 1·1 volts.

Dry Cells. In recent years cells have been introduced under this name; but they should be called unspillable rather than dry, because they will not work unless they are moist inside. They are all modifications of the Leclanché cell, having zinc as the anode and carbon as the kathode. Figure **15** gives a section of the most common variety invented by Hitchcock. In this cell there are two pulpy or plastic layers touching one another. A white one next the zinc contains chiefly plaster of Paris with sal ammoniac as an excitant, and a black one next the carbon contains finely-powdered carbon and black oxide of manganese. Some hygroscopic material such as chloride of zinc is added to keep these layers moist. The cell is closed at the mouth with a layer of pitch, leaving a small vent-hole to permit the escape of gas bubbles.

The Cell as a Source of Energy. The consumption of the zinc furnishes the energy which the cell gives out. We have seen already that electric power is always made up of two factors—the effort-factor, which in this case is the electromotive-force of the cell, and the quantity-factor, which is the current that is drawn fromthe cell.

The electromotive-force depends solely on the chemicals that are used in the cell; thus in the Daniell cell, where we have zinc working against copper, the nett electromotive-force is 1·1 volts; but in the Leclanché cell, where we have zinc working against black oxide of manganese, the nett electromotive-force is about 1·45 volts. The current given out by any cell depends (as we shall see in the chapter on the ELECTRIC CIRCUIT) not only upon the electromotive-force of the cell, but also upon both its resistance and the other resistances in the circuit.

The larger a cell is, the larger will be the metal surfaces which come into working, and the less will be the internal resistance which the liquids inside offer to the flow of the current from one metal plate to the other. If the resistances, both that inside and those of the outer circuit, are kept small, then the current that flows from the cell will be large. The power given out by the cell at any moment will, as explained in Article 2, be the product of the number of volts of the cell into the number of amperes that are being drawn from it. Thus, if we are drawing 6 *amperes* from a Leclanché cell, of which the electromotive-force is 1·45 *volts*, the number of volt-amperes, or *watts*, with which it is working will be 1·45 times 6, that is, 8·7 *watts*.

Energy from Primary Batteries. Now from this we can calculate the cost of getting energy from primary batteries. Let us remember that 1000 volt-amperes for one hour are one Board of Trade unit Hence, if we were using a cell that had an electromotive-force of one volt we should get from it one unit of energy if it gave one ampere for 1000 hours. Now, experiment shows that in any cell where zinc is used the amount of zinc consumed usefully (leaving waste by local action out of account) is 2·66 lb. for every 1000 ampere-hours. But if we had a cell working with a bigger electromotive-force, we should get our unit of energy with a smaller number of ampere-hours. Thus, if we could use a cell of two volts electromotive-force, it would give us a unit of energy with only 500 ampere-hours of current, or a consumption of only 1·33 lb. of zinc. Hence to calculate the quantity of zinc needed in any cell in generating one unit of energy, we must take 2·66 and divide it by the number of volts at which the cell works. The corresponding numbers of pounds of other materials consumed are: sulphuric acid, 3·99 lb.; sal ammoniac, 4·18 lb.; bichromate of potash, 4·1 lb.; oxide of manganese, 7·13 lb. In the Daniell's cell the corresponding quantity of copper deposited is 2·57 lb.

Cost of Electric Energy from Cells. Let us then calculate the cost of one unit of electric energy if given by a battery of Leclanché cells. Let us put the prices as zinc, 3½*d.* per lb.; sal ammoniac, 5*d.* per lb.; oxide of manganese, 2*d.* per lb. Then we shall use of zinc, $2·66 \div 1·45 = 1·83$ lb.; of sal ammoniac, $4·18 \div 1·45 = 3·38$ lb.; of oxide of manganese, $7·13 \div 1·45 = 4·9$ lb. The costs will be zinc, 6½*d.*; sal ammoniac, 17*d.*; oxide of manganese, 9¾*d.*; *total*, 2*s.* 9¼*d.* And this is for one Board of Trade unit, for which the electric lighting companies may not charge more than 8*d.*, and of which the usual supply price is now generally less than 4*d.* Clearly Leclanché batteries will never compete with dynamos in the supply of electric light.

In the case of a battery of Daniell's cells, the weights are: zinc, $2·66 \div 1·1 = 2·42$ lb.; sulphate of copper, $6·5 \div 1·1 = 5·91$ lb.; and the deposited copper $2·57 + 1·1 = 2·33$ lb. The zinc will cost 8¾*d.*; the sulphate of copper at 2*d.* per lb. will cost 11¾*d.*; together 1*s.* 8½*d.*, but from this we must deduct 5*d.* for the copper deposited from solution, so that the nett cost of one unit, if furnished by a battery of Daniell cells, would be 1*s.* 3½*d.* Even if a cell could be found that would work at 2½ volts, the cost of zinc alone (to say nothing of acids, maintenance, supervision and standing charges) would be over 3½*d.* per unit, so that no primary battery using zinc will be able to compete with the electric lighting stations in the public supply of electricity.

To be continued

OBJECT DRAWING, WITH PRACTICAL GEOMETRY

A First Practical Lesson in Object Drawing, Cube and Square Prism. Lines, Angles, and Proportionals in Geometry

By WILLIAM R. COPE

Drawing a Simple Group. We shall now explain the method of drawing a simple group as shown in 67. The student must obtain *real objects* from which to draw, and ought not to copy 67, for he ought now to learn to draw from the "round." A box and a rectangular sheet of paper will serve as models. Place them upon a table at a distance of eight or ten feet away, so that the top of the cube or box is somewhat below the eye level. The objects need not necessarily be exactly of the same proportions as in 67. The drawing should nearly fill a piece of paper not smaller than quarter imperial (15 in. by 11 in.), and larger paper will be required later. When an artist commences a sketch of a landscape he determines where the four boundaries of his picture and the position of the horizontal line will come in the scene before him. The latter can be ascertained by holding a stiff piece of cardboard horizontally, etc., as previously explained, and the boundaries by cutting in the cardboard a rectangular opening of the *same proportion* as the canvas or paper—*e.g.*, if the canvas be 15 in. by 12 in., the opening should be 5 in. by 4 in., then, holding the cardboard vertically and adjusting its distance from the eye, the four edges of the opening will show which objects of the scene will come just on the boundaries of the picture. The same method may be used with the cube and board [68], and more especially as a test, after judgment with the eye alone, of the proportions of the objects and the various directions of their edges.

The right and left-hand boundaries of the group [67] are the imaginary vertical lines *QP* through *B* and *NO* through *D*. These two vertical lines should be drawn first, about an inch from the edges of the drawing-paper, which ensures the paper being fairly well filled with the drawing, and also determines the scale of the latter.

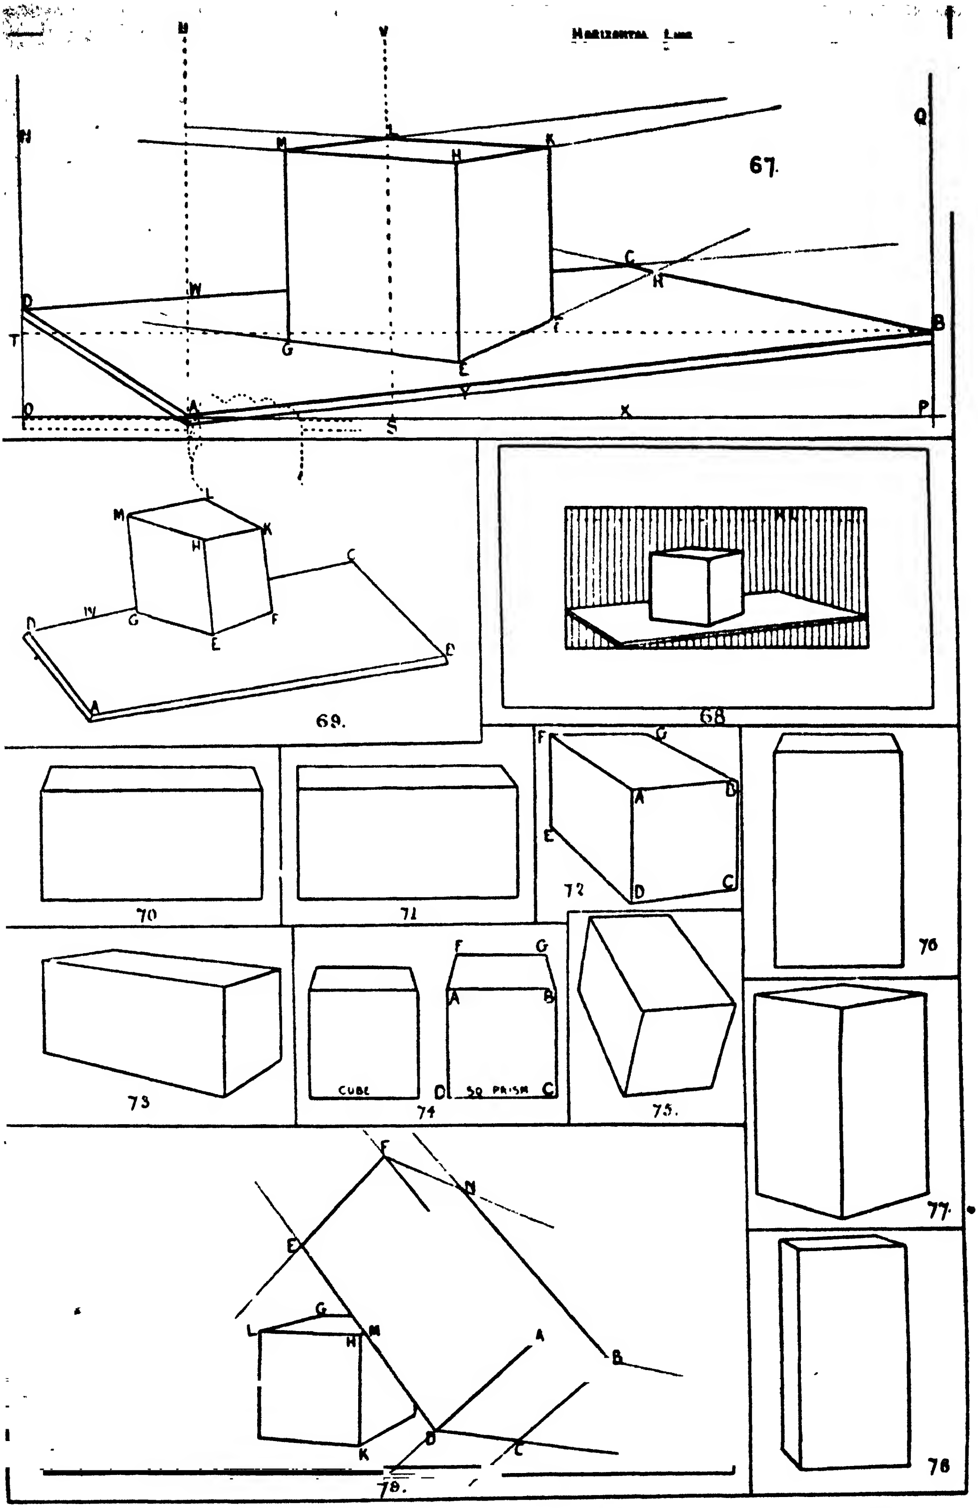
Importance of True Proportion. All representations of masses, edges, etc., must henceforth be kept in true proportion with this scale. Now make a few preliminary, but careful and searching observations of the general proportions—*e.g.* the width *OP* or *TB* of the group is about three and a third times the height *LS*; the vertical edge *EH* is very nearly equidistant from the corners *D* and *B*; the edge *GM* about midway between the corner *D* and the edge *FK*; and the corner *A* is much nearer to the left-hand side of the group than to the right. All these measurements are of course only as they seem to the eye from the point of observation; they are the *apparent* not the *real* distances.

The student must assiduously persevere in making these and every judgment first with the eye alone, and afterwards test by measuring with the pencil held as already advised. The mind being stored with these important facts, the exact position of the corner *A* should be observed by comparing the distance *OA* with *AP*. It will be found that *AP* is about four and a half times *OA*. In testing this the ascertained length *OA* should be carefully stepped along *AP*, and it is most important that the pencil should be held correctly, (see dotted line drawing of hand and pencil in 67), *not* slanting away because the edge recedes.

The Three Most Important Points. The position of *A* should now be marked on the drawing paper, by making the space between it and *QP* four and a half times that between it and *NO*. Do not use the cumbersome and unsatisfactory method (which does not train the eye) of taking a measurement from the objects and then some multiple of it to suit the scale of the drawing. Next obtain the slope of the edges *AB* and *AD*, by observing that the corner *B* is *apparently* slightly lower than *D*, the apparent size of the space between *O*—level with *A*—and *D* is two-twirds of *OA*, and that *PB* is about one-fifth less than *OD* or a little more than one half of *OA*. To test, hold the pencil *vertically* to obtain apparent length of *OD* and *PB*, and *horizontally* to compare them with *OA*. Then mark these positions on the respective vertical lines in the drawing, in the same proportion with *OA* already obtained, and the three most important points are thus determined.

Now fix the position of the *horizontal line* by comparing the distance *AU* with *AP*, and as a check *LV* with *AO*. Then draw the lines *AB* and *AD*; these, if continued to the line *HL* extended, would give their respective vanishing points, which are, as in 67, very often outside the limits of the drawing-paper, but with care their position may be judged. Afterwards draw *DC* very slightly converging with *AB*, and *BC* more quickly with *AD*. The larger the angle at which parallel edges recede the more quickly they appear to converge, as *AD*, *BC*; and the more nearly they appear horizontal, as *AB*, *CD*, the less quickly they converge. The intersection of *BC* with *DC* gives the position of *C*.

Next apply a few tests to the drawing, as any inaccuracy not corrected at this stage will cause great trouble when drawing the cube. For instance, test by holding the pencil vertically, whether the distance *AW* from the front corner to the back edge is in true proportion with *AO*, not as in 69; and that the back corner *C* is opposite a point on the front edge, so that *XP* is two-fifths of *AP*, or two-thirds of *AX*. Then sketch the lines to show the thickness of the



A FIRST LESSON IN OBJECT DRAWING. DIFFERENT VIEWS OF THE SQUARE PRISM

board, and keep the very short lines at the corners *vertical*, not as in **69**.

Drawing the Cube. In drawing the cube, first determine the position of the corner *E*, by comparing the space between *D* and *E* with that between *E* and *B*, or *AE* with *AD*, or *AE* with *EB*. *E* is much nearer to the front edge at *Y* than it is to the back, and is nearly equidistant from *D* and *B*. In **69** the position of *E* is quite wrong. Now draw the lines *EF* and *EG*. The board being correctly drawn, it is quite easy to determine the *direction* of the two edges which they represent, for it will be noticed that *EF* recedes towards a point *R* not far from the corner *C*, and *EG* directly towards the corner *D*. Next ascertain the *apparent* length of *EF*, which is about equal to the distance *FC*, and of *EG*, which is about two-thirds of *GD*. Then draw a vertical line through each of the points *G*, *E*, and *F*, also observe that *EH* is *apparently* rather longer than *EG*. The height of *GM* and *FK* can easily be settled by drawing *HM* converging with *EG*, and *HK* with *EF*, to their respective vanishing points. From *M* draw *ML* converging with *HK* and *EF*, and from *K* draw *KL* converging with *HM* and *EG*, thus obtaining the apparent shape of the top surface. Do not be afraid of producing these lines some distance right and left, as in **67**, in order to see whether they are converging properly. Now hold the drawing vertically at arm's length, compare it carefully with the group of objects, correct any inaccuracies, clean up, and finish with a soft, broad, grey line.

The Secret of True Drawing. The secret of making a true drawing lies in the most careful and searching observation of the proportions between various spaces, and the proper convergence of lines which represent what are really parallel edges. Do not be satisfied with a comparison between one part and *one* other, but make it between one part and *several* others. The mistakes generally made are such as are shown in **69**, where, besides those already mentioned, *AB* and *DC* are diverging instead of converging towards the right, and *AD*, *BC* do not converge to the left, thus causing the board to appear warped and wider at the right end. The edges *EF*, *HK*, are converging towards the right, but *ML* is not; also *EG*, *HM*, *KL*, are not converging towards the left, while *GM*, *EH*, *FK* ought to be vertical. If the invisible back edges were represented it would be seen that the back corners of the cube would appear to be beyond the back edge of the board. The space *DG* is too small, *AD* is too long and slanting in the wrong direction. The point *A* is too far to the left. There are other errors which an observant eye will easily detect.

The Square Prism. In **70** to **78** we give various appearances of the square prism, an object which is square at its ends, and has an oblong for each of its four side surfaces. The method of drawing this is similar to that of the cube, but special attention should be given to the fore-shortening of the long edges in particular views, as in **72** and **74**, where the long edges *AF*, *BG*, *DE*, are represented by shorter lines than *AB*, *BC*, *CD*, *DA*, those for the short edges. Compare the drawing of the cube with that of the square prism in **74**; both are views seen when the spectator is directly opposite the square surface, but the objects are below the eye level.

Figure **75** represents the prism resting on one of its short edges. In **79** we have a more difficult view of the prism resting on one of its corners on the board, and its under surface leaning against one top edge of the cube. The board and cube will give little trouble to draw, but observe that the front and back edges of the board do not converge, because they are not receding from the observer, while the side edges do so rapidly. In this case we have the two extremes, one where apparent convergence takes place most rapidly and the other where there is no convergence at all. The student should place the objects as indicated, and observe that the edges *AB*, *DC*, *FN* are apparently converging downwards to the right, *AD*, *BC*, *FE* downwards to the left, and *AF*, *BN*, *DE* upwards to the left. Even without a knowledge of advanced perspective the position of each set's vanishing point can be determined, if careful attention be given to the apparent direction of any two edges in each set.

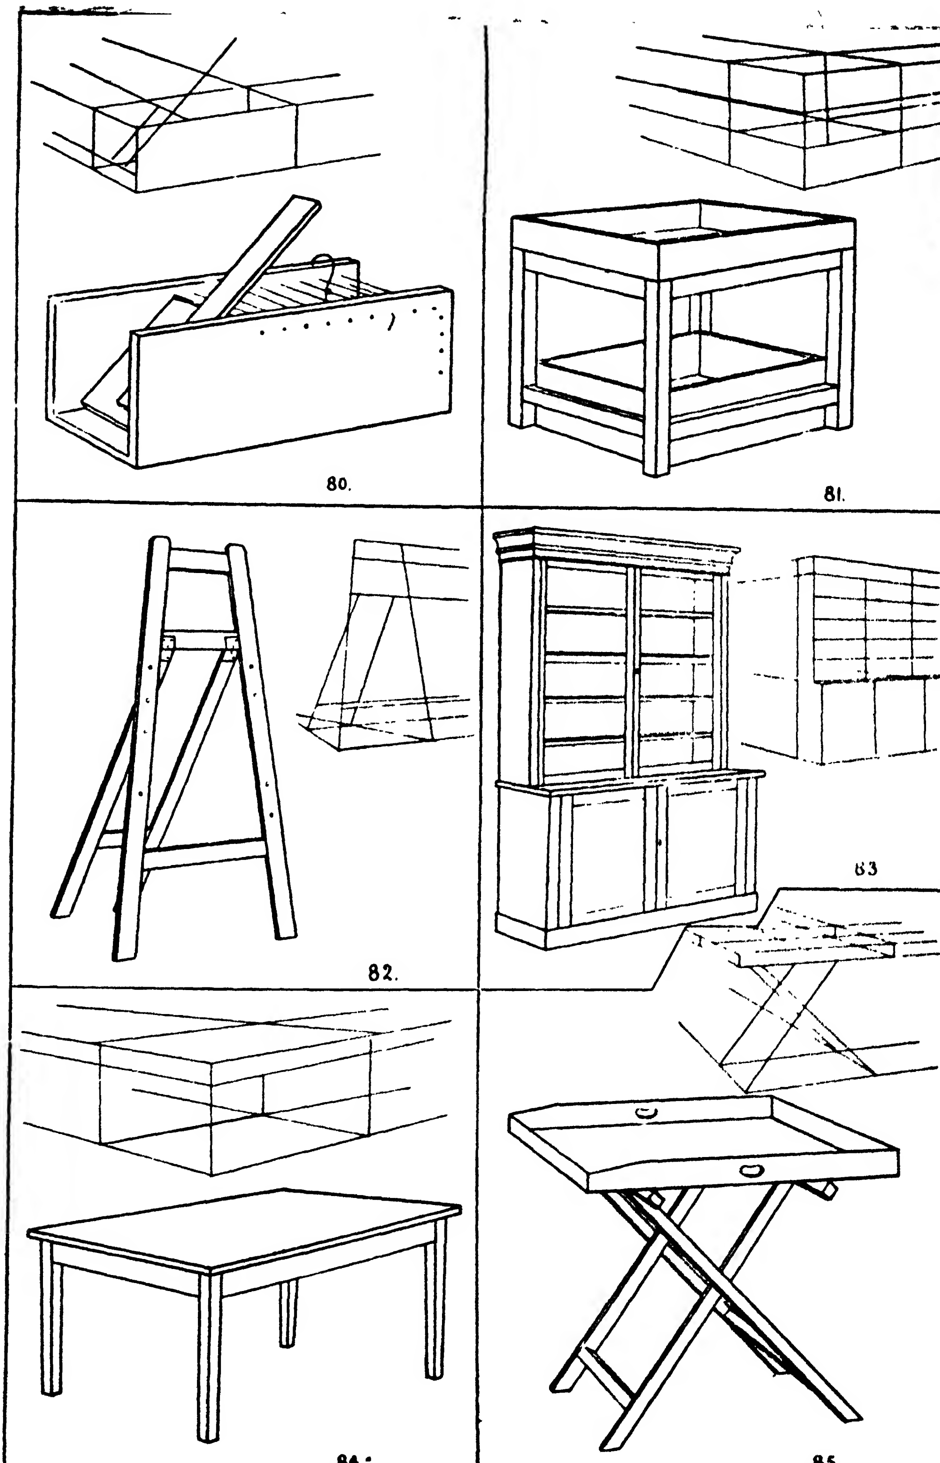
Drawing the Prism. Assuming that the board and cube are drawn, begin the drawing of the prism by obtaining the position of the corner *A*, and next the slant and length of the three edges *AB*, *AD*, *AF*, each of which belongs to a different set. Notice that *D* is rather higher than *K*, and *KD* is about two-thirds of *KH*; *AB* is three-fifths of *AD*; while *AF* is three times as long as *AB*; and the corner *C* is almost vertically under *A* and level with *K*, thus determining the direction of *BC* and *DC*. The point *E* is to the left of *G*, but higher, and the distance *EG* is equal to *KD*, which gives the direction of *FE* and *DE*. The direction of *DE* could be found by observing where it cuts the edge *HM* of the cube. Draw *FN* converging with *AB* and *DC*, and *BN* converging with *AF* and *DE*. Each set should converge as shown in **79**.

Having mastered these geometrical solids, the student should draw from objects similar in construction; such as rectangular boxes, bricks, books, stools, chairs, tables, doors, cupboards, steps, easels, tanks, and picture frames. Some of these are shown in **80** to **85**. He should analyse each object and endeavour to find some simple lines of construction; draw these first correct in proportion and perspective, as indicated by small sketches in **80** to **85**, the study of which will teach him much more than hundreds of words.

PRACTICAL GEOMETRY

Lines, Angles, and Proportionals. The following are preliminary exercises which will often be required in succeeding problems:

86. To Bisect a given Line *AB*. The best way is to do it by trial with the compasses. Another method, **86** *A* and *B*. With centre *A* and any radius longer than half the line describe an arc. With centre *B* and same radius intersect it in *C* and *D*. Draw *CD* which bisects the given line at right angles



EXAMPLES OF OBJECTS DRAWN ON THE SAME PRINCIPLES AS THE CUBE AND SQUARE PRISM

87. To Draw a Perpendicular to a given Line AC, from a given Point A within or B without the Line. This may be done in several ways by intersecting arcs, but the most practical, most accurate, and quickest is by *placing a ruler level with the line AC, and a set square with one of the edges exactly touching the ruler, and the other passing through the given point as shown in* **87**.

88. To Bisect a given Angle ABC. With centre B and any radius describe an arc to cut the lines in A and C. With centres A and C and any radius describe arcs to intersect in D. Draw BD which bisects the angle. By this means an angle may be divided into 4, 8, 16, etc., equal parts.

89. To Trisect a Right Angle ABC. With centre B and any radius describe the arc AC. With centres A and C and same radius cut the arc in D and E. Draw BD and BE which trisect the right angle.

90. To Draw a Line parallel to another AB, at a given Distance C from it, or through a Given Point D. At any point in AB draw a perpendicular GF equal to the distance C. Place one edge of a set square level with AB, then a ruler against another edge of the set square [**90**]. Hold the ruler firmly fixed, but slide the set square along it until the edge (which was level with AB) passes through F, and draw FE the required line. When the point as D is given, the method is the same except that no perpendicular is required [**90**].

91. To make an Angle Equal to a Given Angle ABC. Draw any line EF. With centre B and any radius describe the arc AC. With centre E and same radius describe the arc DF. With distance AC as radius and F as centre cut the arc in D. Draw ED through E and D (Euc. III. 27).

92. Through a Given Point C to Draw a Line meeting a Given Line AB at an Angle equal to a Given Angle H. Through C draw CF parallel to AB. At C make the angle FCD equal to H, and the angle CDB will also be equal to it (Euc. I. 29).

93. To Bisect the Angle made by Two Converging Lines BA, DC, without using the Apex. Draw a line at any convenient distance parallel to AB, and another at same distance parallel to CD to intersect in E. Bisect the angle thus obtained.

94. Through a Given Point E to Draw a Line converging to the Same Point at which Two other converging Lines would meet if Produced. Draw any two convenient lines FG, HK parallel to each other and cutting both AB and CD. Join E and F, E and G. Through H draw HL parallel to FE, and through K, KL parallel to GE, intersecting at L. Draw EL through E and L.

95. In a Given Line AB to find a Point Equidistant from Two Given Points C and D without it. Join C and D, and bisect the line CD by a perpendicular meeting AB in E, which is the required point.

96. To Draw Two Straight Lines to Meet a Given Line CD from Two Given Points A and B without it, and to Make Equal Angles with it. Draw AE perpendicular to CD so that FE equals FA. Draw BE cutting CD in G. Draw AG. Then AG and BG are the required lines.

Proportionals. If a straight line be drawn parallel to one side of a triangle, it cuts the other two sides or those produced proportionally. (Euc. VI. 2).

97. To Divide a Line AB into any Number of Equal Parts (say Seven). Draw AC at any angle with AB, and set off on it any convenient distance seven times. Join $7B$ and from the points 6, 5, 4, 3, 2, 1, draw parallels to $7B$ to cut AB.

98. To Divide a Line AB proportionally to a Given Line CD. Draw AE at any angle with AB. Make $A1$, 1 2, 2 3, $3E$ equal to $C1$, 1 2, 2 3, $3D$ respectively. Join E and B. Draw parallels to EB through 3, 2 and 1 to meet AB.

99. To Divide a Given Line AB in the Same Proportion as the Nos. 3, 5, and 2. Draw AC at any angle with AB, and set off on it 3 + 5 + 2 equal parts. Join 10 and B, and through 3 and 8 draw parallels to $10B$ to meet AB. Then $AD : DE : EB$ are as 3 : 5 : 2.

100. To Find a Fourth Proportional (Greater or Less) to Three Given Lines A, B, and C. Draw DG and, at any angle with it, DH. Set off DE equal to A, and DF equal to B. Join E and F. Set off EG equal to C. Through G draw GH parallel to EF cutting DH in H, then FH is the fourth proportional *greater*—*i.e.*, $DE : DF :: EG : FH$. When the fourth proportional *less* is required, use the same method, but commence with the *longest* line.

101. To Find a Third Proportional (Greater or Less) to Two Given Lines A and B. This is the same as finding the fourth proportional to three given lines, the last two of which are equal (*e.g.*, $A : B :: B :$ required line). Proceed as in **100**, but remember B is used twice (in **101**, CF and CD each equal B). CE is the required third proportional *greater*. For the third proportional *less*, commence with B and use A twice.

102. To Find a Mean Proportional to two Given Lines A and B. On a straight line make CD equal to A, and DE equal to B. Bisect the whole line CE in F and describe a semicircle with F as centre and FC or FE as radius. At D draw DG perpendicular to CE to meet the arc in G. Then DG is the mean proportional—*i.e.*, $CD : DG :: DG : DE$, or $A : DG :: DG : B$.

103. To Divide a Line AB into an Extreme and Mean Ratio—*i.e.*, so that one part shall be a mean proportional between the whole line and the other part. Draw AC perpendicular to AB and equal to half of it (AF or FB). Join B and C. Make CD equal to CA. With centre B and radius BD cut off BE. Then AB is divided at E so that $AE : EB :: EB : AB$, or so that the rectangle AE, AB, equals the square on EB (Euc. VI. 30 and II. 11).

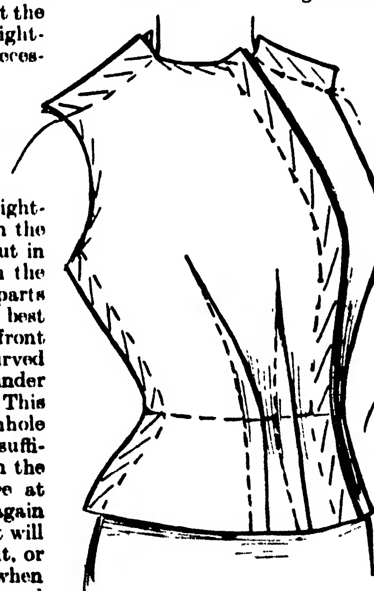
BODICE FITTING & EVOLUTION OF THE BLOUSE

The Fitting and Making of a Bodice. Alterations. Pressing. Sleeves and Collar. The Drafting of Various Blouses from Bodice Pattern

By AZELINE LEWIS

Fitting and Making Up. Before fitting on the bodice, the seams of the back and curved side pieces must be notched at the waist, also an inch above and below the waist-line; the under-arm seams and the darts should not be notched until the bodice has been tried on [28].

Put on the bodice with the seams outside and pull it down into the waist at the back, then pin the front fitting lines together at the waist, bust, and neck lines [29]. See that the waist-line sets well into the curve of the waist. If the armhole feels too tight, be careful not to hollow it out hastily. This point cannot be insisted on too strongly at the very outset, as it is a very common mistake with amateurs, and even with so-called "little" dressmakers, to slope out the armhole at the first suggestion of any tightness. Ascertain the necessary alterations *before* touching the armhole, for, if once cut out too much, a mistake has been made which often results in ruining the bodice. Very often the tightness may be remedied in the course of the fitting, but in any case do not touch the armhole till the other parts have been fitted. The best plan is to snip it at the front to within ½ inch of the curved line, and if too high under the arm, snip here also. This will increase the armhole considerably, and allow sufficient seam for sewing in the sleeve. Lift the bodice at the front waist and again pull the back down, or it will appear too long in front, or too short at the back, when the fronts are finally pinned together. Now bring the waist lines together, pin there and below, pin the front fitting line from the bust downwards, once or twice lifting the bodice at the neck, and putting the hand inside; gently press the bust up, that it may fall into its proper shape, then pin up from the bust line to the neck.

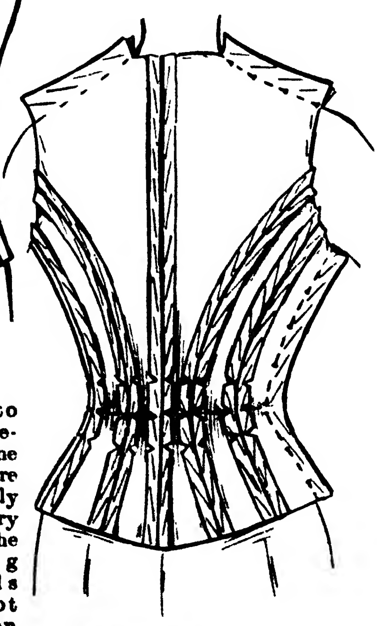


29. FITTING ON FRONT

Alterations. When this is done, the fitting of the outlines should be carefully looked over, to see that the waist-line at the back fits into the hollow of the waist, that the width of back from shoulder to shoulder is sufficient, that the under arm is the right length, and that the curved side pieces sit well into the hollow of the waist and close under the arms.

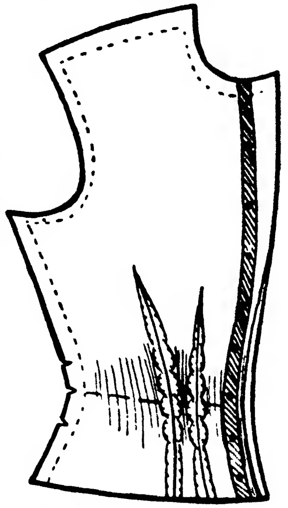
Should the bodice be too short-waisted, let it down at the shoulder seams, taking care that sufficient turning is left for the armhole; if it is too long-waisted, take it up at the shoulders, and hollow it out at the back of the arms. The neck must be altered according to the alterations made, that is, either taken in or let out as far as the bust line. Any other alterations are made at straight under arm seams and shoulder seams, leaving the curved side seams and the darts untouched. For instance, if the waist be a little large, it must be taken in at the side seams, and if the fronts or backs be too long they must be lengthened or decreased from the shoulder seams.

To Make Up. If the fit is satisfactory, take the fronts from the other portion of the bodice, as the required fastenings are easier to put on than when joined together, and see that both sides are exactly alike. The seams should be machined just outside the wheel-marks in order that the tacking threads may be more easily removed. This can be done without injury to the material if the threads are previously cut every ½ inch. The basting threads must not be taken out until



28. FITTING ON BACK

the bodice is finished. Before overcasting the seams cut all frayed edges even, round off the notches, cut at the waist line, leaving ¼ inch turnings, and cut and curve the other seams to correspond. Cut the darts to within ½ inch of the top, leaving ⅜ inch turnings on each side; notch and curve these, then overcast the seams and darts with either silk or cotton of a contrasting colour. This stitch should be worked loosely, as, if pulled up too tightly, it will form a hard ridge, and show through the material when the dress is on. The overcasting stitch is used not only to neaten, but to prevent fraying, and if very "frayey" materials be used, the stitch must be taken down a little deeper.

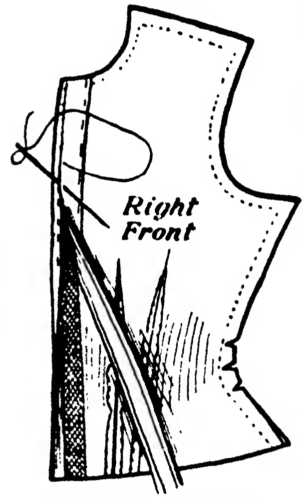


31. LEFT FRONT WITH BUTTONS

Finishing the Darts. The darts require very careful finishing, as the tip of these should melt off at the top as though they were woven in the material. To do this, slope off the line of machine stitching at the "head" or top to a point, then thread the end left (which should be fairly long) on a needle, and finish off with a few stitches of oversewing.

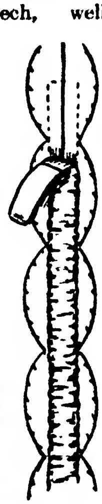
Pressing the Seams. The seams must be pressed on a rounded surface; the rail of a towel-roller, or a long rolling-pin of ash or beech, answers the purpose well, but it should be covered before using. Both sides of each seam must be smoothed with a warm iron. Dip the finger into water, open the seams, and run them lightly along, next press with a hot iron; do this with a firm, gentle pressure, but on no account rub or force the iron along, taking care not to stretch the length of the seams. The tops of the darts should be pressed quite flat, care being taken that here again the bodice is not stretched. The bodice is now ready for the fastenings—either buttons and buttonholes, edge to edge fastenings, or hooks and bars.

Preparation for Dressmakers' Buttonholes. Should buttons and buttonholes be required, the preparation is as follows. Take the right front of bodice and turn the edge in ½ inch from the front fitting line, mark with white cotton; now mark another ½ inch beyond the white cotton on the wrap, cut the rest of the wrap away, turn down and press. Take a strip of tailor's linen or waistcoat canvas, 1½ inches wide, put the raw edge of this strip to the fold of the turn-down, this should be basted to the front twice, holding the front of the bodice well over the hand while basting. Now tack the ½ inch turn-down to the linen. To face the right side of bodice, use a piece of the material or fine Italian cloth 2 inches wide; this wears much better than silk or sarcenet [30]. Turn down the edges of the facing ½ inch on either side and press, this also should be basted down twice on the front, just inside the edge of the bodice (holding the front of bodice well over the hand), then felled down on both sides with a fine needle and silk. This side should be well pressed before beginning the buttonholes, for the working of which see BUTTONHOLES (Part I.) For the button-side see diagram 31, also Part I., where the method of sewing on the buttons is fully explained.



30. FACING FRONT FOR BUTTONHOLES

Fastenings. To strengthen the front for edge to edge fastenings with hooks and eyes, take a strip of linen or lining on the straight, 1 inch wide, tack near the fitting line and again at the other edge, keeping the front of the bodice well over the hand to prevent tightening, cut off the wrap to within ½ inch of the fitting line, turn it down and well press. Machine close to the very edge of the bodice, right up to the top. Now tack, with very small stitches, the linen and lining together ½ inch from the front fitting line, as high as the top of the dart, to form a casing for the edge bone, taking care that the stitches do not go through the material. Fell down the ½ inch wrap to the linen, not taking the stitches through, then fell the outside edge of the strip of linen to the lining, still taking care that the stitches do not go through. Insert the edge bone (a narrow whalebone, ¼ inch wide, the same length as the dart) and fasten the bone securely top and bottom. Treat the left side of the bodice in the same way. The fronts are now ready for the hooks and eyes.

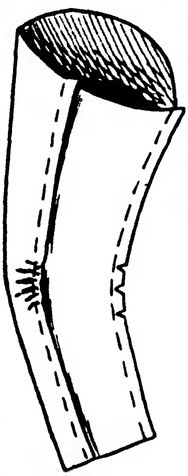


32. BONE CASINGS

To Put on Hooks and Eyes. Measure the distance for the hooks and eyes very carefully, beginning at the waist line and allowing ¾ inch between each. Begin to sew them on at the waist line, a hook and eye alternately, the hooks

being sewn ¼ inch in and the eyes level with the edge to make it fit closely.

How to sew them on is dealt with in PART I. Do not be afraid to put a few extra stitches in each hook and eye, as there is great strain between the waist and the bust, and unless sewn on firmly they will pull away, causing great annoyance and necessitating double work to replace them. The hooks and eyes will be faced after the basque has been turned up. Having arranged the fastenings, join the fronts to the other portions of the bodice; machine the under-arm and shoulder seams, notching them above and below waist. Neaten, overcast, and press in the same manner as the other seams, and complete the casings. The bodice is now ready for turning up the basque.

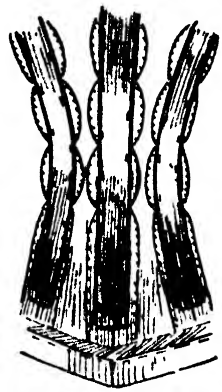


34. SLEEVE READY FOR STITCHING

Turning up the Basque. Before turning up see to the fit where the basque is shaped, and tack a strip of linen or canvas (according to material used for dress), 1 or 1½ inches wide, cut on the cross, round the edge of the basque. Turn up the bodice and tack very firmly, roughly sewing the raw edge to the lining over the canvas or linen. Be sure the stitches do not go through. Carefully mitre the corners of the bodice, as for collar, and well press.

35. FACING WRIST BAND

Facing the Hooks and Eyes. Cut a piece of the material (if thin enough) of fine Italian cloth on the cross, 1½ inches wide, allowing ¼ inch turnings on each side; turn this down and well press. Begin at the top of the neck (the right side), placing the facing well under the bill of the hook, baste it round the bodice and basque, holding it well over the hand, cutting away the folds under the corners of the bodice. Ease the facing there, or the corners of the bodice will turn up; also ease well at the centre of the back. Then baste it up to the left side of the neck, and neatly fell all round and on both sides with silk the same colour, keeping the stitches loose, and being careful not to take them through.



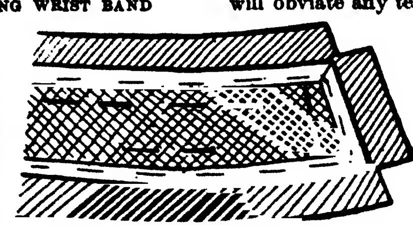
33. STEELS AT BACK OF BODICE

The wrap is a strip of material 2½ inches wide. Turn in ¼ inch on each side, fold and press, and either machine or slip-stitch turnings of ends and long edge. Place the fold on the hooks and eyes on the left side of the bodice, and secure with buttonhole stitch several times. Thick cloth is cut single 1½ inches wide, and the edges are either bound, pinked or overcast. The wrap only comes just a little distance below the waist.

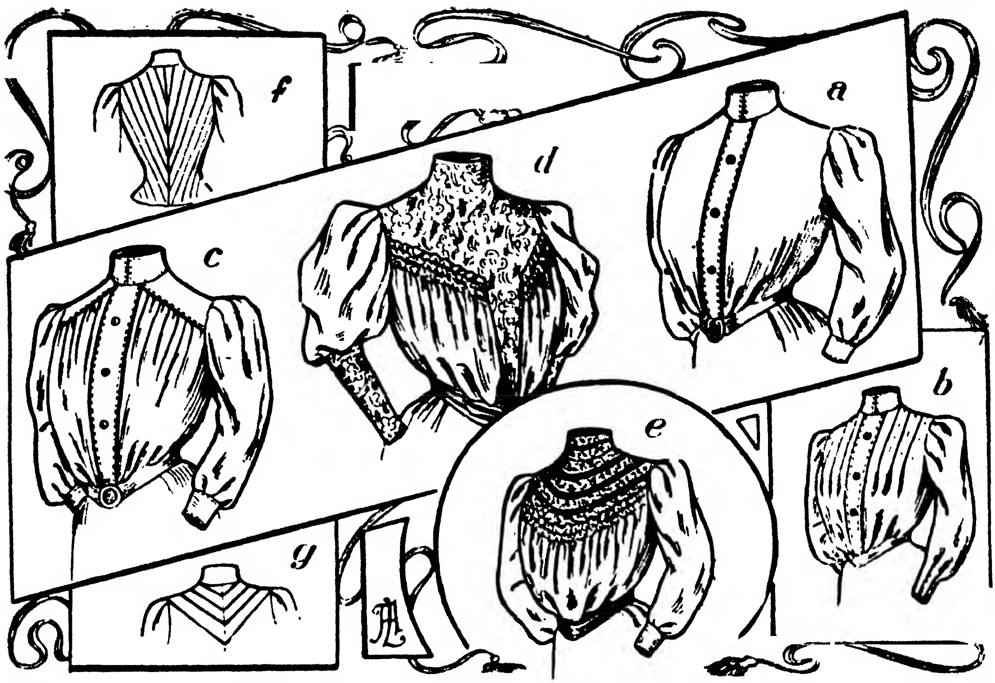
The stiffenings required for the seams must now be put in, and as these may be either bones or steels, we will describe the method of putting in both. There can be no doubt that whalebone is much better for the purpose than steels, but as it and its substitute, feather bone, are both somewhat expensive, and steels have the advantage of greater cheapness and simplicity of working, the latter are often preferred. We will take boning first.

The Bone Casings. Cut the galoon, or binding, into strips, 3 inches longer than the actual length for the seams, 3½ inches longer for the darts. Before running the galoon on the seams, gather slightly all the way down on either side, keeping the centre of the casings directly on the seams. Make the pockets for the darts from 1 to 1½ inches long, fell on one side, then fell or run the casing on the dart seam to within ¾ inch of the edge of basque, and up to the pocket. All the ends of the casings should be free [32].

When all the seams are cased, cut the whalebone (which should be soaked and put into the bodice while damp) the required length, ¾ inch longer than the casings. For the bones which will lie on the darts, the holes should be pierced from 1 to 1½ inches from the end; by this means the bone tops come even with the top of the dart seams, and the loose parts will obviate any tendency to force out the bodice at the bust. The bones for the under-arm seams should be 2½ inches down from the bust line, and the bones at the top of the other seams must be even with them. The holes for these bones are pierced ¾ inch from the top, and should also be left loose; the holes at the lower end of all the bones are pierced ¼ inch from the end. The holes for this purpose are



36. COLLAR



37. YOKE BLOUSES DRAFTED FROM BODICE PATTERN

easily made with a hot knitting needle. See that the ends are well rounded with a sharp penknife or file. Before putting the bones in, bend them well with the thumb and finger; but remember they are not put in until the basque has been turned up, when they are slipped into the casings, then the sides of the pockets are felled up, and the bone firmly fastened to the casing through the perforated holes. Finish off the ends with a fan stitch.

Covered Steels. Start at the centre back seam, pin the steel ½ inch from the turn-up of the basque. Measure the length of the steel on the bodice, and lower it ½ inch. Pin firmly, press the ½ inch well into the hollow of the waist, that is, 1¼ inches above and below the waist-line, pin there, and again between the waist and the top of the dart with fine pins. Begin to sew the steel ½ inch from the top of the seams and 1¼ inches from the top of the darts, leaving all ends free. Place the first stitch at the back of the steel under the seam, bring the needle out at the side of the steel, put the needle back at the same place, bring it out under the seam, this forms a back stitch; now put the needle in again 1 inch away from the last stitch, still at the back of the steel; make another back stitch, continue this on both sides of the steel, leaving the lower end loose ½ inch from the basque, using a double stitch at the waist [33].

Putting the Sleeves Together. In putting the sleeves together, always keep the largest side uppermost. Pin the elbow lines together and pin from the top of sleeve to the wrist; turn the sleeve round still with the larger part uppermost, and pin up from the wrist-line to the top of sleeve on the inner side. Now tack with small stitches from the top of the sleeve to elbow line, and from elbow to wrist, also from wrist to the top of the sleeve of the inner part. For the left sleeve reverse the process. The sleeves will then be ready for machining. Having done this, be sure to notch the inner seam an inch above and below the elbow line [34]. Round the notches, oversew neatly, and press on a roller. Cut a strip of muslin on the cross 1¼ inches wide, fold it, and place the fold on the wrist line, baste over the hand. Now tack the raw edge to the lining, and face with material of Italian cloth, cut on the cross, or to the shape of wrist; baste to sleeve, and fell with silk and fine needle, holding the sleeve well over the hand [35].

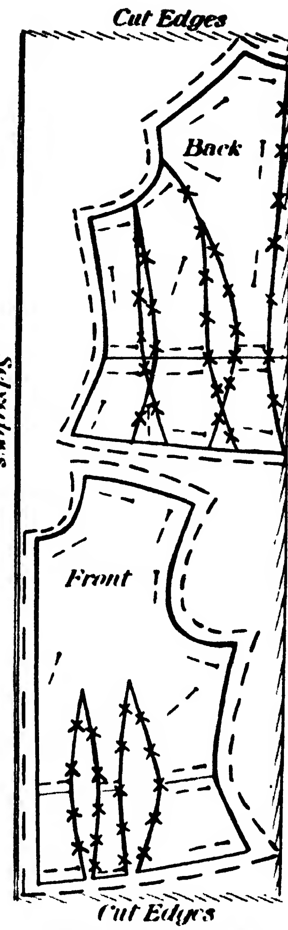
To Set in the Sleeve. Pin the front seam of the sleeve to the inset mark, and the back seam to the curved side-piece, within 2 inches of the shoulder seam. Pin the sleeve to the under part of the bodice, well easing it under the arm, and slightly easing it from the inset mark to 1½ inches above this. Next gather the top of the sleeve and distribute the gathers evenly between the inset mark and the curved side piece. Be sure to tack the sleeve in the wheel marks, and hold it towards you when putting in. Care spent on this part of the bodice is always repaid, as an imperfectly setting sleeve will spoil the whole effect.

Cutting and Making the Collar. Fold a piece of paper, and place the back of the pattern to the fold. Trace all round, excepting at the fold, not allowing turnings, remove the pattern and cut out the part traced. For the collar, about 3 inches of buckram or tailor's canvas will be required. Place the pattern on the canvas with the fold to a straight thread, and the fronts on the cross, and cut out. Next cut out two pieces of very thin lining or muslin, the same size as the canvas, place the latter between them, and tack all round the edge of the canvas. Now cut the material, allowing ½ inch all round for turnings. This should be herring-boned down to the top, bottom and sides of the canvas interlining, taking care to cut away the fold of the material that overlaps at the corner of the collar [36], snipping the top of the material to make it set flat along the curved upper side. Now press the inside of the collar with a hot iron as directed for sleeves.

Sew on the hooks and eyes alternately, the hook ½ inch from the end of the collar, and the eye just touching the edges, but not projecting beyond. If the material is very thin, it should be lined with lawn or muslin.

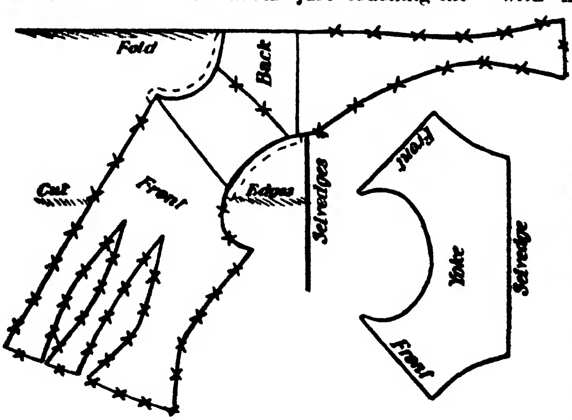
To Set on the Collar. Halve and quarter the collar, also the neck of the bodice; pin the centre of the collar to the back of the bodice, also pin the ends to the front fitting line; then hold the inside of the bodice towards you, having the collar and bodice well over the hand; pin the collar halfway between the pins, and again, midway between the other pins. After it has been well pinned, it should then be firmly stitched on from the inside, taking care to sew in the wheel marks. The collar should be faced with silk, sarcenet or lining, cut the same size as the material with ½ inch turnings, and felled neatly to it all round.

Putting on the Tight Band. Take a piece of webbing for a band, which should be ½ inch less than the waist measure after the ends are turned in. This is fastened with either one or two hooks and eyes. Before the band is adjusted, the skirt hooks are sewn to the casings of steels or bones on the three back seams, the bill of the hooks just touching the waist line. The webbing is slipped under the bill of the hook, with the centre of the webbing to the centre of the back seam of the waist. Now fasten the webbing to the bone casings of the bodice with a large cross stitch, with the same coloured silk as that used in overcasting the bodice seams.



38. A PLAIN BLOUSE

The Blouse. Dame Fashion, in spite of her changeableness, has remained faithful to the allurements of her old favourite, the blouse, and though frequent prophecies to the contrary have been made, it is still with us, and too firm a favourite to be ignored in a dress-making course. For this we credit the fickle lady with much good sense, although the blouse of to-day is a very different affair from its ancestress, the garment introduced by Garibaldi, and much worn somewhere in the sixties.



39. AN AMERICAN YOKE

It would be quite impossible to deal with the many guises assumed by the blouse, but from the following examples and explanations we hope a worker will see how easy it is to reduce the apparent intricacies of any model to its elements, and evolve almost any design she pleases. It may, however, be well to point out that whatever be the method of expression, whether the blouse be unlined or made up on a fitted lining, without or with a yoke, the latter either plain or tucked, of lace, of strips of material or insertion united by faggot-stitching, the underlying principle of all blouses is the fitting bodice and coat sleeve, the drafting and

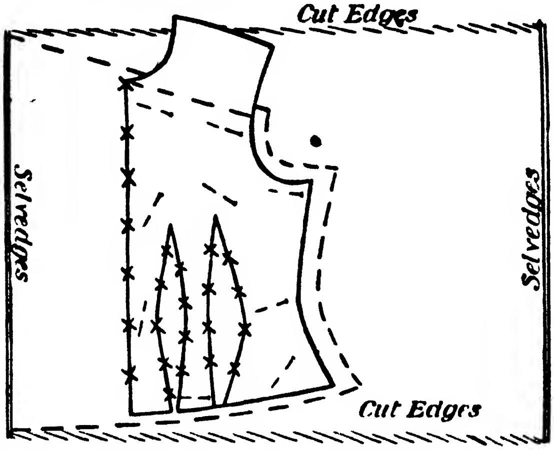
making of which have been fully described. This will, perhaps, explain why we have begun with the making of a bodice and not a blouse. We will now turn to the diagrams, first of all explaining that the portions NOT to be cut are marked —X—X. The turnings are indicated by a broken line — — —, and the outline of the pattern by a firm one.

In diagram 37 we have five blouses, as well as a back and yoke, cut on the cross, marked respectively *a*, *b*, *c*, *d*, *e*, *f*, and *g*, all of which can be evolved from the bodice pattern just described—or any other—as will be seen clearly in the following diagrams.

How to Cut the Blouse. We will now describe each of the blouses sketched, and begin with *a*, which is a perfectly plain one suited to morning wear. To show how to obtain it we must turn to diagram 38, where the method of cutting it from the bodice pattern is shown, using that, of course, of the size required. Place the front of this to the selvedge 1½ to 2 inches from these and pin carefully in place. Now arrange the back portions above this as shown, placing the centre part first, then the curved side-piece, and the under-arm piece next. Pin all these carefully in position, so that they will not slip, mark them, and cut round the outline thus made, as shown by the broken line. Remember to keep the waist lines even and allow good turnings at the fronts, shoulder, and under-arm seams. This will give one back and two fronts, the method of cutting the sleeve being described later on, whilst the collar is the pattern given in the drafting of the bodice. If the back be a trifle wide, it is quite easy to reduce the under-arm piece in width and add what has been thus taken off to the front part.

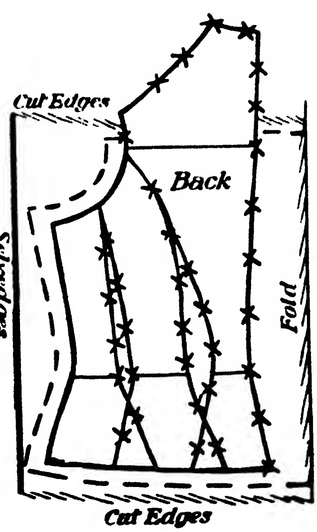
Blouse *b* is cut exactly the same as that we have already described, except that the material fronts—and back too, if preferred—are tucked *before* cutting out, the tucks being the deep ones stitched as described in PART I. (see TUCKING), but they can be arranged in any way desired, provided the tucking be done before cutting out, as already said. This method is more satisfactory than when the material is cut out first, when it is neither easy to keep the tucks regular nor the right way of the material.

An American Yoke. In the third of the group of blouses under consideration, marked *c*, we have one with what is known as the American yoke, this being cut all in one, and for which our bodice is still the basis. In this shape the fronts come on the cross, the back being cut selvedge-ways. The diagram shows how to obtain this, but it is well to remember that for this shape the pattern must fit perfectly at the shoulder, as no alteration is possible when it is once cut out.



40. FRONT OF AMERICAN BLOUSE

Place the back and front portions together as shown, the two shoulder lines meeting, and the centre back to the fold and of the depth required. Pin in place, draw a line across from neck to armhole, for the depth needed, and cut out as indicated by the broken line. The result will be a piece like that shown in the opened-out yoke. Two pieces of the same shape and size are required, as it must be double, like nearly all yokes for unlined shirt blouses [39].

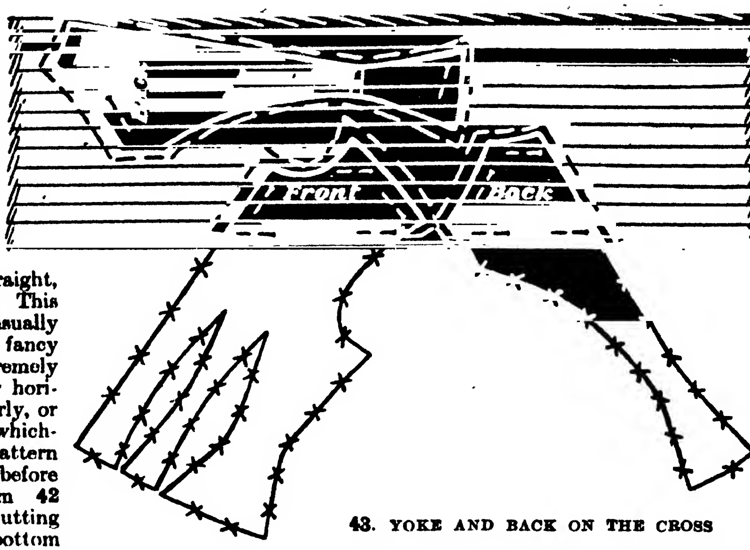


41. BACK OF AMERICAN BLOUSE

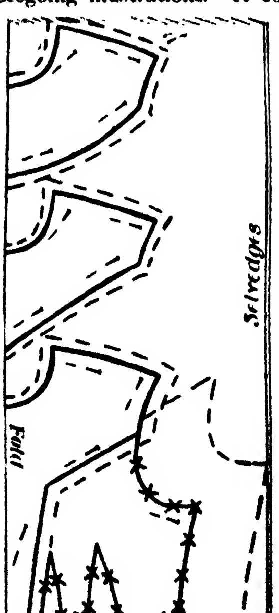
Having obtained the yoke, we must turn to the next diagram, for the method of cutting the blouse front [40]. In this the centre front is placed from 4 to 6 inches (depending on the thickness of the material and the size of the pattern) from the selvedges to allow for the front fulness. Measure the depth of yoke, and then draw a line slanting upwards across the material, as indicated by the broken line. Always allow a sufficiency of fulness in the front of a blouse, so that it shall set well and easily, as skimpiness not only makes it uncomfortable, but detracts in no small degree from the effect of an otherwise well-made blouse. For the back, place the various portions of the pattern as described and shown in diagram 41, allowing a little fulness at centre back, and for the depth of yoke.

We will now take *d* of our evolutions. Here

we have a yoke extending in a point to the waist in front, a style which enjoys much popularity at the moment, and makes up becomingly and smartly. It could be varied in several ways. For instance, the sides could be rounded off downwards, or made quite straight, as fancy may dictate. This style of yoke is usually expressed in lace or fancy material, but looks extremely well if tucked either horizontally, perpendicularly, or V-shaped fashion; but whichever be preferred, the pattern of the yoke is needed before tucking. In diagram 42 we see the method of cutting it out depicted, at the bottom of a trio of yokes. The outline is shown by a firm line, the turnings by a broken one, whilst the shape of the side-portions is further indicated by a broken line [42]. The back of the blouse is quite plain, and the method of cutting-out will be easily understood from the foregoing illustrations. It could, of course, be made in any other way preferred, whilst the fronts may be tucked instead of gathered, but in this case a little fulness should also be allowed, especially if the material happen to be of thin texture.



43. YOKE AND BACK ON THE CROSS



42. THREE DIFFERENT YOKES

Other Yokes. The fifth of the group of blouses (*e*) illustrates one with a rounded yoke, the method of cutting which is seen in the top one of the trio, the lower front portion being cut to fit this, as described for the last.

The centre one of the trio of yokes from which we have already obtained *c* and *e* depicts a pointed affair which may be preferred to the rounded one, in which case the bodice portion is cut similar to the front for the American yoke-blouse, except that the slope will be reversed, as the greater depth is required at the sides. The yoke of blouse *e* in the sketch is made of strips of lace united by faggotting, for which the pattern is needed.

The last sketches of the group in 37—those marked *f* and *g*—show an arrangement of stripes for yoke and back, as it may happen that a much better effect can be obtained by not having them quite straight. In the case of broad stripes, for instance, for a rather stout figure, the result would be more becoming and graceful were they arranged to come in a V at the back as shown. The method of cutting both yoke and back is indicated in the diagram. Be careful to get the stripes to meet in both cases, and if the fronts be cut to match, they should be arranged in the same way [43]. With respect to the yokes of *shirt* blouses, the back should always be cut selvedge-ways, as the strain and wear mostly falls on this portion.

NOTE. The amateur should first cut the pattern in paper to get the right shape, and to avoid wasting the material.

In the blouses sketched the ordinary high collar has been shown, but of late transparent, or unlined, ones have been the fashion. When this is the case, the neck must be neatened by a narrow binding before putting on the lace. To do this cut a strip of crossway material (if the edge be not shaped it will do on the straight) long enough to allow turnings at each end, and about 1 inch wide, or a trifle less. Put the edge of this to the neck-edge on the right side, run together, turn over to meet the other edges, being careful to neaten the ends, and sew the lace to this on the right side.

To be continued

THE STATE LADDER OF LEARNING,

AND HOW TO CLIMB IT

THIS is the age of efficiency. In the keen competition of individuals and of nations we cannot afford to waste either time or money, and least of all can we waste men without paying the penalty in the race of progress.

Wherever there is a brain of exceptional power or a character of unusual pertinacity, it is the duty of the State to seek out its possessor, and to set him on the ladder by which he may raise himself and his fellows. And while it is the duty of the State, at once to itself and to the individual, to offer to every promising boy the means by which he may fit himself to do a man's work in the world, it is no less the boy's duty to himself and to his country to avail himself of the means so placed at his disposal.

Recent legislation has shown that the State at least realises its responsibility, and what is now required is that every boy in the kingdom should recognise that if he has fair ability and the will to do a certain amount of hard work in his youth, no position in the land is closed to him.

Every county and county borough has its own "scheme," and discharges its educational functions in its own way, but the general features of all the schemes are very much alike, and may be shortly described.

The First Rung of the Ladder. The first rung of the ladder is formed by the minor, or junior scholarships given by the local education authority to children in the public elementary schools, and in many cases to the children of parents of small means, whether they attend a public elementary school or no.

These scholarships are usually awarded to children between the ages of 10 and 14, on the result of examination. The number given in different counties and districts varies considerably. In London there were last year 14,000 candidates for junior county scholarships out of about 80,000 elementary schoolchildren of eligible age—between 11 and 12 years—and 2,166 scholarships were awarded; so that about 2¾ per cent. of the children leaving the public elementary schools of London in a particular year became scholarship holders.

The minor scholarship given by the different education authorities carries with it not only free education at a grammar-school or similar institution, but also a small grant towards the maintenance of the child. In London free education is given between the ages of 11 or 12 and 16 or 17, in addition to which parents whose income is less than £160 a year receive a grant of £6 per annum during the first three years, and £15 per annum during the two remaining years, parents with larger incomes receiving a smaller grant. Provincial authorities are not, for the most part, so liberal in the matter of maintenance grants, but the proportion of scholarships given to the number of children in the schools is about the same. The provision in some counties is particularly good. In Essex about 4 per cent. of the elementary school-children obtain scholarships.

The education of a minor scholar qualifies him for many positions in business, or for Civil Service clerkships and similar posts; but for the more ambitious boy it is only a stepping-stone to higher things.

Prospects at the Age of Seventeen. In some districts a boy can hold a minor scholarship up to the age of 18 or 19 years, but in the great majority of cases emolument lapses when the scholar has attained the age of 16 to 17 years. There are then three courses open to him:

1. He may enter a trade or profession, and attend a course of commercial or technical instruction at an evening school. Small scholarships are offered in most counties to pay the cost of such a course, and are easily obtainable.

2. He may obtain a continuation or intermediate scholarship, and proceed to study for two, or in some cases three, years at a technical college, qualifying himself for the better positions in the engineering and other scientific trades; or

3. The same scholarship will enable him to continue his grammar-school course, or in many cases to enter a conveniently situated public school as a day-boy.

Intermediate scholarships vary greatly both in value and in the number given. One hundred such are awarded in London, and children who have not held minor scholarships are allowed to compete if their parents' income is less than £400 a year. With these additional competitors in the field, the result is that only one in 20 of the London minor scholars is able to secure an intermediate scholarship. These provide free education at any of the London secondary schools, including St. Paul's and Merchant Taylors', as well as a maintenance grant of £30 a year.

Scholarships in the Provinces. In the provinces a larger number of children in proportion to the population are able to secure the scholarships, but these are not so valuable as the London ones, and in many counties they are so small that it is not possible for a scholar to attend a good school without a certain amount of hardship. But it is worth while to undergo the hardship, not so much for the sake of the better teaching which may be provided at the more expensive school, but rather in order to be able to enter Oxford or Cambridge on the same footing as the public-school boys, of which class these universities are largely composed.

The writer remembers well one of his own schoolfellows—a boy who seemed to us all to be a little peculiar, and whom we consequently "ragged" to a certain extent, until someone discovered that the boy's father was a mechanic, who pinched himself to enable his son, with the aid of a county scholarship, to keep up appearances at school. Then the boys' attitude changed at once; all were friendly to him at school, and their homes were open to him in the

holidays. He has passed through the university now, and is doing good work in the world in a sphere very different from that which he would have filled without the ladder by which he arduously climbed.

We have seen that it is possible for any boy of average brains and application to secure, by means of a minor scholarship, a good education up to the age of 16. The competition for intermediate scholarships is more severe, particularly in London; but fortunately these are not the only scholarships available for boys of 14 to 17 years of age. Nearly all grammar-schools, many of the City companies, certain charities, and pious foundations offer scholarships tenable for the most part at particular schools. The City of London and some of the Northern counties are particularly rich in such foundations, and information as to those available in any district can usually be obtained from the local education authority.

Help from Local Authorities. The body now responsible for public education in every county borough is the Borough Council. All districts outside the boroughs are directly under the authority of the County Councils as far as education is concerned.

Scholarships are granted in every case by the responsible authority, and a boy living in a borough is not in general eligible for a county scholarship. The proper course for a would-be candidate for any public scholarship is to write to the Clerk of the Education Committee of the County or Borough Council, under whose jurisdiction his parents reside. The clerk is generally in a position to give information, not only as to the scholarships granted by the committee, but also as to all the others for which boys residing in the district are eligible.

By one means or another, then, the child of the mechanic or of the labourer can obtain an excellent education up to the age of 18 to 19. At that time he is confronted by a serious problem. For many of the higher walks of life a university degree is a valuable, if not a necessary qualification. Shall he seek it at one of the old universities of Oxford or Cambridge, or at one of the many new ones dotted about the country?

The University Problem. There can be no doubt which of these degrees is the more valuable to the possessor, and if by any means a boy can get to Oxford or Cambridge, he should go there. On the other hand, a course at one of the other universities is far cheaper, costing from £30 to £40 a year to a boy living in the town, to which must be added the cost of lodgings in the case of a boy coming from a distance. The lowest cost at which it is reasonably possible to pass through Oxford or Cambridge is £140 a year, unless all the social advantages of the institutions are to be neglected. At some colleges, indeed, the cost is even greater. A man can scarcely live at Trinity College, Cambridge, for example, on less than £160 a year. It is possible to cut down expenses by entering as a non-collegiate student, but this is to reject the many scholarships offered by the different colleges.

Individual Ability the Best Guide. The real guide of a boy's proper course after leaving school is his own ability. Most local education authorities offer one or more scholarships to boys of limited means, to help them through the university. In London about 50 scholarships of a maximum value of £90 per annum are given yearly; but these and the smaller scholarships given in the provinces are not sufficient to enable a boy to go to one of the old universities unless he can also win an open scholarship for himself. The competition for these, however, is more severe, as the son of a mechanic may have for his opponent the descendant of several generations of scholars.

Now, there can be no doubt that a boy of really marked ability should enter at one of the more famous colleges, where the competition is heaviest and the prizes greatest. If he is so fortunate as to secure also a leaving exhibition from school, he may leave the senior county scholarship to a boy who needs it more, and save money at the university at the same time. On the other hand, a boy of more modest attainments may do very well for himself at one of the less-known colleges, though at Balliol, Oxford, or Trinity, Cambridge, he could not hope to win any emolument.

A boy who cannot secure any of the scholarships offered at Oxford or Cambridge had better abandon the idea of a career at either of these universities; but no boy of ordinary intelligence need anticipate such failure if only he will put his back into his work at school.

There are numerous scholarships and charities available, particularly to London boys, for the purpose of providing a higher education. The most valuable of these are the four Whitworth engineering scholarships, worth £125 a year for three years, open only to practical engineers. Of all these particulars can be obtained from the Board of Education, South Kensington.

There are also 22 science scholarships given annually to graduates of any university in the British Isles or Colonies, by the Commissioners of the 1851 Exhibition. The award is made on the recommendation of the College, and holders pursue their studies on lines approved by the Commissioners.

The Rhodes Scholarships. The most valuable of all the open scholarships to Oxford are not open to English boys. These are the scholarships founded by the will of the late Cecil Rhodes, and are worth £300 a year for three years. Sixty of these scholarships are assigned to the British colonies—namely, 9 to Rhodesia, 15 to South Africa, 18 to Australia, 6 to Canada, and 3 each to New Zealand, Newfoundland, Jamaica, and the Bermudas. Two are also given to each State or territory of the United States of America. Appointments to one-third of these scholarships are made every year. Five scholarships of the value of £250 for three years are also allotted annually to German boys.

The Rhodes Scholarship scheme is administered by Dr. Parkin, C.M.G., of 40, Elvaston Place, London, S.W

How to Obtain Technical Education. It is not always advisable for a boy, even if he has the ability, to pursue a course of study on public school lines up to the age of 18 or 19. Many boys' ambition points to success in the profession of engineering, or in one of the technical branches of science, rather than to a university career. The most usual course for a technical student is to enter a day technical college at the age of 17, but the selection of the college is a rather serious matter.

There can be no doubt that the engineering training given at Cambridge University is the best all round engineering course obtainable in this country. An ideal training for an engineer would perhaps be a Cambridge course, followed by a year of special study in America or Germany, before entering the shops; but the son of parents of slender means will find it difficult to justify such a course of action to himself.

A very excellent training can be obtained by means of a two or three years' day course at one of the provincial university colleges or such of the technical institutes as provide for day students. The cost of the former course is generally about £30, the latter about £15, per annum.

The selection of a college depends on the neighbourhood and the branch of science which is to be studied. Each institution has its special features. Thus, the Armstrong College at Newcastle is unrivalled for coal-mining and marine engineering, the Battersea Polytechnic for the mechanics of motor-cars, and the Sheffield University College for the science of metallurgy.

It is impossible here to give a general criticism of all the technical institutes of Great Britain, but a certain amount of guidance will be found in the table appearing in a later issue, and it is generally possible to get information as to local institutions by application to the local authority.

Scotland's Educational Advantages. The ladder is a steep one everywhere, and requires arduous climbing, but perhaps a Scotch boy has more facilities for the ascent than a native of the sister kingdom.

In Scotland, as in England, education is free up to the age of 14, but in Scotland it is now possible, thanks to the munificence of Mr. Carnegie, for every necessitous Scotch student to get, at any one of the four universities, his fees paid and books supplied, on application to the trustees. Besides the Carnegie trust, there are bursaries given by the universities and other institutions on the result of examination.

The real crisis of a Scotch boy's career arrives at the age of 14. The years between 14 and 17 are not provided for by junior scholarships in the systematic way prevalent in England, though in the larger towns excellent higher-grade schools are provided. There are, however, numerous local and miscellaneous scholarships available, and it must be remembered that the cost both of education and of living is lower in Scotland than in England, and that the greater sparseness of population makes it possible for a boy to combine schoolwork with lucrative duties in a very effective way.

To a certain extent, this will have to be done also by the Englishman who wishes to make the best of his university career. The scholarships at the Oxford colleges are seldom worth more than £80 a year; while at Cambridge, at the smaller colleges, at least, £60 a year is above rather than below the average, and a boy of average ability will find it very difficult to make more than £150 a year all told—a sum which does not supply a great margin for vacation expenses. Fortunately, a university man can generally secure some light tutorial work in the vacation; and some men who have desired a greater change of occupation have tried haymaking and harvesting with considerable success.

Ireland's Needs. Education has not as yet been systematised to the same extent in Ireland as in Great Britain—partly perhaps because the State has found it possible to leave the whole matter to the intensity of religious party feeling. In any case, education other than elementary is furnished almost entirely by schools conducted by religious societies such as the Christian Brothers.

These societies also divide the task of elementary education with the voluntary schools, and they do, to a certain extent, take it upon themselves to pass boys up from the lower to the higher schools under their control, by which means a ladder is provided, though not so broad a one as in England or Scotland.

Scholarships are provided in Ireland by the National Government. They are divided into Junior, Intermediate and Senior. The number awarded in 1905 were:

	Boys	Girls	Value
Junior to 16	83	38	£10—£20
Intermediate to 17	40	15	£10—£30
Senior to 18	56	13	£30—£80

Compared with the scholarships awarded in England, and particularly in London, these are rather small and few, but it is satisfactory to note that quite a large number of poor boys have passed with credit through Trinity College, Dublin, and the Royal University of Ireland, while a large proportion of the Maynooth students are entirely without private means.

What School-Board Boys Have Done. One of the chief difficulties in the way of the poor boy who enters into competition with the children of richer parents is the difficulty of getting room and quiet to work at home. Indeed, the struggle to climb the ladder which the last few years have provided requires not only pluck and effort on the part of the climber himself, but a great deal of devotion and self-sacrifice on the part of his parents. Happily, all these qualities are to be found in thousands of British homes. Thousands of boys are climbing up the ladder of learning, and every year they touch a higher point. Two board-school boys have been Senior Wranglers, and this year, for the first time, a board-school boy was elected to a Fellowship of Trinity College, the most distinguished reward of merit that Cambridge University can offer.

WHAT EVOLUTION REALLY MEANS

Reproduction—continued. Why does Variation take place? Acquired and Inborn Differences. Traits of Individuals. True Meaning of Evolution

By DR. GERALD LEIGHTON

The Germ Cell. We now know that the process of reproduction, as studied in the species we have taken, is in the first instance a very simple process of simple division of a complete individual into two. In that case the individual may be regarded as the germ cell, and the germ cell as the individual; there is no *specialisation.* Next we see two whole individuals concerned in the reproductive process, each exchanging a portion of themselves, as in paramœcium, but at the same time having the power of dividing into two as well. Then comes a stage in which a multicelled animal, hydra, reproduces also in two distinct ways, but in a definite order and in response to considerations of environment, producing first asexual individuals asexually; these, however, as they grow developing special parts of themselves as reproductive organs, male and female in one individual. The reproductive power in this generation is a specialised function, not a general one, a distinct advance in complexity. Germ cells (*i.e.*, sperms and eggs) are produced, from the union of which sexually new individuals arise which repeat the twofold method of reproduction.

Physical Immortality. The later stage still is that of the higher animals, in which the method of reproduction is restricted to that of sexual germ cells alone, which are continuous from one generation to another, and are not produced from the body cells of the individual at all. Moreover, the sexes separate, one individual carrying only male germ cells, the other only female germ cells. In the single-celled amœba death is not a necessary part of its history; it divides into two and is physically immortal as long as amœbæ exist. The individual is immortal because it is a germ cell. In the higher animal, where the germ cell and the individual have become distinct, the germ cell alone has the power of continued life. The individual dies sooner or later, but before doing so hands on the germ-plasm within to form the next generation. As it was received, so it is handed on, affected more or less (a problem to be considered later) by its temporary sojourn in the body of an individual. It is this continuity of the germ-plasm which alone makes the phenomenon of heredity possible, and maintains the distinctive characters of a species almost unimpaired as far as the most prominent characters of that species are concerned. The gravest problem that man has to study is to what extent and in what manner is the germ-plasm within the individual affected by conditions of external surroundings, if at all.

We have now taken a general view of the process of reproduction in relation to the continuity of life. We have seen how it is that individuals can arise similar to those which preceded them, either by simple fission or one of the other more complicated reproductive processes. In other words, we have seen the origin of the likenesses in individuals of a species. It lies in the continuity of the germ-plasm.

Variation of Living Beings. But individuals, even of the same species, are not all identical in every respect, though all have something in common. The next matter, therefore, to which we must direct our attention is the question of variation in living beings. We are here on the threshold of the deepest of all biological problems. Why do the various members of a family differ from each other? Whence the variation? Of what advantage is it? What part does variation in offspring play in the great problem of evolution? These are the questions to which we must seek an answer, even if it be a very imperfect answer. They are the questions which have engaged the best thought of mankind for generations, and in the elucidation of which the greatest minds are still engaged. The reason is obvious. The future of man is wrapped up in the answer to them, just as his past is explained by their correct understanding.

The very first thing to do in studying such a problem as this is to define our terms. Unless we are perfectly clear about the meaning of the terms we use, it is quite hopeless to come to a definite idea on the whole subject. Half the disputes on problems of this sort arise from different writers or teachers using the same word in different senses. A certain number of technical terms are unavoidable in any science, indeed they are most useful, so long as their meaning is exactly understood. Some of these terms are explained in the glossary attached to this course, but there are others which cannot be dismissed in a word or two, and which we must now examine more closely. To these we must give particular attention in order to understand what follows. It is specially to be noted that these terms have a wider and more extended use in popular language and literature than they have in biological science.

Definition of Terms. First we may define a group of terms all of which have reference to the various traits or characteristics of animals or plants. These terms are the following: *Inborn, Innate, Germinal, Congenital, Acquired, Somatic, Variation, Spontaneous, Evolution.*

Theoretically, at least, all the traits or characters which any living organism possesses belong to one of two groups; they are either inborn or they are acquired, and it is of the first importance that we should be perfectly clear as to what constitutes an inborn and what an acquired

character. The fundamental distinction is one of origin. In order to decide whether any given character is to be referred to one or the other group we must answer the question—Whence does this character arise? "*Inborn traits or characters are those which take origin in the germ-plasm*, which arise because the germ-plasm is so constituted that it tends, under fit conditions of shelter and nutrition, to impel or cause the germ cell to proliferate into an individual having those characters. Thus a man's head is inborn. It arises because the germ-plasm in the fertilised ovum whence he sprang was so constituted that it impelled that germ cell to proliferate into an individual having a man's head."

Acquired Characters. "*Acquired characters*, on the other hand, do not take origin in the germ-plasm; *they are modifications of inborn characters* caused by the play of forces from the environment on those characters after (as a rule) they have developed from the germ cell. Thus a man's hand is inborn. But if it be modified by use, disuse, accident, or the play of other forces from the environment the *modification* is an acquired character. All the effects of exercise are acquirements—for example, the enlargement which exercise causes in muscles. The effects of lack of exercise are also acquirements—for example, the changes in a diseased lung or an injured arm. Every modification of the mind is also an acquirement—for example, everything stored within the memory. If a man be blinded by accident or disease, his blindness is acquired. But if he came into the world blind—if he be blind by 'nature'—his blindness is inborn. If a son be naturally smaller than his father, his inferiority of size is inborn; but if his growth be stunted by ill-health or lack of nourishment or exercise, his inferiority is acquired. Inborn characters take origin in the germ. They express the hereditary tendencies of the individual, and, with variations, those of the race. Acquired characters take origin (as a rule) in the cell-descendants of the germ cell. They express the modifications of the hereditary characters of the race which are caused *in the individual* by the play of forces from the environment." (Dr. Archdall Reid.)

The Traits of Individuals. If we review the whole of the traits of any given individual, it is quite easy, by means of the above definitions, to say that certain of these traits are inborn while others are as certainly acquired. Thus, a head with two eyes, a hand with five fingers, the possession of organs for seeing and hearing, and so forth, are all obviously inborn characters. They are common to the race, and to many animals besides man. They take their origin in the germ-plasm from which these animals are developed. But there are other traits which cannot be so easily referred to one or other of these categories. Here is an individual who is an extraordinary mathematician. Is his mathematical faculty inborn or acquired? It depends on its origin. Some individuals have the mathematical faculty inborn; they are "born mathematicians." Others become very proficient in mathematics only by great and prolonged effort of study, by long subjection to a mathematical environment. Their proficiency is obviously acquired entirely; it is an acquired character.

The Fundamental Distinction. When we come to consider the problem of heredity, we shall see that it makes all the difference in the world. Meantime it is to be noted that while certain individual traits are obviously inborn, there are others which may be either inborn or acquired. In the same way there are certain traits which are obviously acquired. Thus the thickening of the skin on a coachman's hand in certain positions is plainly due to the constant irritation of the pressure of the reins. It is an acquired modification. The hand and skin are inborn, the thickening from the environment is aquired. So the power of expressing our thoughts in language is acquired. No infant was ever born able to speak. The organs of speech are inborn in the human race as is the *power of acquisition* of speech, but not speech itself. Speech comes only from the individual being placed in an environment of speech—it has to be acquired by gradual practice.

The fundamental distinction, then, between individual traits is one of origin, and a clear apprehension of this simple fact will prevent us falling into many an error. We saw previously that the two kinds of cells possessed by the higher animals are the germ cells and the cells composing the organs and tissues of the body. The terms "inborn," "innate," "congenital," and "germinal," all refer to characters which take their origin in the germ cells, and are synonymous terms in biology. They should never be used in any other sense in biology, or endless confusion follows. Similarly, all the characters which take their origin from the cells of the body are termed "acquired," or "somatic" (pertaining to the body).

Abnormal Characters. But now comes a most important consideration. It is a commonplace of observation that every individual differs, however slightly, from his parents even in inborn characters. No two are exactly alike, however close the resemblance. That is to say, every individual exhibits some new inborn characters, in addition to any differences which may be afterwards acquired. He differs *congenitally*. It generally happens that these new inborn characters are more or less slight modifications or alterations of characters which existed before. The skin may be thicker or more hairy, the nose larger, the mouth smaller, the foot broader, the sight keener, the hearing duller, and so forth, all alterations in traits which existed in preceding generations. All these new characters which are inborn, innate, germinal, or congenital, whether the new trait be a very pronounced one or merely a slight difference in degree of some former trait—all these are termed technically *variations*. If the new character is something quite unlooked for, and not in keeping with the usual characters of the species, it is termed an *abnormality*. Thus the possession of six fingers on the hand instead of the normal five is an abnormality.

Variation and Evolution. Variation, then, may be said to be the appearance of new characters which take origin in the germ-plasm, with the result that no two individuals even of the same species are exactly alike. It is the existence of variation in animals and plants which lies at the root of the problems of evolution, for without variation there could be no evolution. The fundamental importance of variation was fully recognised by Darwin, and he was the first to collect any large mass of facts bearing upon the matter, these being published in his work, " Variation of Animals and Plants." Darwin early realised that without variation there could be no such thing as organic evolution—evolution of living creatures, that is—and insisted upon this in his " Origin of Species." But the student of the problem nowadays must recognise that most of Darwin's facts relate to animals and plants in the domesticated state and not growing wild, and it seems probable that he himself hardly realised the magnitude and universality of variation in natural conditions.

" As to the causes of variation, Darwin did not hazard many conjectures. To do so would have been premature, and from actual lack of knowledge almost impossible. For many years after the publication of Darwin's work, the additions to our knowledge of the subject of variation were exceedingly small. Scientists seemed to rest content with the material he had collected, and to theorise on this alone, rather than to test their theories by a search after fresh facts and data. Within the last decade, however, the importance of the scientific study of variation has begun to be more thoroughly recognised, and has resulted in its being attacked with considerable vigour from several entirely different points of view. Investigations from the mathematical side have shown that many of the apparently disconnected facts of variation can be expressed with ease and lucidity by exact mathematical expressions, and that much material which has hitherto been regarded as quite outside all law was in reality amenable to treatment, according to the well-known laws of chance. Again, investigations from the experimental side have suggested much concerning the causes of variations, both genetic and somatic. Still, again, a fresh burst of activity in the collection of data regarding the actual facts of variation, more especially in respect of organisms found in a state of nature, has shown us how much in this branch of the subject there remains for us yet to learn." (Vernon.)

Variation is Universal. It cannot be too strongly insisted upon that not only does every animal show some variation, but that it varies in respect of all its characters, of whatever kind these may be. The variation may be greater or it may be less, but it always exists to some extent. Moreover, variation in one direction may be, and often is, quite independent of variation in another. Because one person has a longer arm than another, it does not necessarily follow that his neck will also be longer. On an average this may be so. Indeed, there is doubtless some degree of correlation between most parts of the body.

So much by way of consideration of the meaning of " variation," a phenomenon which we recognise as inherent in living matter and as being of universal occurrence. It remains to add that while most variations, as we have said, are somewhat small differences in characters already seen, other variations are of much greater magnitude. They are sudden appearances which do not seem to be mere continuations of former characters. Such sudden and striking differences are termed discontinuous variations. As we shall see later, it is very probable that these discontinuous variations have been the means of the evolution of species at a much more rapid rate than was formerly supposed. Next we must turn our attention to the meaning of the term " Evolution," after which we shall be in a position to discuss the causes of variation and their bearing upon the problem of evolution.

The Misuse of "Evolution." At first sight it might be supposed that it is quite unnecessary to explain a word which is in such common use at the present day, but as a matter of fact hardly any term is so commonly misused. All sorts of people use it to mean all sorts of things, and for that reason we must here consider very carefully in what sense we ourselves use it. It is also necessary to point out some of the more popular misconceptions of the term. The word itself etymologically means an act of unfolding or unrolling. In the science of obiology the word came into use in the early part of the eighteenth century to signify the theory which asserted that all the parts and organs were pre-formed in the germ, and that these gradually unfolded themselves, so to speak ; in fact, it was thought that a sufficiently powerful microscope would enable the observer to see all the structures of the animal pre-formed in the egg. " We now know that the original theory of evolution or unfolding of pre-formed organs and tissues was nonsense." (Saleeby.)

" The word owes all its meaning and value to Herbert Spencer, who had begun by attempting to show that there is in nature a law of progress. [See his great essay, " Progress, its Law and Cause."] The title of another essay, now historic, ' The Development Hypothesis ' (1852), indicates the word then used to indicate the process which he later came to call organic evolution. It was in the year 1857 that, having found that the law of universal and ordered change is anethical, and is by no means necessarily synonymous with progress, Spencer introduced the word evolution to indicate that ' universal redistribution of matter and motion ' which his genius discerned even in the days when all astronomical authority opposed the nebular theory." (Saleeby.)

The word, then, has a much wider and more far-reaching significance than popular usage is apt to associate with it. It refers not merely to animals and plants, but to every element in the universe, whether living or non-living. Applied to living organisms, whether plant or animal, we must speak of " organic evolution," not merely of " evolution." The necessity for this precise and accurate use of the term is to be found in

the great advancement of thought upon the whole subject of the origin of the present condition of the universe. The organic evolution of plants and animals is only one phase of a universal principle "proceeding in earth and sea and furthest sky, before time was and when time shall cease to be—for time is merely a human symbol, and the whole of human history is but as a watch in the night, a scarce considered stride in the path of the Eternal." (Saleeby.)

A Fascinating Theory. Professor G. H. Darwin, son of the immortal champion of the theory of organic evolution, has in his recent address to the British Association laid stress on the fact of this wider evolution. He reminds us that "the fascinating idea that matter of all kinds had a common substratum was of remote antiquity. In the middle ages the alchemists, inspired by that idea, conceived the possibility of transforming the baser metals into gold. . . . The object of alchemy, as stated in modern language, was to break up or dissociate the atoms of one chemical element into its component parts, and afterwards to reunite them into atoms of gold. Natural selection might seem, at first sight, as remote as the Poles asunder from the ideas of the alchemist, yet dissociation and transmutation depended on the instability and regained stability of the atom, and the survival of the stable atom depended on the principle of natural selection. Until some ten years ago the essential diversity of the chemical elements was accepted by the chemist as an ultimate fact, and, indeed, the very name of atom, or that which could not be cut, was given to what was supposed to be the final indivisible portion of matter. The chemist thus proceeded in much the same way as the biologist, who, in discussing evolution, accepts the species as his working unit. Accordingly, until recently the chemist discussed working models of matter of atomic structure, and the vast edifice of modern chemistry had been built with atomic bricks.

"Within the last few years, however . . . electrical researches . . . had shown that the atom, previously supposed to be indivisible, really consisted of a large number of component parts . . . . They were surely justified in believing that they had the clue which the alchemists sought in vain. . . . If the elements were not eternal in the past, they must ask whether there was reason to believe that they would be eternal in the future. Although the conception of the decay of an element and its spontaneous transmutation into another element would have seemed absolutely repugnant to the chemist until recently, analogy with other moving systems seemed to suggest that the elements were not eternal."

Atoms not Eternal. "At any rate it was of interest to pursue to its end the history of the model atom which had proved so successful in imitating the properties of matter. The laws which governed electricity in motion indicated that such an atom must be radiating or losing energy, and therefore a time must come when it would run down, as a clock did. When this time came it would spontaneously transmute itself into an element which needed less energy than was required in the former state. Thomson conceived that an atom might be constructed after his model so that its decay should be very slow. It might, he thought, be made to run for a million years, but it would not be eternal. Such a conclusion was an absolute contradiction to all that was known of the elements until recently, for no symptoms of decay were perceived, and the elements existing in the solar system must already have lasted for millions of years. Nevertheless, there was good reason to believe that in radium, and in other elements possessing complex atoms, they did actually observe that break-up and spontaneous rearrangement which constituted a transmutation of elements. It was impossible to say as yet how science would solve this difficulty, but future discovery in this field must surely prove deeply interesting. It might well be that the train of thought he had sketched would ultimately profoundly affect the material side of human life, however remote it might seem now from our experiences of daily life." (Presidential Address to the British Association.)

A New Realm of Ideas. It is impossible to read the above extract from Professor Darwin's address without being struck with the immensity of the thought which the modern use of the term evolution suggests. It seems to lift us into a new realm of ideas altogether, to bring before us conceptions of the universe undreamed of even a few years ago—conceptions which, though doubtless they have floated vaguely through the scientific imaginations of physicists and biologists, now for the first time are seen to be gradually assuming a definite shape. We realise that evolution really means that all things, living and non-living, are on an ordered journey, a journey which is immensely greater than what we usually associate with the term progress, and a journey which by no means necessarily coincides with our limited conception of what progress is. We realise that there is an inorganic evolution as well as an organic, and that both are included in any accurate usage of the word by itself. Evolution is *adaptive change*, and every theory of evolution is an attempt to supply the human mind with a reasonable explanation of such changes as are observed.

Misconceptions of the Term. If we have carefully followed the above explanation, a very few words will suffice to dismiss the popular misconceptions of the word evolution. Nothing can better exemplify the popular abuse of the word than the common query, "Do you believe in evolution?" In most cases what is meant is, "Do you believe that man has descended from some sort of monkey?"

This is no exaggeration; every teacher of biology has had the question put to him in this sense. In the light of what we know to be the meaning of the word, the question is absurd upon the face of it. Evolution does not mean, and never did mean, that man is a modified chimpanzee. That may be a true belief, or it may not—it does not affect the point; but it is not the meaning of evolution.

BOOKKEEPING EXPLAINED & SIMPLIFIED

A Business Transaction Defined. Double Entry Explained. A Complete Transaction Recorded. Problems in Posting

By A. J. WINDUS

BOOKKEEPING is the art of recording in a methodical manner those transactions to which money values can be assigned. For instance, a certain banker gave his daughter upon her marriage a cheque for £10,000. Obviously, this is a transaction which falls within the scope of our definition, and as such we should expect to find it duly recorded in the banker's books of account. But the banker was also concerned in a far more important transaction. In the cathedral at the marriage service he gave away his daughter to the bridegroom. This transaction was one to which no money value could be attached, and consequently no written or printed account of it could be regarded as bookkeeping.

Definition of a Transaction. For present purposes, therefore, we shall limit the meaning of the word *transaction* by defining it as any act involving the transfer of money or money's worth. Here, again, we must distinguish between a transaction and a business transaction. The banker's gift of £10,000 was an illustration of the former; a sale of bricks to a builder would be an example of the latter. If we insert the words "for value" in our former definition we shall then have the true meaning of the term "business transaction"—namely, any act involving the transfer for value of money or money's worth. The measure of the selling value of an article is called the *price*, and in some form or other every business transaction is done for a price. Even professional men place their knowledge and skill at the service of clients in return for a price, which may be variously designated as *honorarium* by a barrister, *bill of costs* by a solicitor, *charges* by an accountant, *fees* by a doctor, *commission* by a stockbroker, and so on.

The next point to consider is that every transaction wears a twofold aspect to each of the persons engaged therein. Thus the brickmaker sold bricks on credit to the builder, and thereby (1) his stock of bricks was diminished, but (2) he became a creditor of the builder for the price of the bricks. On the other hand, (1) the builder received £100 worth of bricks, but (2) he became a debtor for their value to the brickmaker who supplied them.

Double Entry. Now, it is the proper function of bookkeeping to record transactions in such a way that their twofold or double effect is clearly seen. It is not enough for the brickmaker's ledger to show that the builder owes £100 for bricks delivered—that would be mere single-entry bookkeeping—it must also show that the stock of bricks has been diminished. This would appear from the Sales account, which would be credited with £100, the amount already debited or charged to the builder. For every debit there must be a corresponding credit.

Again, in the *builder's* books of account it is not enough for the ledger to show that the brickmaker is credited with £100—that, again, would be mere single-entry bookkeeping—it must also show that the builder received the bricks. This would appear from the Purchases account, which would stand debited with £100, the amount already credited to the brickmaker. For every credit there must be a corresponding debit.

Originally it was thought that the observance of this cardinal principle made it necessary to enter the separate amount of every transaction under two different headings in the ledger, and hence arose the term *double entry*.

Double Entry Abridged. But in the United Kingdom it has long been recognised that it makes no difference to the final result whether, for example, sales for £50 to A, £75 to B, and £100 to C—after being duly debited to the personal accounts of A, B, and C respectively—are credited one by one to the Sales account as £50, £75, £100, or are posted to that account in one total of £225. The saving in time and labour by the second method is considerable, and we cannot fail to notice that whereas the term "double entry" implies six postings to the ledger—twice three entries, as above—we accomplished our object by the second method with four only—three debits and one credit. As a matter of fact, the accounts in a set of books kept by double entry arrange themselves in the form of a mathematical equation. The debit of any particular account is not necessarily equivalent to the credit of the same account, but if we have done our work properly, if we have carefully followed out the rule that there must be no debit without its corresponding credit, then the following equation holds good:

Sum total of all debits = sum total of all credits.

We may demonstrate this by taking the foregoing example and slightly elaborating it. Assume that A and B settled their accounts in full on April 28th, 1905, and that C paid his account on April 8th, less 2½% discount. Suppose, moreover, that X, from whom A, B, and C bought their goods, contemplated going out of business, and that in executing the several orders received from A, B, and C in March, 1905, he had cleared out the remainder of his stock-in-trade at cost price. On the

1st April, 1905, the position was this: X had already disposed of his fixtures, fittings, and office furniture and the lease of his business premises, and had realised all the business debts owing to him—sometimes termed Book Debts—except those of A, B, and C. There was standing to his credit in the books of his bankers on April 1st the sum of £922 10s.—reduced later in the day by cheque £20 drawn for Petty Cash—but X owed £125 to D for money lent, and, as we have seen, A, B, and C together owed X £225. On the 29th April, just before the books of X were finally closed, the various ledger accounts appeared as under:

EXTRACT FROM THE BOOKS OF X.

A Trial Balance. We may now construct a table of debits and credits, or, to use the technical language of Bookkeeping, we shall proceed to draw out a *Trial Balance.*

DEBITS.	£	s.	d.	CREDITS.	£	s.	d.
Cash	1145	0	0	Cash	20	0	0
A	50	0	0	A	50	0	0
B	75	0	0	B	75	0	0
C	100	0	0	C	100	0	0
D	—	—	—	D	125	0	0
Stock	225	0	0	Stock	—	—	—
Sales	—	—	—	Sales	225	0	0
Trade Expenses	22	10	0	Trade Expenses	—	—	—
X Capital	—	—	—	X Capital	1022	10	0
Total Debits .. £	1617	10	0	= Total Credits .. £	1617	10	0

Thus we find that, although the debits to a particular account are not always equivalent to the credits on the same account—D, for example, has a credit of £125, but no debit—yet the sum total of all the debits equals the sum total of all the credits. Indeed, to the reflecting mind, no other result is possible. Once let it be granted that the *posting*—or entry—of a debit to any account in the ledger pledges us to the entry of a credit for a like amount somewhere in the ledger, then, no matter how numerous the postings are, if we have done our work correctly, the sum total of all the debits will invariably equal the sum total of all the credits. Therefore, by double entry we are always in possession of a most valuable check upon the mathematical

accuracy of the books of account. Going a step farther, we agree that it is immaterial to the final result whether we post items one by one or in total, so long as we observe the rule that the whole is equal to the sum of its parts.

For instance, we notice in the Sales account a credit of £225, which corresponds to the separate debits of £50 to A, £75 to B, and £100 to C, so that we are as truly carrying out the fundamental law of double entry in this case as if we had posted three credits to Sales account of £50, £75, and £100 respectively, instead of a total credit of £225.

But a new question now confronts us. We are informed, for example, that C has taken a discount of $2\frac{1}{2}$% off the statement of account for £100 sent to him by X, leaving a balance of £97 10s., which C has remitted by cheque. We are asked to show how these transactions would appear in C's own ledger. We cannot do this, however, until we know whether to debit or credit X for the cheque remitted and for the discount deducted. At this point, therefore, it would be well for us to commit to memory the six secondary rules derived from the primary law of a debit for every credit and a credit for every debit.

Rules Relating to Debit and Credit. Of these six rules, three relate to debits and three to credits. Incidentally, it may be mentioned that the debit side of an account is always to the left and the credit side always to the right of a page or folio in the ledger.

Charge or Debit to the Accounts of	(*a*) Those persons who receive anything, the value of what they receive. (*b*) Those things which come in (as Cash, Goods, Office Furniture), the value thereof. (*c*) Losses, Expenses, and Allowances, items relating thereto.
Discharge or Credit the Accounts of	(*d*) Those persons who give anything, by the value of what they give. (*e*) Those things which go out (as Cash, Goods, Bills Payable), by the value thereof. (*f*) Profits, or sundry gains, by the items relating thereto.

Remember that three G's are credited:

1. Persons who *give.*
2. Things which *go out.*
3. Sundry *gains.*

We are now able to answer the question proposed above as to C. It was stated that he sent a cheque for £100, less $2\frac{1}{2}$% discount, or £97 10s. *net*, to X in full discharge of his indebtedness. Here are two transactions, or, rather, it is one transaction in two parts—first, the deduction of discount £2 10s.; second, the giving of a cheque for £97 10s. Take the second first. Cash goes out, therefore, by rule (*e*), cash is credited £97 10s.; and X receives cash, therefore, by rule (*a*), X is debited £97 10s.

Now for the other part of our transaction. X, by means of a printed notice on the statement of account sent to C—such as "subject to $2\frac{1}{2}$% cash discount if paid within ten days"—promises C that he will make him a present of sixpence in the pound if the whole amount of the debt is paid promptly. C avails himself of this offer, and thus makes a gain of £2 10s. By rule (*f*), some account representing profit must be credited by the amount of the item, and accordingly we post £2 10s. to credit of "Discounts Received" account. But if £2 10s is credited, a similar amount must be debited.

A Problem in Posting. It is a little puzzling at first to know where to post this debit, and the rules do not seem to throw much light on the matter. No doubt we shall speedily arrive at the conclusion that because X was a creditor for £100 for goods supplied, but has since received £97 10s. *in settlement*, there ought to be no balance at all on his account, and that by debiting £2 10s. thereto we should kill two birds with one stone, for we should get rid of an inconvenient debit, and in doing so close the account of X in C's ledger. In fact, this procedure would be perfectly correct, but it is important that we should be able to justify it by a reference to one or other of the six secondary rules above mentioned. These, when thoroughly understood, will give us every information required to enable us to record in proper debit and credit form all the multifarious transactions with which modern bookkeeping is concerned.

Let us, therefore, attack the problem from another direction.

X tells C that, on one condition, he will accept £97 10s. in settlement of the debt of £100. Why does he do this? Are we to assume that X is giving money away to C, whom perhaps he has never seen? Not at all! X is one of those men who believe that "business is business" and not a mere parlour game, and we may rest assured that he did not forgo any portion of his full "pound of flesh" or any fraction of the whole debt of £100 without receiving some advantage therefrom. What was the advantage? Surely it was the benefit derived from prompt payment.

On referring to C's account in the books of X, we find that the goods were sold on March 31st, and that C paid for them on April 8th, or less than ten days thereafter. If he had chosen to keep X waiting for his money for a month or two, paying the full amount of £100 at the end of that time, X could not have objected. But X remembers the proverb that "He gives twice who gives quickly," and it is well worth his while to offer C an inducement to pay before the actual due date. The reasons which influence business men to offer discounts and other concessions will be discussed more fully hereafter; but as to X, his impending retirement and intention to go abroad as soon as possible are sufficient grounds for his anxiety to collect with all speed the debts due to him.

PRACTICAL GEOMETRY & OBJECT DRAWING

Plain and Diagonal Scales. Scale of Chords. Sector. Application of Scales. Triangles and Quadrilaterals. A Lesson on the Cone and Cylinder

By WILLIAM R. COPE

Scales. It is often necessary to make drawings larger or smaller than the objects represented. It would be very inconvenient to draw the plan of a building full size, as it would be too large for practical use; but if it were drawn smaller, with the same ratio in all its parts, it would enable anyone to tell the relative size or proportion of all parts. To obtain these proportions correctly a scale is used. Thus, if for every foot on the building we use one inch on the drawing, the latter would be $\frac{1}{12}$ the size of the building, or we say the scale of the drawing is one inch to the foot. The $\frac{1}{12}$ is called *the representative fraction*, because it indicates the ratio each line of the drawing bears to the object represented.

There are occasions when it is advisable to make the drawing larger than the object, such as the details of the small parts of a watch, clock, and small instruments.

The simplest form of a scale is one of equal parts, and is called a *plain scale*. All scales must be constructed with very great care, and drawn with a very sharp pencil or fine pen to ensure absolute accuracy. By studying a few examples the student will soon understand their construction and use.

Plain Scales. 104. To Draw a Scale of $\frac{3}{4}$ in. to 1 ft. to Measure 6 ft. and Show Feet and Inches. Draw two parallel lines about $\frac{1}{10}$ in. apart. Set off $\frac{3}{4}$ in. six times, then each of these parts represents 1 ft. Divide the first part into 12 equal divisions, each of which will represent 1 in. When figuring and naming the parts it is important that the *zero* should be placed as shown, so that dimensions may be taken off readily with the dividers. Thus, to take off 3 ft. 8 in., place one leg of the dividers on point 3 ft. and the other on 8 in. The distance between the legs represents 3 ft. 8 in. The representative fraction is obtained thus:

$$\frac{\frac{3}{4}\text{ in.}}{1\text{ ft.}} = \frac{\frac{3}{4}\text{ in.}}{12\text{ in.}} = \frac{3}{48} = \frac{1}{16}$$

105. To Construct a Scale of $1\frac{1}{2}$ in. to 1 yd. to Measure 3 yds. and Show Yards and Feet. Draw two parallel lines as before. Set off $1\frac{1}{2}$ in. three times, and divide the first part into three equal divisions, which represent feet. Representative fraction:

$$\frac{1\frac{1}{2}\text{ in.}}{1\text{ yd.}} = \frac{\frac{3}{2}\text{ in.}}{36\text{ in.}} = \frac{3}{72} = \frac{1}{24}$$

106. Draw a Scale of $2\frac{1}{4}$ in. to 1 mile to Show Miles and Furlongs, and to Measure 2 miles. Draw two lines as before. Set off $2\frac{1}{4}$ in. twice to represent miles, and divide the first part into eight equal divisions, which represent furlongs.

Diagonal Scales. These are used when the divisions become very minute. From 107 it will be seen that the construction is based upon the principle of similar triangles. Let the rectangle *ABCD* [107] be divided into four equal parts by parallels to *AB*, and the diagonal *BD* be drawn, then a number of similar triangles will be formed. Thus the triangles *CBD* and *JBF* are similar; therefore if *BJ* is half of *BC*, then *JF* is half of *CD*; in the same way *KE* is one-quarter of *CD*. As *CD* may be as small as we like, it can be easily realised how valuable this principle is. From a *plain* scale we obtain two dimensions, such as miles and furlongs, or yards and feet; but from a *diagonal* scale we may obtain three dimensions, such as yards, feet, and inches.

108. Draw a Diagonal Scale Showing Inches, Tenths, and Hundredths of an Inch, and to Measure 4 in. Draw a line and mark off on it four separate inches. Divide the first inch into 10 equal parts for tenths of an inch, then on a perpendicular erected at 10, set off 10 equal parts to any convenient unit, and through each draw parallels to the first line. Erect perpendiculars at 0, 1, 2 and 3; join 9 and *B* and through each division for tenths of an inch draw the other diagonal lines parallel to 9*B* as shown. The distance *CD* is $\frac{1}{100}$, *EF* is $\frac{5}{100}$ of an inch, and *GH* is $2\frac{27}{100}$ in. or 2·27 in.

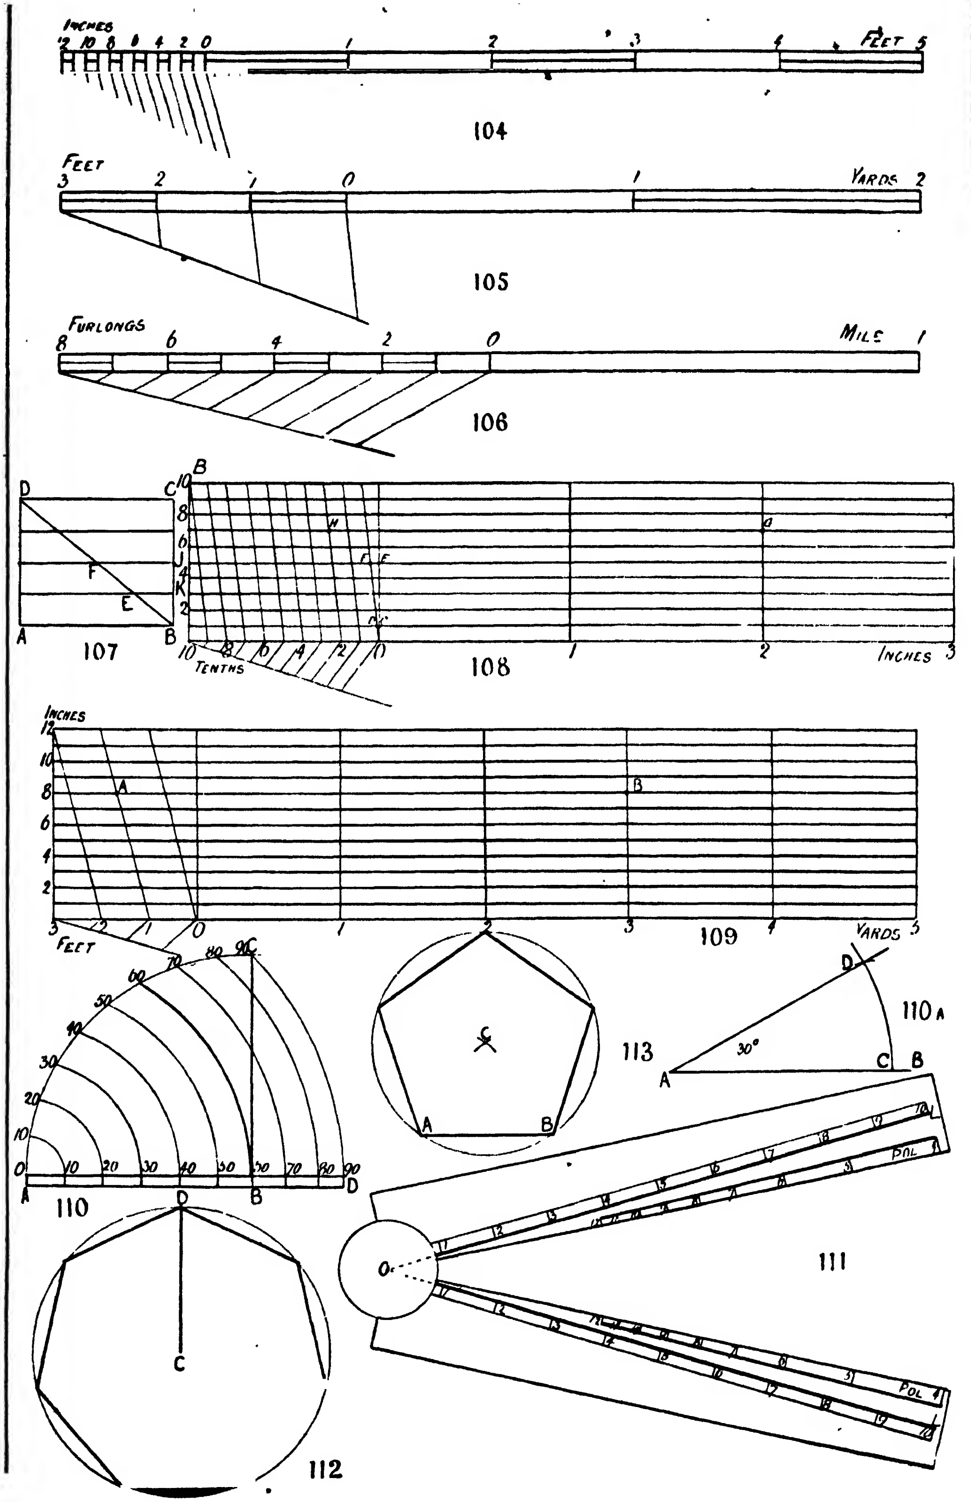
109. Draw a Scale of $\frac{1}{48}$ to Show Yards, Feet, and Inches, and to Measure 6 yds. This $\frac{1}{48}$ means $\frac{3}{4}$ in. to a yard, for $\frac{1}{48}$ of 1 yd.

$$= \frac{1}{48} \times \frac{36}{1}\text{ in.} = \frac{36}{48}\text{ in.} = \frac{3}{4}\text{ in.}$$

Draw a line, and mark on it $\frac{3}{4}$ in. six times, to represent yards. Divide the first division into three equal parts for feet. On a perpendicular erected at 3 feet set off 12 equal parts of any convenient unit, and through each part draw parallels as before. Erect perpendiculars at 0, 1, 2, 3, 4 and 5 yards. Join 2 ft. and 12 in., and draw other diagonals parallel to it. Figure and name divisions on scale as shown. *AB* represents 3 yd. 1 ft. 8 in.

Scale of Chords. This is used for measuring angles, and is marked on a ruler or protractor by the letters *CH* or *CHO*. The best way to know how to use this scale is to learn its construction.

110. Make a quadrant *ABC*. Divide the arc *AC* into nine equal parts of 10° each. The divisions 10, 20, 30, &c., on *AD* are found by taking *A* as centre with radius *A*10, *A*20, *A*30, etc., on arc *AC*, and marking them from *A* along *AD* as shown by concentric arcs. The distance from *A* to each division on *AD* is the chord of



PLAIN AND DIAGONAL SCALES. SCALE OF CHORDS. SECTOR

the angle containing that number of degrees. The divisions become smaller as they approach 90°. The distance 0 to 60 is *always* the radius of the arc to be used in making any angle.

Thus, to make an angle of 30°, draw any straight line *AB* as in **110A**. With either end, as *A*, as centre, and radius *A*60 in **110**, describe an arc *CD*. With *C* as centre and *A*30 in **110** as radius cut *CD* in *D*. Join *AD*, then *DAC* is an angle of 30°.

111. THE SECTOR. This instrument is formed of two flat legs hinged at *O*. Lines *OL* are drawn radiating from *O*, one on each leg, and are called *the line of lines*, by the use of which problems in proportion can be readily solved. There is also *the line of polygons* marked *POL*. Care must be taken to measure always from points on the lines (thick in illustration) drawn from the centre *O*. The following five problems show some of its uses.

TO BISECT A LINE. Open the sector until the transverse distance from, say, 8 to 8 on *OL* equals the given line. Then the distance from 4 to 4 is half the line.

TO DIVIDE A STRAIGHT LINE INTO FIVE EQUAL PARTS. Open the sector until the transverse distance from 5 to 5 on *OL* equals the straight line, then the distance from 1 to 1 will be $\frac{1}{5}$ of the given line.

FIND x IN THE PROPORTION $2 : x :: 5 : 2\frac{1}{4}$. With the dividers measure $2\frac{1}{4}$ in. Open the legs of the sector until the distance between 5 on *OL* of one leg and 5 on *OL* of the other is $2\frac{1}{4}$ in. Then the transverse distance between 2 and 2 on *OL* is the required distance x.

112. TO INSCRIBE A REGULAR HEPTAGON IN A CIRCLE. Open the sector until the distance from 6 to 6 on *POL* equals the radius *CD* of the circle. Then the transverse distance from 7 to 7 on *POL* is the side of the heptagon.

113. TO CONSTRUCT A REGULAR PENTAGON ON A GIVEN LINE *AB*. Open the sector until the transverse distance from 5 to 5 on *POL* equals *AB*. With *A* and *B* as centres, and the transverse distance from 6 to 6 as radius, make arcs intersecting at *C*. With centre *C* and same radius describe a circle. Set off *AB* round it.

Use of Scales. **114.** TO CONSTRUCT AN IRREGULAR POLYGON FROM A ROUGH DIAGRAM, THE DIMENSIONS ON A DIAGONAL *AE*, AND THE ORDINATES *bB*, *cC*, *dD*, etc., BEING GIVEN. *AE* = 9 ch., *Ah* = 1 ch. 30 l., *Ab* = 2 ch., *Ag* = 4 ch. 40 l., *Ac* = 6 ch. 30 l., *Af* = 6 ch. 80 l., *Ad* = 7 ch. 15 l. The ordinates *hH* = 2 ch. 60 l., *gG* = 1 ch. 25 l., *fF* = 2 ch. 20 l., *dD* = 1 ch. 60 l., *cC* = 1 ch. 10 l., and *bB* = 2 ch. 80 l. Scale, $\frac{1}{2}$ in. to 1 ch.

First construct the scale as shown. The diagonal scale is for obtaining measurements of 5, 10, or 15 l. Draw *AE*, 9 ch. long, according to scale, then set off *Ah*, *Ab*, *Ag*, &c., on it. At the points *h*, *b*, *g*, *c*, &c., erect the ordinates according to scale. Join *A*, *B*, *C*, *D*, *E*, *F*, *G* and *H*.

115. TO ENLARGE OR REDUCE A DRAWING BY A PROPORTIONAL SCALE. Say, to enlarge the given drawing of a gate, so that *AB* shall be $2\frac{1}{4}$ in. First construct the proportional scale by drawing the two lines *AB* and *Ab* at any angle with each other, making *AB* = *AB* and *Ab* = $2\frac{1}{4}$ in. Mark the several distances on small drawing on *AB*. Join *B* and *b*, and through *H*, *D*, *E*, *F*, *C* and *G* draw parallels to *Bb* as shown. Then the respective measurements along *Ab* are the required ones for the various parts for larger drawing.

116. TO ENLARGE A MAP. Make a proportional scale as before, and as shown in **116**. Set out the squares for the larger map according to enlarged scale, and then draw the map so that all parts come in corresponding positions in the larger squares to those of smaller squares.

Triangles. **117.** TO CONSTRUCT AN EQUILATERAL TRIANGLE ON A GIVEN STRAIGHT LINE *AB*. With centres *A* and *B* and *AB* as radius, describe arcs intersecting at *C*. Join *AC* and *BC*. Then *ABC* is the triangle required. (Euc. I.1.)

118. TO CONSTRUCT A TRIANGLE WITH SIDES 2.5 IN., 1.8 IN., AND 3 IN. First draw one side, say, *AB* = 3 in. as base; with *A* as centre and a radius of 2.5 in. describe an arc, and with *B* as centre and 1.8 in. as radius, describe another arc cutting the other in *C*. Join *AC* and *BC*, which complete the triangle required.

119. TO CONSTRUCT AN ISOSCELES TRIANGLE, THE BASE *AB* AND THE ALTITUDE *CD* BEING GIVEN. Bisect *AB* in *E* and at *E* erect a perpendicular, *EF*, equal to *CD*. Join *FA* and *FB*.

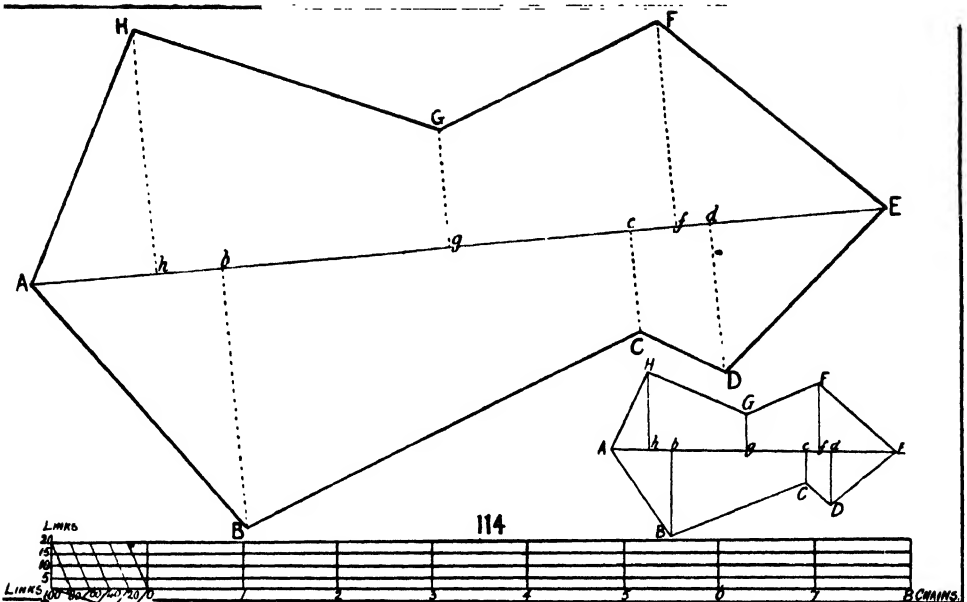
120. TO CONSTRUCT AN ISOSCELES TRIANGLE HAVING GIVEN THE VERTICAL ANGLE *CDE* AND THE BASE *AB*. With *D* as centre and any convenient radius cut off *DC* equal to *DE*. Join *CE*. At *A* and *B* make angles each equal to *ECD* or *CED*. Then *AFB* is the triangle required.

121. TO CONSTRUCT AN ISOSCELES TRIANGLE, THE VERTICAL ANGLE *C* AND THE ALTITUDE *AB* BEING GIVEN. Draw *DE* perpendicular to *AB*. Bisect the angle *C*. At *B* construct an angle. on each side of *AB* each equal to half the angle *C*. *DEB* is the required triangle.

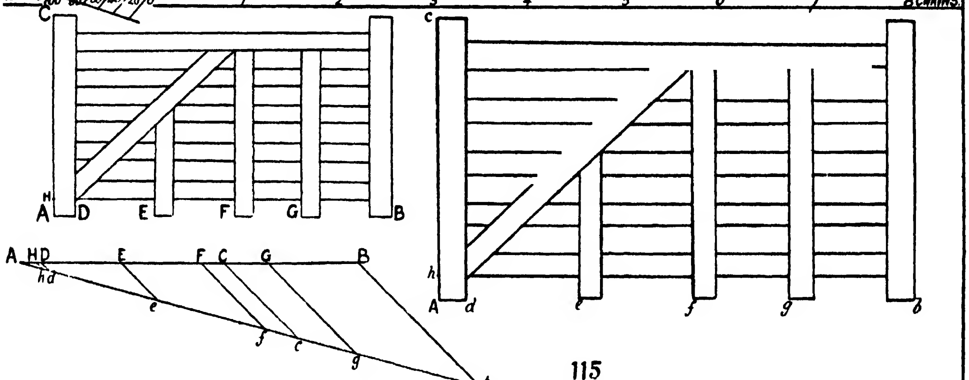
122. TO CONSTRUCT A TRIANGLE, THE BASE *AB* AND THE RATIO 2 : 4 : 3 OF THE ANGLES BEING GIVEN. Produce *AB* any length. With *A* or *B* as centre, describe a semicircle and divide it into nine equal parts (2 + 4 + 3). Draw *AC* through 2. Join *A*4. Through *B* draw *BC* parallel to *A*4, meeting *AC* in *C*. *ABC* is the triangle required.

123. TO CONSTRUCT A RIGHT-ANGLED TRIANGLE THE BASE *GH* AND HYPOTENUSE *CD* BEING GIVEN. Take a line *AF* equal to *CD* as diameter, and bisect it in *E*. With *E* as centre, describe a semicircle *FBA*. With *A* as centre and *GH* as radius, cut the semicircle in *B*. Join *BF* and *AB*. *ABF* is the triangle required, with the right angle at *B*. (Euc. III. 31.)

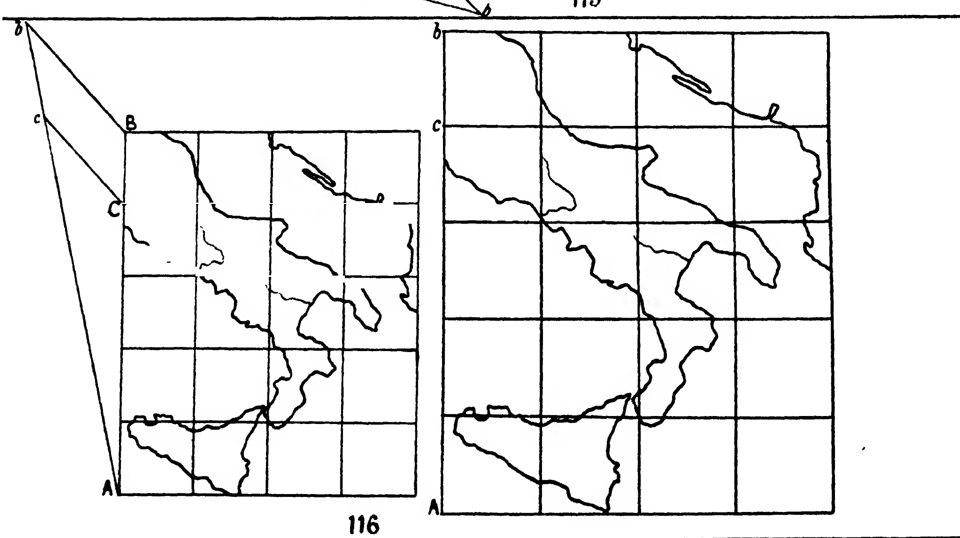
124. TO CONSTRUCT A RIGHT-ANGLED TRIANGLE, THE HYPOTENUSE *AB* AND AN ACUTE ANGLE *C* BEING GIVEN. Bisect *AB* in *D*. With *D* as centre describe a semicircle on *AB*. At *A* construct an angle *BAE* equal to *C*. Join



114



115



116

APPLICATION OF PLAIN AND PROPORTIONAL SCALES

BE. *ABE* is the triangle required. (Euc. III. 31.)

125. On a Given Base *AB*, to Construct a Triangle similar to a Given Triangle *CDE*. Make the angles at *A* and *B* respectively equal to those at *C* and *D*. Then *ABF* is the triangle required.

126. To Construct a Triangle, the Altitude *CD* and the Base Angles *A* and *B* being Given. Through *C* and *D* draw lines *EF* and *GH* perpendicular to *CD*. At *C* make the angle *ECG* equal to *A* and *FCH* equal to *B*. *CGH* is the triangle required.

127. To Construct a Triangle, the Base *AB* 1.75 in. Long, the Vertical Angle *C* 30°, and the Altitude 1.5 in. being Given. Bisect *AB* in *D*, and erect a perpendicular at *D*. At either end of *AB* make an angle of 60° (90°—angle *C*, 30°), intersecting the perpendicular at *E*. With centre *E* and adius *EA* draw the arc *ABFG*. Draw *FG* parallel to *AB* and 1.5 in. from it. Join *FA* and *FB*. *ABF* is the triangle required. The angle at the centre is always twice the angle at the circumference; thus, the angle *AEB* is twice the angle *AFB*. (Euc. II. 20.)

128. To Construct a Triangle whose Perimeter shall be equal to a Given Line *AB*, and the Sides in the Proportion 2 : 3 : 4. Divide *AB* in the proportion 2 : 3 : 4 as shown. With *D* and *C* as centres, and *DA* and *CB* as radii respectively, describe arcs intersecting at *E*. Join *DE* and *CE*. Then *EDC* is triangle required.

129. To Construct a Triangle, the Base *AB*, the Sum *CD* of the other Two Sides, and One of the Base Angles *E* being Given. A *B* make an angl *ABF* equal to *E*. Make *BF* equal to *CD*. Join *FA* and bisect it by the perpendicular *GH* cutting *FB* in *H*. *ABH* is the triangle required.

Quadrilaterals. **130.** To Construct a Square, the Side *AB* being Given. At *A* and *B* erect the perpendiculars *AD* and *BC* respectively, each equal to *AB*. Join *CD*.

131. To Construct a Square, the Diagonal *AB* being Given. Bisect *AB* by the perpendicular *CD*. With centre *E* and radius *EA*, describe a circle cutting *CD* in *C* and *D*. Draw *AD*, *DB*, *BC* and *CA*.

132. To Construct an Oblong or Rectangle, the Two Sides *AB* and *CD* being Given. At *A* and *B* erect the perpendiculars *AF* and *BE* respectively, each equal to *CD*. Join *EF*.

133. To Construct an Oblong, the Diagonal *AB* and One Side *CD* being Given. Bisect *AB* in *E*. With centre *E* and radius *EA* describe a circle. With centres *A* and *B* and radius *CD* cut the circle in *G* and *H* on opposite sides of *AB*. Join *AG*, *GB*, *BH*, and *HA*.

134. To Construct a Rhombus, the Side *AB* and One of the Angles *C* being Given. At *A* make an angle equal to *C*, and make *AE* equal to *AB*. With centres *B* and *E* and radius *AB* describe arcs intersecting at *D*. Join *BD* and *ED*.

135. To Construct a Rhombus, the Diagonal *AB* and One Side *CD* being Given. With centres *A* and *B* and radius *CD* describe arcs intersecting at *E* and *F*. Join *AE*, *EB*, *BF*, and *FA*.

136. To Construct a Rhomboid, the Two Sides *AB*, *CD*, and an Angle *E* being Given. Draw *FG* equal to *CD*. At *F* make an angle equal to *E*. Make *FJ* equal to *AB*. Through *J* draw *JH* parallel to *FG*, and through *G* draw *GH* parallel to *FJ*, cutting *JH* in *H*.

137. To Construct a Rhomboid, the Diagonal *EF* and the Two Sides *AB* and *CD* being Given. With centres *E* and *F* and radius *AB* describe arcs on opposite sides of *EF*. With the same centres and radius *CD*, describe arcs on opposite sides of *EF* intersecting the first arcs in *G* and *H* respectively. Join *EG*, *GF*, *FH*, and *HE*.

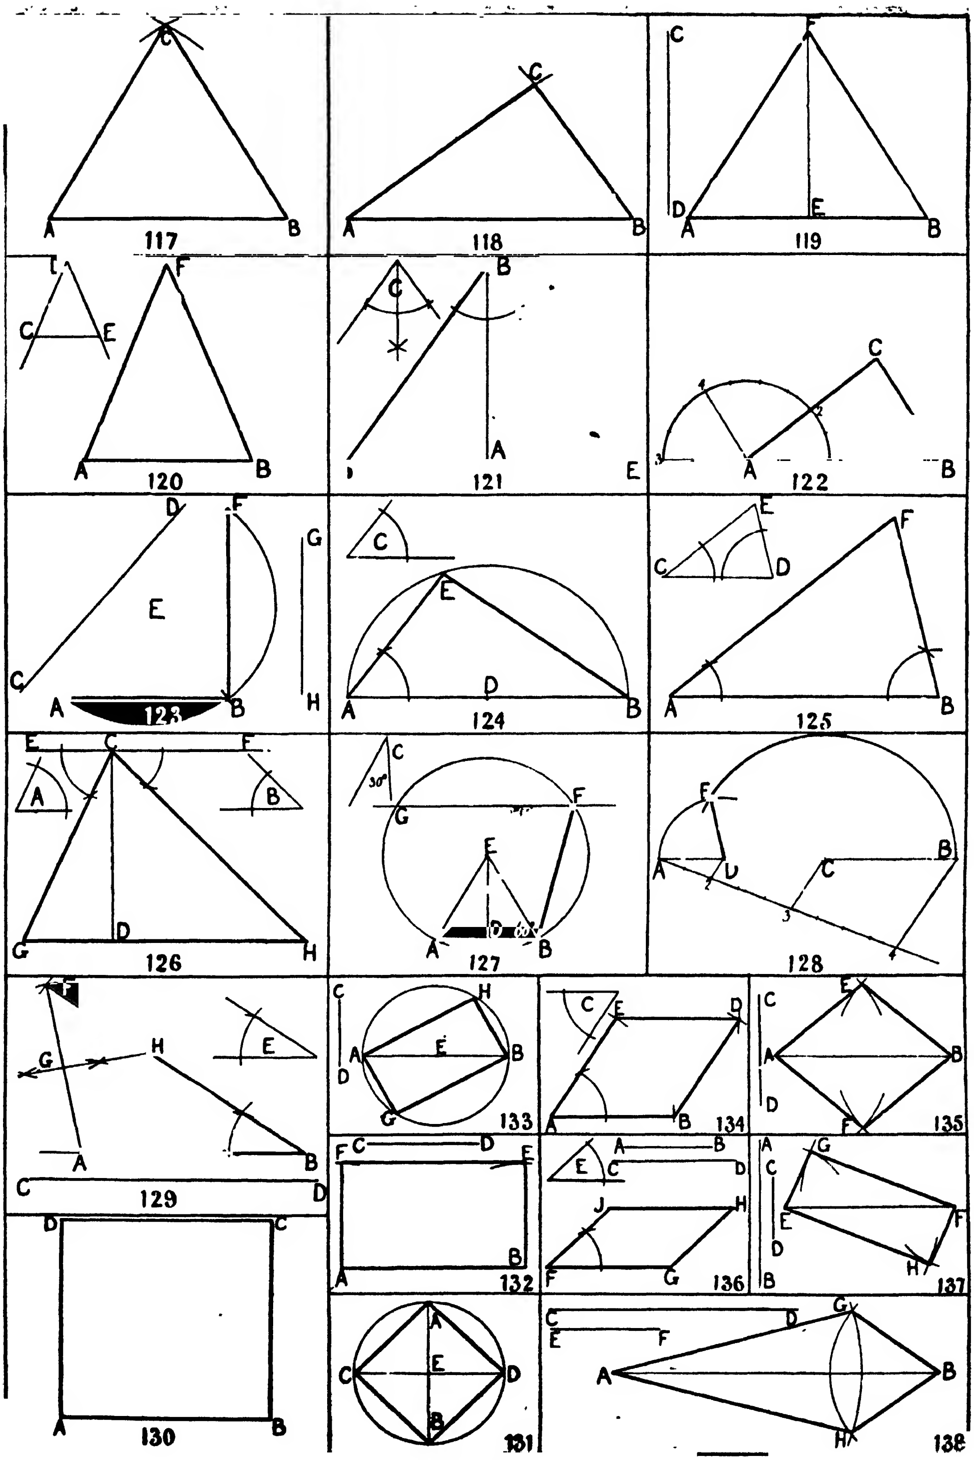
138. To Construct a Trapezium, the Diagonal *AB* and Two Pairs of Equal Sides *CF* ahd *EF* being Given. With centre *A* and radius *CD* describe an arc. With centre *B* and radius *EF* describe another arc intersecting the first in *G* and *H*. Join *AG*, *GB*, *BH*, and *HA*.

MODEL OR OBJECT DRAWING

In this part we shall explain how to draw conical and cylindrical-shaped objects. It is necessary that great attention should be given to the very important principles underlying the representation of the many thousands of such curved objects. More errors are made by beginners in drawing them than perhaps any other shapes.

The different appearances of a circle have already been explained [See **17**], so now let us take a simple one as our model. This object, like all others, may have an infinite number of apparent shapes, some of which are shown in **139–144**. To understand the fundamental principles of drawing such an object, let us imagine there is a line, called *the axis of the object*, passing through the middle of the cone from the apex to the centre of the base (*AB* in **139**), and another line, *CD*, called *the major axis of the ellipse*, along the surface of the base. It will be noticed that these two lines are at *right angles* to each other, and they *always* appear so, no matter in what position the cone may be placed. [See **139–144**.] From this we deduce the following very important rule: *The major axis of the ellipse always appears to be at right angles to the axis of the object.* This rule holds good, not only for the cone, but for the cylinder and all other similar shaped objects, such as tumblers, flower-pots, pails, jars, bottles, vases, barrels, etc. [See **145–160**.]

The Cone. It is sometimes difficult to see that this is so, but the student must endeavour to train his eye to see this fact by careful observation and comparison. It is as essential to remember it as carefully as the rule that receding parallel lines appear to converge. A great help at this stage would be to get a cone (or, if this be unavailable, a large funnel would do), place it in such positions as indicated in **139–144**, and endeavour to see that the rule holds good *always*.



TRIANGLES AND QUADRILATERALS

Fig. 139 is a view of the cone when standing upright with its base below the eye level, but 140 is the appearance when the base AB is level with the eye. Here, again, the outline alone does not represent the roundness of the cone, but if it were shaded, as was done in 30, it would appear round. Fig. 141 is a view of the cone lying down with its apex turned away from the spectator, while 142 is the apparent shape when the apex is towards him.

Fig. 143 shows the appearance when the cone is tilted with the edge of the base resting on a horizontal plane, and the apex raised and turned away from the observer. Notice how very much the length is foreshortened. Fig. 144 shows the cone lying down on a horizontal plane with its apex pointing directly towards the student. In 142 and 144, although the base is turned away from view, yet we see more than half the ellipse.

It is generally best to commence drawing the cone by sketching the straight lines CA, CB in 141 and 143, noting carefully the slant of each; then draw the axis CD of the object, which bisects the angle BCA, next determine the position of the point D, by observing what the apparent length of CD is, and afterwards draw through D the major axis EF of the ellipse *perpendicular* to CD, comparing its length with CD. Then obtain the apparent length of the minor axis GH, thus obtaining the four points F, H, E, G, through which the ellipse should be drawn. It must be noticed that CA, CB do not necessarily intersect the ends of the major axis at E and F, but they are *always tangents to the curve of the ellipse*.

The Cylinder. After all this explanation concerning the cone, the drawing of the cylinder should not give a great deal of trouble. It will be seen in 145–150 that in every case the major axes of the ellipses are perpendicular to the axis of the object. But there is another very important observation to be made, and that is, the ellipses at each end are not exactly of the same shape. With an opaque object this difference is difficult to realise; but if the student makes a study of an object like that represented in 152 (which is constructed of two circular and equal pieces of stiff cardboard, with their centres joined by a piece of wood or stiff wire, so that the circles are kept rigidly parallel to each other, and perpendicular to the wood or wire), he will easily be convinced, by measuring with the eye and a pencil, that the further ellipse is *apparently rounder*, or more like a circle, than the nearer one is; the major axis of the further ellipse is a little shorter than that of the nearer one, while the minor axis of the further ellipse is (within certain limits) longer than that of the nearer one.

Commence to draw the cylinder by sketching the straight lines AB and CD [See 148], and before doing so, three facts must be observed: First, what slant AB and CD make with the surrounding objects; secondly, what distance apart they must be in order to obtain the correct relative thickness of the cylinder; and, thirdly, the right amount of convergence, since they recede. Next draw the axis EF, and afterwards proceed as with the cone, but bearing in mind the apparent different shapes of the ellipses. The straight lines which are part of the drawing of the cone or cylinder do not represent *edges*, but the boundary between the visible and the invisible portion of the curved surface of each object. This well illustrates how conventional *outline* drawing is.

Fig. 145 is the appearance of the cylinder in a vertical position below the eye level. Notice the different distances from front to back of the top and bottom ellipses. Fig. 146 shows the view when upright, but the eye directly opposite point A. Fig. 147 is the representation when the cylinder is lying on a horizontal plane, and the eye is directly opposite the left-hand edge. Fig. 148 gives the appearance when the object is lying in a horizontal plane but slanting away from the observer. Fig. 149 is an end view with the length very much foreshortened. Fig. 150, when resting on one edge, and the further end tilted up away from the student. In 151 is shown a very common error in drawing the cone when in the position shown in 141. It should be noticed that in 151 the major axis of the ellipse is not at right angles to the axis of the object, as it ought to be. Fig. 153 is an incorrect drawing of the cylinder, and shows two common mistakes, viz., the major axes of the ellipses are not perpendicular to the axis of the object, and the further ellipse is not wide enough. Fig. 153 ought to be drawn as in 148. In the wrong drawing [153] the major axes are vertical, and students may at first think that they ought to be so because the ends of the cylinder are really vertical planes; *but it does not follow that, because the ends are vertical, the apparent longest axis of the ellipse is vertical.* If the student will make searching observation of the object, he will see that the *apparent longest direction* of the ellipse is *slanting*, as shown in 148.

Useful Exercises. Good exercises at this stage would be to make studies of groups as shown in 154, and give most careful and searching observation to the proportion and perspective of the objects, in order to still further improve the power of *seeing correctly*. *Do not forget the spaces.*

EMPIRES OF THE EAST

History of Assyria—continued. Semiramis, Sardanapalus, and Nebuchadnezzar. Phœnicia and its Fleets. The Medes and Persians

By JUSTIN McCARTHY

A Famous Queen. One of the later Assyrian rulers was the consort of the famous Queen Semiramis, and Semiramis at his death became Sovereign of Assyria. To her was due the enlargement of Babylon, the construction of quays and great hanging gardens, and the protection of the city by a broad surrounding wall more than 40 miles in circuit. The last ruler of this Assyrian Empire was Sardanapalus, who has been made a frequent figure in the romance and poetry of many a modern nation down to the days of Lord Byron, whose famous tragedy is still sometimes presented on the English stage. He led, according to some traditional and possibly romantic accounts, a life at once effeminate and tyrannical, and provoked a rebellion among his Median subjects. The rebels at last conquered and imprisoned Sardanapalus in the capital. Sardanapalus refused to surrender, and rallying his remaining energies for one last and desperate resolve, he made elaborate preparations for a dramatic death. He had a funeral pyre prepared for him—the funeral pyre devoted in those days to receive the dead body of some great personage—and into its flames he flung himself alive, and there finished an inglorious career by a spectacular suicide.

Nearly two centuries after this event, some narratives tell us that another Assyrian king, who found himself unable to hold his throne against a coalition of the Babylonians and the Medes, sacrificed himself, after the example of Sardanapalus, on a funeral pyre, and the conquerors, becoming masters of Nineveh, destroyed the city altogether. Nineveh and all its monumental memorials were lost to the world for many centuries, and there was no actual certainty as to where its site had been. Even its ruins seemed to have passed away. Modern discovery, however, penetrating beneath the surface of the earth, found monuments, sculptures, and inscriptions enough to secure for the lost capital its place in the history of the world.

Modern Discoveries. Paul Emile Botta, a Frenchman by birth and bringing-up, the son of an Italian poet and historian, was endowed with a genius for archæological research and discovery. In 1843, within the memory of living men, he set himself to explore the site of Nineveh, and he discovered evidences enough beneath the earth, in monuments, figures, and inscriptions, to justify all that had been said about the arts, the civilisation, and the history of the long-lost city.

A little later Sir Austen Henry Layard made larger and more complete excavations through the region which had once known the great city, and there found the remains of four palaces. In one of these palaces, that supposed to have been erected by Sardanapalus, he discovered monuments adorned with bas-reliefs and cuneiform inscriptions, and some enormous images of human-headed and sometimes winged bulls and lions. He published " Nineveh and its Remains" in 1843, and " Monuments of Nineveh " in 1850. Botta sent his discoveries to the Louvre in Paris, and Layard sent his to the British Museum. Layard, who died in 1894, played an important part in English political life and in diplomacy, but his place in the world's history and the enduring celebrity of his name will be made for him by the triumphs he accomplished in helping, with such marvellous success, to restore the lost city of Nineveh to its secure place in human recollection. Other and more recent explorers have added, and we may be sure will still add, to his work; but we of these days may remember with complacency that the long-buried Nineveh was re-created by the genius, the energy, and the good fortune of men who belonged to our own time.

Nebuchadnezzar's Achievements. We must now return to the closing days of the Assyrian Empire. Babylon became the capital of Assyria after the destruction of Nineveh. Nebuchadnezzar recovered many of the lost provinces of Assyria, restored the ruined parts of Babylon, and restored also many of the temples throughout the whole land. Modern explorers have found many monuments which are themselves records of his successes, and records also of the destruction he inflicted on conquered enemies. He destroyed Jerusalem nearly 600 years before the Christian era, and he endowed Babylon with many magnificent trophies of his conquests and his captures.

But the great days of Assyria were coming to an end. The fame of the country and the conquering expeditions made by some of its kings had naturally begun to create powerful enemies outside its frontier lines and to tempt invasion. The Persian invaders under Cyrus, then king, besieged Babylon and captured it. Cyrus did not destroy the city he had taken, but made it his capital. The life and the exploits of Cyrus have been described by many Greek historians, but these histories are for the most part fanciful and even mythological relics of old-time hearsay supplemented by a good deal of guesswork, and have suffered much disparagement from the practical discoveries of modern days. It is certain that Cyrus became the most powerful of Asiatic sovereigns in his time, and that he adopted a policy, rare in those far-off days, and rare, indeed, in modern days, a policy of conciliation towards the differing religious faiths and practices of the races who had come under his rule.

The era of the Assyrian Empire thus came to an end. During her ages of independence Assyria made a deep mark on the history of Asia. Her system of government was somewhat advanced for an Asiatic despotism at that early stage of the world's progress. The sovereign of Assyria, like other Oriental sovereigns, was regarded as the absolute master over the lives and properties of all his subjects, but the king was not worshipped as a divinity, nor were there any castes in recognised existence—there was not even any system of sanctified or specially recognised classes among the subjects of the monarchy.

Many Gods. The religion of the Assyrians appears to have recognised the idea of one supreme divinity, Assur, but there were also many other divinities, including the nature triad, Anu, Bel, and Hea, and the celestial triad, Sin, Shamas, and Istar, and to these, too, worship was always offered. The sun-god was one of the highest of the deities, and to him high homage was paid and the adoration of the stars made a part of the national religion. There were also some minor divinities. The Assyrian priests were closely engaged in the study of astronomy, as it was known to their observation, and it is even said that the first regularly arranged and ordered system of astronomy and the measurement of time by the movement of the planets is due to their observation of the changes taking place in the position of the heavenly bodies. The Assyrians, or at least the less educated classes among them, had bird-gods and fish-gods and other divinities representing the various forces of nature. The inhabitants were very industrious, and were especially skilful in agriculture and commerce, in the making of carpets, textile fabrics, and ornaments of gold. We have already spoken of their remarkable skill in the sculptor's art, and the Greeks themselves derived some inspiration from Assyrian monuments and carved figures. Assyria may be described as one of the brightest constellations which our world could show in this dawn of its history.

Early Traders. The Phœnicians come next in the order of our narrative. Phœnicia was a country on the sea-coast of Selia in Western Asia, and its people were among the first, the most venturous, and the most successful navigators known to antiquity. As far back as twenty centuries before the Christian era the Phœnicians had been establishing colonies along the shores of the Mediterranean and in its islands. They are believed to have pushed their explorings even farther, and there is some substantial evidence to show that they visited Great Britain and Ireland. Among their principal cities were Sidon, Tyre, and Acre. The Phœnicians had, in the earliest days of which we can trace any evidence, been wanderers in search of a suitable settlement, and had established themselves in the region afterwards made famous by their name. The physical conditions of their settlement were in themselves an incitement and an assistance, for they had the sea in front of them and great mountain ranges behind them, in which mountain ranges were ancient forests offering ready material for the building of ships. The inhabited country thus became very prosperous, cities were founded and soon multiplied, and the populations greatly increased.

After a while the Phœnicians found it necessary to plant colonies elsewhere, partly to relieve the overcrowding of the home region, and partly with the object of spreading their commerce and adding to their revenues. They established themselves in the Ægean Islands long before the time of the Greeks, they sent their emigrants to establish commercial enterprises in Africa, Spain, Italy, and France, and at one time they had founded three cities in Sicily alone. Carthage, which played so important and powerful a part in history, was founded by Phœnician enterprise on the African coast.

The Wealth of Phœnicia. The Phœnicians compelled the Hebrews to yield to them two ports on the Red Sea, from which their fleets incessantly went forth on the quest for ivory and gold dust in the famous land of Ophir, spices in Arabia, pearls in the Persian Gulf, and all manner of valuable products in the Indian region. The Phœnician caravans went through Persia, Arabia, and Thibet, and brought back the silks of China, the furs of Tartary, and the jewels of India. The flourishing commerce of Phœnicia soon had the effect to be expected in those days, and in much later days, and it tempted the cupidity of invaders. The Pharaoh sovereigns were among the conquering invaders. Tyre was captured by many successive conquerors, and was reduced almost to absolute ruin by Alexander the Great.

Phœnicia had by this time lost her place among the ruling empires of the East, but she had the happy faculty of taking from her conquerors much that they had to give of art, industry, and science. Thus she obtained from Babylon a metric system, and got from Memphis the principle of alphabetical writing, which came to be adopted in one form or another by all the civilised peoples of the world. The story of the Phœnicians is in many of its characteristics a narrative of the earliest development of scientific education and of organised commerce. The Phœnician religion appears, like that of many other nations, to have begun as monotheism and to have degenerated into polytheism. Some of the best known names of their deities are Baal, Astoreth, Rimmon, and Molech. The Phœnicians were very religious, and carried their faith with them everywhere.

Medes and Persians. The Medes and Persians played a very important part in early history. They belonged to the race known as Aryan, and were made up of fair-skinned tribes which had found a settlement in the region of the Indus, and of the Iranians, who made their home in Media and in Persia. The separation of this race into two divisions is generally believed to have been caused by a difference as to religious belief. Both alike regarded Zoroaster as their great legislator, whose teachings are enshrined in the Avesta, the Persian sacred book.

Lofty Teachings. The principle of those teachings appears to have been considerably in advance of that of other polytheistic creeds. The central idea was that of a strife continually going on between the spirit of good and the spirit of evil. The spirit of good typifies the highest principle of life, and has for its emblem the sun, which was regarded as the type of all light and all progress towards happiness ; while the spirit of evil represented the whole combined forces which tend to the moral and physical degradation of man.

These two rival spirits had around each of them a vast and even infinite number of spiritual followers, a complete hierarchy, each struggling unceasingly to make its chief the ruling power over all. The divinities of good were believed to labour incessantly to teach man how to make his life all light, virtue, and progress towards happiness here and hereafter, while the evil spirits were occupying themselves in endeavouring to thwart man's progress towards good and to bring upon the earth all manner of demoralising influences and even all manner of destructive animal creatures. But this creed always accepted as an immutable end the ultimate triumph of good over evil, and it even went so far as to make it the consecrated belief that in the end the deity, who typified the spirit which the modern world regards as that of the Supreme Creator, was not only to conquer but even to pardon the enemies who had so long set themselves against his divine will. The goodness of the Creator was declared to be eternal as to time and limitless in its application, and even those worst of beings who incessantly and deliberately endeavoured to defeat his benign purposes were after a time to be called to redemption and enabled to enjoy the pure delights of heaven, and all the misled wicked ones of earth whom the influence of the demons had corrupted were also to attain redemption.

Zoroastrianism. The Persian heaven was a very exalted creation of mortal thought and feeling at such an early stage of the world's growth, and the Eastern races in general have not developed a higher ideal down to the present day. Zoroaster may be regarded as the founder of this reformed Persian faith which succeeded the creed adopted up to his time. The name of Zoroaster is but an ancient Greek modification of its Persian form, which has long since dropped out of European use. There is but little definitely known as to the period when he lived and taught, but it would appear that it cannot be assigned to any date later than 800 years B.C., and that it may even have belonged to a considerably earlier time. The teachings of Zoroaster insisted on faith as necessary to salvation, but also demanded good works. These teachings did not glorify or even recommend mere asceticism where the asceticism had no purpose for the general good of humanity, but taught that man's earthly career was in itself a sacred thing, and that work with a high purpose might be made as holy as prayer. Every religious service required prayers and an offering, and the prayer often was a confession of sin and a plea for mercy.

The exalted character and the pure form of worship which belonged to this people did not prevent their rulers and them from causing many troubles and disturbances in those parts of the world which were accessible for invasion and conquest, and we shall have to refer many times in the course of this history to some of the calamities which Persian sovereigns brought on the lands which they were eager to subjugate.

The Medes. We only begin to have anything like an authentic account of the Medes from the records and monuments of the seventh century before the Christian era. The Medes were an Aryan people, and followers of the faith of Zoroaster. Somewhere about that period Arbaces governed Media as an Assyrian province. Although a representative of the Assyrian king, he was led to revolt against Sardanapalus, and his rebellion proved unexpectedly successful. The Medes were now free from foreign rule, but their first enjoyment of freedom displayed itself for a considerable time in something like anarchy.

The right man appears to have come at the right time. This man was Dejoces, who obtained great influence over the people, and reigned for more than half a century, during which his people had a period of absolute peace and of growing prosperity. This era of peace did not last long. The son and successor of the Median sovereign made war against the Persians, and was himself killed by a king of Nineveh. The son of the slain sovereign sought to take vengeance by attacking the city of Nineveh, and the city was rescued only by an invasion of the Scythian race. The Scythians were at that time a barbaric people, and for more than half a century they made themselves known throughout Western Asia by their invasions and rapine.

The Banquet of Death. The story is told that the Median sovereign Cyaxares disposed of the Scythian chiefs by inviting them to a great banquet, during which the chief of the foreign guests were put to death and their followers expelled. That same Median sovereign afterwards captured Nineveh and reduced to subjection a large extent of Asia Minor. Lord Byron, in one of his Hebrew Melodies, has vividly commemorated the destructive powers of the Medes and Persians. The poet describes to us a great festival held at the court of Belshazzar, and tells how, at the high moment of the feast, the fingers of a hand were seen to write some letters on the wall. The King insisted on the meaning of the written words being revealed to him, but the wisest of his advisers were unable to decipher the inscription. One interpreter, however, presented himself—Daniel the Prophet. He was able to read the lines and expound their meaning, and they predicted the ruin and the death of the monarch. The closing lines of the poem foretell the fate and the ruin of Belshazzar, and predict his immediate death.

The Medes may be said to pass out of history when their separate dominion passed away, and they became absorbed into the domain of Persia.

THE WARFARE OF PLANT LIFE

The Struggle for Existence. How Plants Compete for Food and Light. Parasites. Plants that Feed upon Insects

By Professor J. R. AINSWORTH DAVIS

Naked-seeded Plants. We shall have occasion to mention some of these plants (*Gymnosperms*) in various connections; a few general remarks about them here will, therefore, be appropriate. As already mentioned, the ovules are not enclosed in an ovary, so that the pollen grains fall directly upon them, and there is no need for long pollen-tubes, as in pod-plants (*Angiosperms*), where the pollen grains fall upon a stigma.

The groups of Gymnosperms are three in number: (1) Switch-plants, etc. (*Gnetaceæ*); (2) Cone-bearers (*Coniferæ*): and (3) Cycads (*Cycadaceæ*).

Switch-plant Family (*Gnetaceæ*). The switch-plants (*Ephedra*), together with two other genera, make up a small family of somewhat peculiar forms, limited to the hotter parts of the globe. They present an approach to the pod-plants in the fact that their small flowers possess a perianth, and in this respect are more specialised than those of other gymnosperms.

Cone-bearers (*Coniferæ*). The great majority of gymnosperms belong here, familiar examples being monkey-puzzle (*Araucaria*), pine-trees (*Pinus*), firs (*Abies* and *Picea*), cedar (*Cedrus*), larch (*Larix*), cypress (*Cupressus*), juniper (*Juniperus*), yew (*Taxus*), and others. Many are forest-trees of considerable or great size, and in some parts of the world may cover large areas, as, *e.g.*, in the cooler parts of the Northern hemisphere. Among them are the gigantic Wellingtonia (*Sequoia gigantea*) and redwood (*S. sempervirens*) of North America. The former may attain a height of over 460 feet, exceeding every other known tree in this respect, though a species of eucalyptus is a good second (over 422 feet). The circumference of a Wellingtonia trunk may be as much as 112 feet, but this is exceeded by several other forms, sweet chestnut heading the list with 204 feet.

The resinous timber of various cone-bearers, the "soft woods" of forestry, is of immense economic importance.

Most members of the group are evergreen, with tough, leathery leaves, which, as a general rule, are either needle-shaped or resemble scales. The simple flowers are of two kinds, male and female, which in nearly all cases are in the form of cones, and possess no perianth [66].

Cycads. These are a small group (*Cycadaceæ*) of comparatively lowly forms, which in past geological times were very numerous and widely distributed, but have since been supplanted by higher types. They are limited to the hotter parts of the globe, especially Central America and Australia. A cycad is not unlike a palm in appearance, but usually with a much shorter trunk [67]. There are male and female cones, as in the last group.

THE STRUGGLE FOR EXISTENCE

We now come to the most fascinating part of botany, which deals with the relation between form and structure on the one hand, and the mode of life on the other. The constant struggle for existence which has taken place for countless ages, has led to the evolution of innumerable devices for the maintenance of the life of the individual and the perpetuation of the species.

Competition for Food and Light. We have already seen that food is largely taken up by roots from the soil, but, as the supply is limited, a plant is obliged to struggle vigorously to obtain its due share, and failure spells death. *Shallow-rooted* forms do their best to extract nutriment from the surface layers, and we may convince ourselves of the keenness of the competition in these layers by examining the under-side of a piece of turf, when we shall find innumerable pale rootlets tangled together in inextricable confusion. By sowing an assortment of grass seeds in a prepared patch of ground, we shall ultimately find that certain forms soon get the better of others, very largely owing to the possession of more numerous and more vigorous roots.

Deep-rooted plants mainly rely upon the water with dissolved salts to be found at some distance from the surface. The roots of many desert and shore plants are obliged to penetrate for an astonishing depth before they get what they require. In sand-sedge (*Carex arenaria*) and sea-holly (*Eryngium*), for example, a vertical length of some 48 ft. may be attained; while in some of the plants which live in the African deserts the roots may be twenty times as long as the parts above ground.

Fungi which Help Roots. The roots of most forest-trees and some other plants are invested in a close sheath of delicate threads (*mycorhiza*), which belong to the group (fungi) in which toadstools and moulds are included. These threads are closely connected with the roots, and may penetrate more or less into them [68]. We have here what is probably a mutual benefit association between tree and fungus. At any rate, the latter provides the former with some of the nitrogen-containing food which it requires, though it is doubtful how far a return is made for this.

A much clearer case of mutual benefit is afforded by leguminous plants, such as peas, beans, and the like. If the roots of one of these

are examined, a number of little swellings, or nodules, will be found here and there [69], which contain a large number of minute fungi, probably to be regarded as bacteria. These are provided with a sheltered home, and no doubt absorb some of their food from the root in which they live, but not to an injurious extent, though th nodules in which they live are the result of abnormal growth set up as a result of the irritation caused by their presence.

How a Plant Enriches the Soil. The benefit conferred by these microscopic plants on their large associates is very considerable. As we have already seen, nitrogen is an absolutely essential element in plant-food, and this, in the uncombined gaseous form, constitutes the greater part of the air, including, of course, that which is present in the soil. A green plant, however, is incapable of using this free nitrogen as food, for which purpose it must be combined with other elements to form *nitrates*. But the microscopic fungi in the nodules are able to cause the free nitrogen of the air in the soil to enter into combination, so as to form these very nitrates which are of such importance for the life of the leguminous plant.

Hence we see the desirability of including clover, or some other leguminous form, in a rotation of crops, for the arrangement described renders it unnecessary to apply expensive manures for the sake of the nitrogen they contain. Not only does such a plant cater for itself in this matter—or rather, is catered for by its fungus friend—but it actually leaves the soil enriched with nitrates for the benefit of the succeeding crop.

Competition Between Leaves. As leaves absorb from air the carbon dioxide which constitutes an essential part of plant-food, it is clear that the competition above ground for this must be as keen as the competition below ground for food of other kind. But here the matter is complicated by the fact that the leaves build up the simple nutriment of the plant into complex organic substances, and this can only be done by aid of the characteristic green colouring matter *chlorophyll*, which can only work in the light. Hence leaves have to compete for light as well as food.

Many plants adopt the bold policy of growing vertically upwards in the search for food and light. This is naturally carried to an extreme in forms which live for a number of years—*i.e.*, perennials. As we have seen, certain trees attain an enormous height, and in those which are either Dicotyledons or Gymnosperms the trunk thickens by annual additions of wood to the exterior, thus providing support to the increasing mass of foliage, while, at the same time, the root-system is correspondingly enlarged. The age attained by some of these trees is prodigious, a few of the best authenticated cases being as follows: cypress and yew, 3,000 years; sweet chestnut, oak, and cedar of Lebanon, 2,000; spruce, 1,200; lime, 1,000.

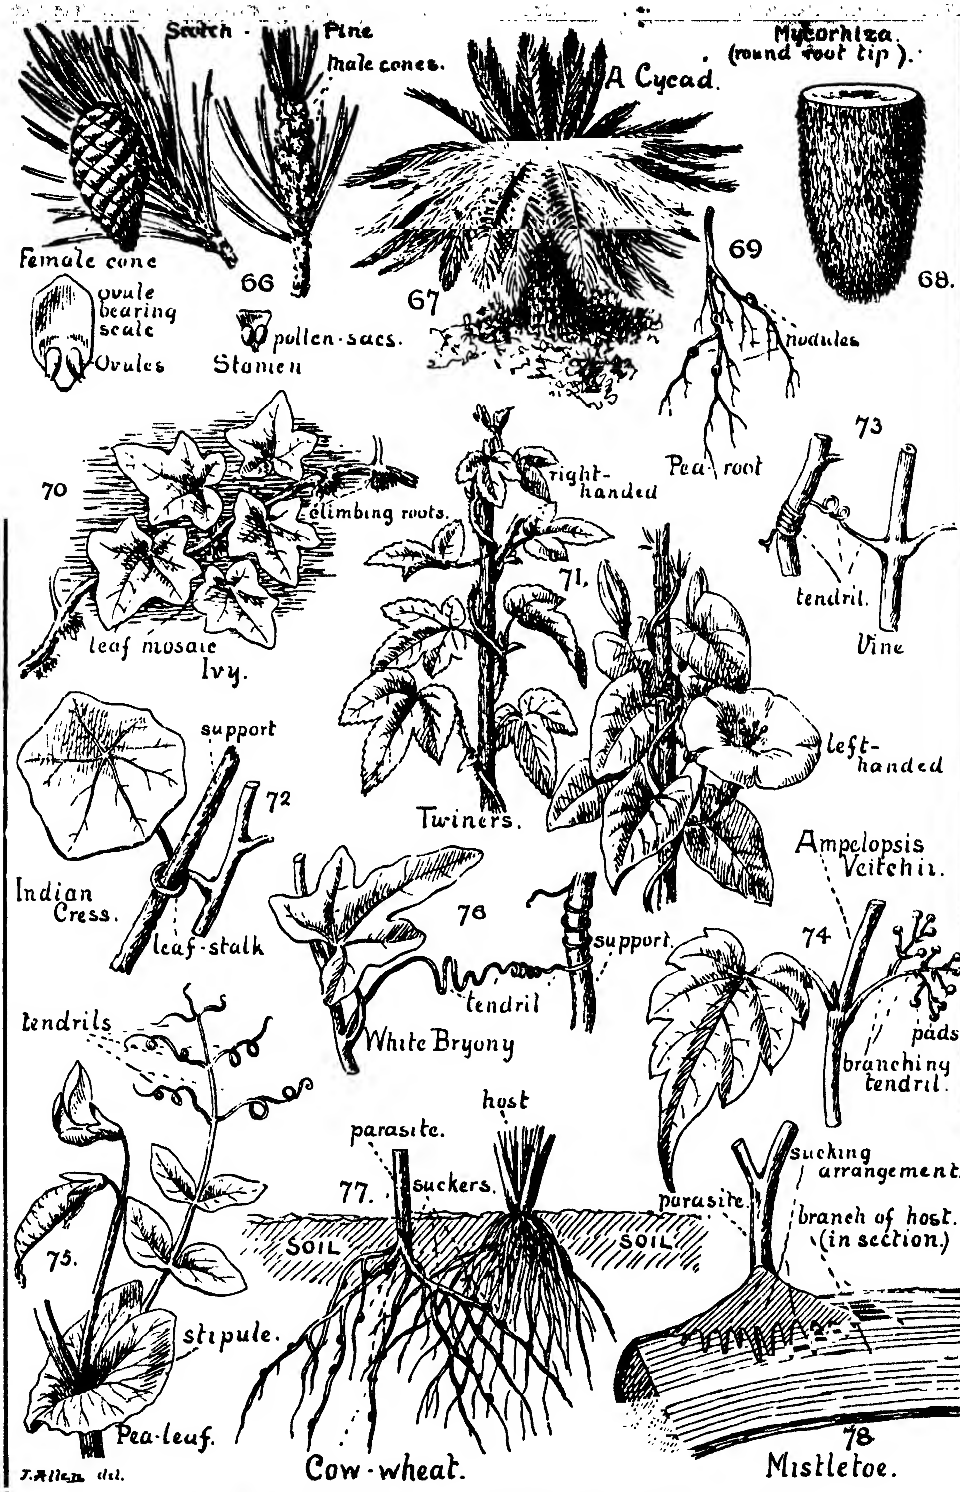
When trees are associated together into forests, their branches and foliage form a huge screen, by which light is more or less excluded from the ground beneath. In the case of pines, firs, and other evergreen forms, the obscurity thus brought about is permanent, and plants which require much light are unable to grow in the soil so overshadowed. Toadstools and other fungi, however, which are independent of light, flourish in woods and forests. Where the associated trees are *deciduous*—*i.e.*, shed their leaves in autumn—it naturally enough follows that the ground is sufficiently illuminated in spring to enable the growth of herbs which require plenty of light. And at this time of the year we shall find a number of plants carpeting such a "hard-wood" forest, and hastening to unfold their leaves and flowers before they are plunged into gloom by the growth of a dense green canopy above them. Conspicuous among such herbs are wild hyacinth, or English bluebell (*Scilla*), snowdrop (*Galanthus*), wood sorrel (*Oxalis*), and wood anemone. At the edge of such a wood, or in its open glades, herbs and shrubs are naturally more abundant.

Climbing Plants. By adopting a climbing habit, many plants are able to secure their due share of light without having to waste their substance in the manufacture of a strong vertical stem. A number of forms, without actually climbing, secure the display of their leaves by trailing or sprawling along the ground, as may be seen in periwinkle (*Vinca*). From this we pass to cases where the stem is studded with hooks, which render climbing possible, as in blackberry or bramble (*Rubus fruticosus*), that scrambles over hedges. An example on a large scale is afforded by the climbing palms, which stretch from tree to tree—holding on by their spiny leaves—and may attain the length of 650 feet.

The *root-climbers*, such as ivy (*Hedera helix*), adopt another method of ascent, for they hold on to tree-trunks, walls, or other objects by means of tufted roots which grow out from the nodes of the stem [70].

Another interesting method of struggling up to obtain light is afforded by the *twiners*, in which the stem winds itself round and round some support. This may be effected either in a right-handed or left-handed way, where the tip of the plant moves round in the direction of the hands of a clock or the contrary respectively [71]. To the former belong honeysuckle (*Lonicera*) and hop (*Humulus lupulus*); to the latter, bindweed (*Convolvulus*) and scarlet-runner (*Phaseolus multiflorus*). Indian cress (*Tropæolum*), clematis, and some other forms ascend by means of their leaf-stalks, which twist themselves round any firm objects of suitable shape [72].

Methods of Tendrils. All are familiar with the slender climbing organs known as *tendrils*, which are extremely sensitive to contact, and move about until they touch some stem around which they can firmly twine themselves. These peculiar structures may be specialised branches, as in the vine (*Vitis*) [73] and Virginia creeper (*Ampelopsis*). In most cases a tendril holds on to a cylindrical



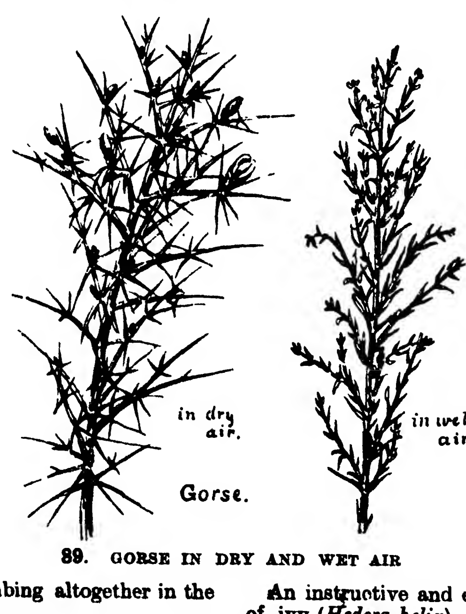
EXAMPLES OF NAKED-SEEDED, CLIMBING AND PARASITIC PLANTS

support, but in one kind of Virginia creeper (*A. Veitchii*) there is an arrangement by which even smooth walls can be climbed, for the tips of the tendril-branches swell into sticky pads, which adhere firmly to brick or stone [74]. The garden pea (*Pisum*) and many of its relatives have converted some of the leaflets of their compound leaves into tendrils [75]. In the white bryony (*Bryonia dioica*), our only native representative of the cucumber order, there are simple tendrils, which, after twisting round a support, coil into a tight spiral about the middle of their length [76]. This not only pulls the bryony firmly against the hedge up which it is climbing, but every spiral acts as a spring, which yields to the wind, preventing the plant from being forcibly torn from its anchorage.

Many tropical orchids and certain other forms are to be found growing on trees far from the ground, using these merely as a support, and not preying upon their sap. Such plants are *epiphytes*. Their roots, which are necessarily in the air, are of peculiar structure, absorbing moisture from the humid atmosphere of the forest in which they live.

88. LADY'S MANTLE

Parasites. A number of the higher plants have, more or less, given up the struggle for obtaining food in a legitimate fashion, and have adopted the parasitic habit, developing suckers, by which they extract food from other forms which are getting an honest living. A number of such forms are to be found in forests, where they attach themselves to the roots of various "hosts," as organisms are called, which must perforce give up some of their juices to unscrupulous associates. The phenomenon is by no means limited to forests, but may be seen here and there wherever vegetation is dense and rank, and where the device of parasitism has saved certain plants from succumbing altogether in the struggle for existence.



89. GORSE IN DRY AND WET AIR

Half Parasites. Some members of the foxglove order (*Scrophulariaceæ*) are green in colour, and partly get their food in a legitimate, partly in a parasitic, fashion. Such half parasites are eyebright (*Euphrasia*), louse-wort (*Pedicularis*), and cow-wheat (*Melampyrum*). Upon their roots are little swollen suckers, which fix themselves to the roots of their neighbours [77]. The mistletoe (*Viscum album*) fixes itself to the branch of a tree [78].

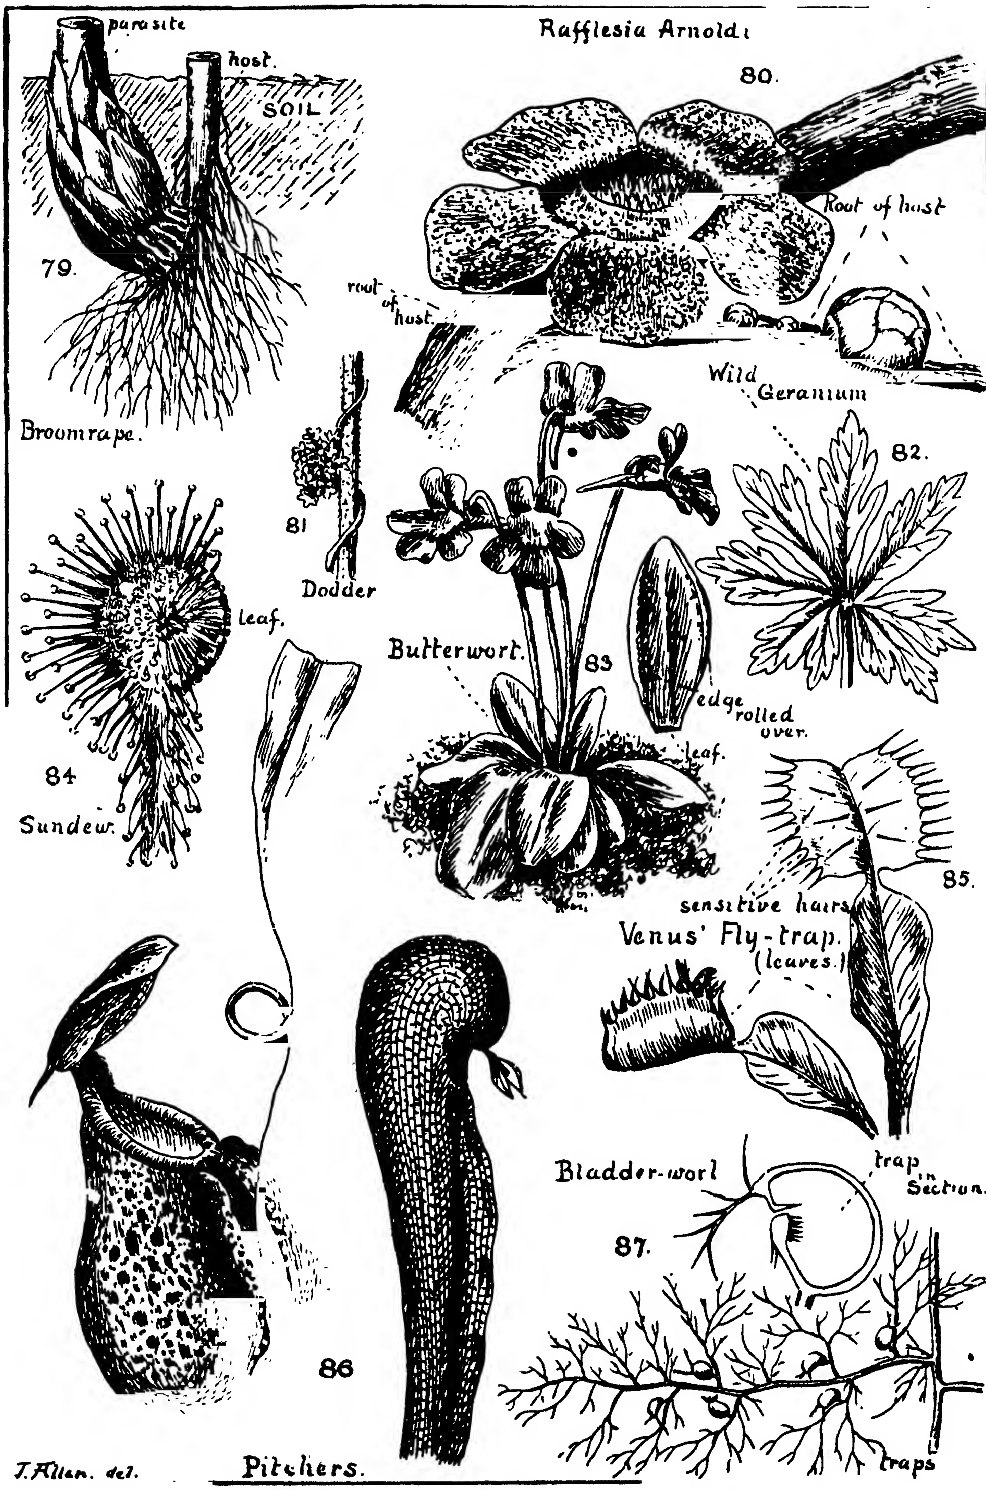
Full Parasites. Not distantly related to the plants last mentioned are the brownish broom-rapes (*Orobanche*), which have given up the green colouring matter for which they have no need, and of which different species attack the roots of broom and other shrubby leguminous forms, ivy, hemp, milfoil, scabious, etc. [79].

The members of one small order of parasites (*Rafflesiaceæ*) are found in the tropical forests of both old and new worlds, and some of them are remarkable for the enormous size of their blossoms. The most extraordinary species in this respect (*Rafflesia Arnoldi*) is native to Sumatra, where it grows upon the roots of wild vines, and bears gigantic flowers over a yard in diameter, the largest known [80]. They smell like putrid meat, and attract carrion-flies.

Another very notable parasite is dodder (*Cuscuta*), a degenerate member of the bindweed order (*Convolvulaceæ*), which twines round the stems of its victims and extracts their sap by means of sucker-like organs [81]. Hemp, clover, and flax are among the cultivated plants attacked.

Leaf Mosaics. We have seen that the shape of leaves and the method of their arrangement have reference to the utilisation of light. In a climate like our own, where sunlight is not too abundant, the necessity for making the most of it has caused the evolution of a great variety of *leaf mosaics*, in which a number of adjacent leaves or parts of leaves fit together to make up an almost continuous sheet of green, without blank spaces, and suggesting the relation of parts in a piece of mosaic work. The leaf rosettes of daisy, dandelion, etc., and the foliage of many trees furnish excellent examples.

An instructive and easily studied case is that of ivy (*Hedera helix*). When this plant applies itself closely to the ground, a tree trunk, or a wall, its leaves are illuminated from one side only, and each of them is provided with five sharp lobes, which fit neatly into the corresponding indentations of their neighbours [70]. But in such a place as the top of a wall we shall find shoots growing straight up into the air, and



EXAMPLES OF PARASITIC CARNIVOROUS PLANTS

receiving light from all directions. Under such circumstances the leaves are of a continuous egg-shaped outline, retaining only the angle at the tip.

The blades of many leaves are deeply divided, sometimes in a very complicated fashion, and in a "compound" leaf there is a splitting into a number of distinct leaflets. Such an arrangement is often found in plants which are crowded together—*e.g.*, in a hedgerow, and it is clearly of advantage in enabling a plant to take advantage of narrow spaces through which light penetrates. A good example is the common herb Robert, or wild geranium (*Geranium Robertianum*) [82]. Such a division, however, may have come about as an adaptation to conditions of other kind. Sometimes, for instance, it may be explained as an arrangement for preventing wind from tearing the delicate tissues of the leaf.

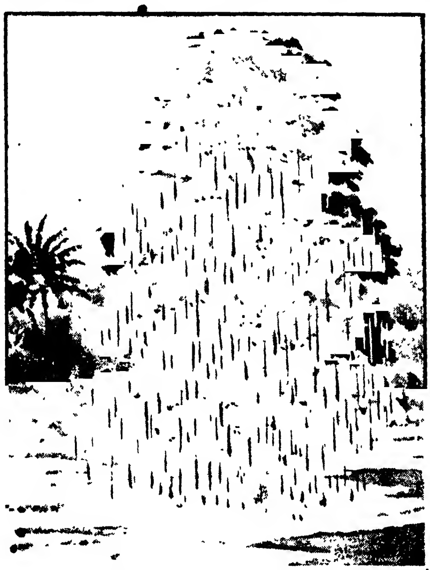
Carnivorous Plants. While parasitic plants live partly or entirely at the expense of other forms of vegetation, the flesh-eating, or *carnivorous plants*, have evolved arrangements by which they are enabled to feed more or less upon small animals, especially insects.

One of the most familiar carnivorous plants is the butterwort (*Pinguicula*), common in the damp patches near moorland streams and springs [83]. The flowers are something like those of violets, and rise from the centre of a rosette of pale-green leaves, which, being slippery to the touch, have given rise to the popular name. On the upper sides of these leaves, near their margin, are a large number of peculiar hairs, which pour out a sticky fluid. Should a small insect be so unfortunate as to settle on some of these it is held fast, and the sensitive margin of the leaf curls over it. The fluid possesses digestive properties, and reduces parts of the body of the victim to a solution, which is absorbed by the leaf as food.

Associated with the butterwort we often find the sundew (*Drosera*), which is a still more deadly foe to insects, even large ones. Here, again, we find a leaf-rosette, the members of which have a remarkable appearance [84], for the rounded or, it may be, oval leaf-blade is studded with reddish tentacles, shaped like pins, upon the tips of which glisten drops of fluid—hence the name "sundew." This fluid, however, is not dew, but a sticky digestive fluid which exudes from the ends of the tentacles and serves the same purpose as the fluid in butterwort.

Venus's Fly-trap. Venus's Fly-trap (*Dionæa*), is a North American relative of the sundews, possessing leaves which are specialised into a peculiar kind of capture apparatus [85]. Each half of the leaf-blade is fringed with long spines, and upon its upper surface are three sensitive hairs. If an insect is unfortunate enough to touch one of these, the leaf rapidly folds up, and two sets of spines interlocking so as to render escape impossible, a digestive fluid is now poured out from minute hairs which stud the surface of the leaf, and the last act of the drama is as usual.

In the pitcher-plants, of which numerous species inhabit the warmer parts of the globe, we find that the leaves are modified into variously shaped receptacles which prove fatal to many insects [86]. These are attracted by the colour of the pitchers, which are commonly blotched with purple, and also by a sweet fluid secreted in the neighbourhood of their mouths.



90. WEEPING TREE

The small organisms which swarm in fresh water are not altogether spared by carnivorous plants. In bladder-worts (*Utricularia*), for example, parts of the leaves are swollen into little rounded traps [87], each of which has an inwardly opening door.

Influence of Water in Plant Life. A large amount of water evaporated from the leaves and young stems of plants is a process which is known as *transpiration*. A plant which has a large amount of water at its disposal transpires to a corresponding extent, and also possesses arrangements by which superfluous moisture is prevented from accumulating upon it. Such a plant is termed a *hygrophyte*. If, on the other hand, the water supply is scanty or difficult to absorb, transpiration is checked by various devices, and there may be arrangements for storage of liquid. Conditions of the kind have led to the evolution of *xerophytes*.

It has been proved experimentally that many plants alter completely in appearance if the water at disposal is varied in amount. A good case is that of the gorse (*Ulex Europæus*) [89].

Some leaves are able to get rid of water in the liquid form, generally at or near their edges. This is the origin of the drops of liquid which may often be seen sparkling on Indian cress (*Tropæolum*) and lady's mantle (*Alchemilla*) [88]. In tropical forests transpiration goes on more rapidly as soon as the sun rises, and the water vapour condenses into a sort of fine rain. The so-called "weeping tree" (*Cæsalpinia pluviosa*) is a notable example [90].

THE USE OF THE SHOP WINDOW

The Mission of the Window. Importance of a Central Idea. The Danger of Overdressing. Colour Harmony. A Useful Colour Scheme

By W. B. ROBERTSON

The important subject of the arrangement of window display—window-dressing proper—comes up for consideration. Many shopkeepers place too little value upon their windows. But they seem to be learning wisdom. We do not see so frequently as we formerly did that retailers have allowed some enterprising firm of soap or patent food manufacturers the monopoly of their windows for a stipulated time. The window is the most direct, valuable, and practical method of advertising at the command of a shopkeeper, and he should use it accordingly.

Mechanical Attractions. The sole object in window-dressing should not be to draw crowds. It is possible to draw crowds that will not do the shopkeeper any good. Mechanical figures used to be common in some shop windows. Their value was questionable. It was certainly overestimated. A tumbling figure or a dancing doll is not a business-bringing attraction in a shop window unless the automaton has some direct relation to the article advertised by its agency. The figure of a prim white-capped waitress bearing a tea-tray and a teapot, for example, is an extremely appropriate "draw" to sell a special blend of tea. There must be appropriateness between the article to be sold and the medium of selling.

Figures in motion always command attention. If they are particularly clever or appropriate they impress. There is a shop in London where the thorough appropriateness of a mechanical device may be seen. The article to be sold is a food chopper, and the maker wishes to impress the public with his claim that the machine will chop anything edible. A procession of tiny figures of ducks, geese, rabbits, pigs, oxen, fish, bread, vegetables and fruit moves on an endless band into the hopper of one of the choppers and emerges at another part of the apparatus to continue the round again. Other instances might be cited, but none more telling than this.

The accessibility of the window contents is a point which has been already urged. Our illustration reproduces a prize provision window at the recent Grocers' Exhibition, and shows how this accessibility may be secured. This window may be taken as typical of what a well-dressed provision window ought to be. It is not crowded to excess, the arrangement is good, and there is nothing that could not be conveniently reached and withdrawn.

Window Pricing. It is a disputed point among many retailers as to whether a system of window pricing is remunerative. The practice may claim this in its favour, that the most prominent and most successful firms adopt it, and many of them have built up large businesses chiefly through its agency. Nothing should be priced in a window which will not bear scrutiny and comparison. Many purchasers wish to know prices before they enter to buy a coveted article. Others like to compare prices in various windows before deciding who is to have their custom. Such purchasers the shopkeeper with displayed prices attracts. In these days it cannot be denied that there is in most shopkeeping departments a demand, and in many instances a necessity, for window pricing in plain figures.

Seasonable Goods. Most shopkeepers would resent the counsel that they should display in their windows only goods of a class that is in season at the time, but the caution is not always superfluous. There is, however, a complementary rule which should be observed. It is: "Emphasise season's goods." At the time of special season's goods the purchases of that class are being made for a whole year, and to refrain from making the utmost out of opportunity is to lose the chance which will not recur for another twelve months.

The manner of emphasising season's goods is by a prominent window display. The best seasonable window display that we have seen for a long time was that in the window of a London tailor a few months ago. He wished to draw attention to his shooting and sporting suits, and he put in a characteristic sporting window. His sporting suitings were well displayed, and the floor of the window was covered with heather from the hills arranged to resemble natural growth as nearly as possible. A fox lurked at the side of a roll of cloth, a deer's head protruded from one corner, pheasants and partridges, lapwing and quail, and even to the humble sparrow the feathered kingdom was represented. A gun rested in front. The whole display exhibited fidelity to one idea, a homogeneity, and an appropriateness to the season that served its purpose well. Many a city man paused on his way to his office and dreamed that he felt the wind from the moor come from the little shop window in front of him, and the message of the window was accomplished.

Overdressing. Shop windows are usually overdressed. A window may give a more effective display with half a dozen pairs of boots in it than it will do with two hundred pairs. The first lesson that window-dressers have to learn is that quantity is not essential to window dressing. The window must be considered from what it can be made to bring in, and it should be made to talk. The man who starts to dress a window without a central idea, without a mental conception of the message he intends to cause the window to express, will fail

in making a "talking" window display. The dresser of a window should go to work like the painter of a picture. He should have a clear conception of his aim—a central idea, a prominent feature—all else should be in the nature of accessories, subordinate to the main idea, emphasising it, if possible, but not robbing it of some of its potency. Let us take, for example, a bootmaker's window. There is a well-known bootmaker in London who works this central idea even into a boot window, where one might think everything bore so close a resemblance to everything else that nothing could be well emphasised and the importance of nothing modified. Yet, in this case, by the expedient of putting forward a glass shelf with a special attachment to hold one boot at a special angle right beneath the eye level of the passers, he compels attention to that boot. One may examine more closely the other boots shown, but he is not forced to do so. But that single boot is there, and one cannot get away from it. It must be noticed.

Where the business is mixed, it is not well to mix the window contents unduly. There is a shop in Dublin where one idea—not a central idea only—is carried out in the windows. The windows are dressed afresh every morning. There is only one class of merchandise, and not too many samples of it, on view at one time. One morning it may be, say, white wood articles of ornament—nothing but white wood ornaments—not crowded. On the following morning it may be brown earthenware vases and so on, one thing at a time, and that thing well shown.

Half the shop windows in our streets would be more effective bringers of business if half their contents were withdrawn, and the remaining half arranged to carry their message.

Show Remunerative Articles. No merchant finds everything he sells equally remunerative. On many articles the profit is so small that time and money would be saved if they were not handled at all. Yet many shopkeepers make displays of such things for the simple reason that there is an attractive show card illustrating them or that the containers are pretty. This is folly. The first business of a window is to earn money for the shopowner, and if the window is being made to sell the products of a manufacturer whose goods do not carry their proper burden of profit, it is being sent on a false errand. Preference should always be given to the most remunerative articles, and if there are certain widely-advertised specialties, the sale of which does not pay, a good window show of lucrative competing articles should be made.

The temptation always exists to exhibit in the window the best goods to be found on the shelves. Sometimes this is wise. Often it is the reverse. If a draper is in a neighbourhood where common articles of apparel are almost the only kind bought, it will convey a false impression of his stock if he exhibits only high-class articles. He ought to show what his customers are likely to buy. By exhibiting, say, silk blouses at 25s. each, he may sell perhaps one a week, but if he had shown articles more in keeping with the class of people by whom he is surrounded, he might have done far more business and made more money.

Assisting the Advertisement. Some retailers make a practice of having conformity between the window displays and the advertisements in the local papers. This is good. The window is then the stepping-stone between the newspaper announcement and a visit to the shop. The customer is interested by the printed page, impressed by the window, and inspired by both with a desire to examine more closely and handle the article advertised. The window may be made to supplement the story of the newspaper column, to intensify any interest aroused by reading the weekly sheet, and to this end the articles shown in the one should be those written about in the other.

Outside displays have a value, but in this country they are confined to shops of the cheaper class. In Paris and other continental towns the pavement trade, even by large and important departmental stores, is enormous. Our climate makes it impossible that we should display goods in the open as do the Parisians, and it is unlikely that it will ever become the fashion to vend soilable merchandise in this manner. Local regulations governing displays on the side-walk are also stricter in this country.

Colour Harmony. Those who aspire to make window-dressing an art and to put into that art the best work of which they are capable, will not neglect to study colour harmony. There are many departments of shopkeeping where outrage upon good taste in the colour schemes of window displays is frequently perpetrated. In the drapery, outfitting, and house decorating shops a knowledge of colour values is highly desirable. In these trades the shopkeeper must impress with his taste in the selection and arrangement of the merchandise, and how can he do so if his windows testify to an ignorance or a carelessness regarding the canons of art in colour blending? If the window-dresser has the artistic sense highly developed he already knows and appreciates the importance of colour harmony. If, on the other hand, it be a subject upon which he is comparatively uninstructed, he may be certain that many of the public whom he wishes to attract will judge him by the selection of colours placed together. The drapers' assistant who has to arrange in his window only the cheap muslins, flannels, and serges which sell to a poor working-class population may, if he choose to develop the faculty, make his windows expressive of beauty. Beauty is a passive rather than an active quality. It consists in the absence of anything that offends the sense of proportion in form or colour. It has been expressed as a proposition thus: "True beauty results from that repose which the mind feels when the eye, the intellect, and the affections are satisfied from the absence of any want."

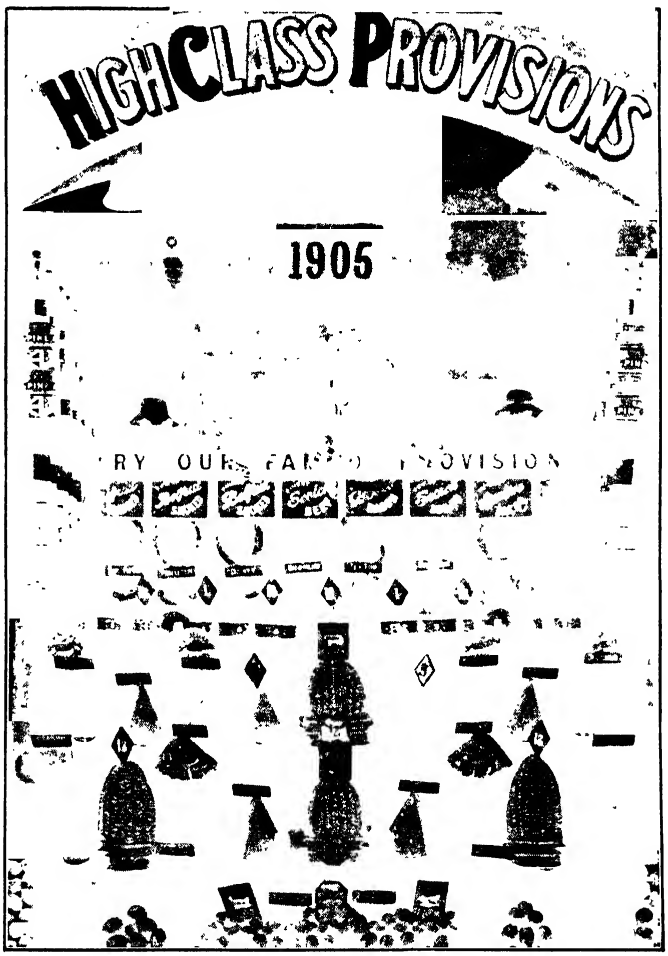
But attempts to analyse beauty of either form or colour fall a long way short of enabling us to express our meaning in exact terms. The

formulation of definite rules for combining colours so as to produce artistic effects is impossible. General rules are encrusted with so many exceptions that they lose their value as rules.

Complementary Colours. Generally speaking, *complementary* colours go well together. While we shall not here make exhaustive study of colour analysis, we may explain the meaning of "complementary colours." The sum of all colours is white. Take any colour away from white and that which is left is the complementary colour to that taken away. In the following pairs of colours the one colour is complementary to the other in each case:

Red and green; Orange and blue; Yellow and violet; Orange-red and blue-green; Orange-yellow and violet-blue; Greenish yellow and reddish violet. But although in many of these contrasts the effect is pleasing, in others it is found too hard and loud. For this reason the colours are often softened to give harmony. One authority submits the following table as a guide in colour schemes, and the window-dresser who follows its conditions will be very unlikely to offend the eye for fine colour effects.

Red and yellow	better than	red and orange
Red and blue	,, ,,	red and violet
Yellow and red	,, ,,	yellow and orange
Yellow and blue	,, ,,	yellow and green
Blue and red	,, ,,	blue and violet
Blue and yellow	,, ,,	blue and green
Yellow and orange	,, ,,	red and orange
Yellow and green	,, ,,	blue and green.



A MODEL PROVISION WINDOW
Awarded First Prize at the Grocers' Exhibition of 1905

Some Rules for Window-dressers. There are several other ascertained facts that the designer of window displays would do well to remember. Colours on white grounds appear darker, and on black grounds lighter. When two tones of the same colour are placed together, the light colour will appear lighter and the dark darker. When two different colours are placed together each will receive a touch of the complementary colour of the other. Thus, if orange and red be placed side by side the orange will seem slightly greenish and the red tinged with blue. When ornaments are on a gold ground they should be separated from the ground by a darker edging. Gold ornaments on any coloured ground should always be outlined with black. Edgings of white, gold, or black to ornaments are usually harmonious. Ornaments in colour or gold on white or black ground go well without edging.

These may be held the chief rules that should guide the window-dresser. But, being an art, window-dressing cannot be taught like Euclid. Success demands enthusiasm. If it be true that art is the expression of pleasure a man puts into his work, there is no department of shopkeeping into which art can enter more deeply than into that of window-dressing. The mission of a shop window is to tempt. A tart in a baker's window, for example, is to him not so much an article of consumption as an agent of temptation—an allurement to cause children to disobey their parents, and invalids to disregard their medical advisers!

To be continued

Group 29 **TRAVEL** 4 Continued from page 394	# HOW TO TRAVEL ABROAD **Companionship in Travel: Its Advantages and its Drawbacks. The Different Modes of Travel. Language. Food. Money. Clothing. Economies**

By J. A. HAMMERTON and WILLIAM DURBAN, B.A.

FAR more people are possessed of the travel temperament than are conscious of the fact. Multitudes are naturally endowed with fine perceptive capacities, but have never given their faculties a chance of development. Intelligent and sympathetic people should, if possible, travel somewhat while they are still young. Very recently the daily Press reported the discovery of an old lady living in a London court who has never been inside an omnibus, and is exceedingly proud of the fact that her practical acquaintance with geography extends little beyond that narrow court. That is, after all, only an exaggerated type of a too common order of mind, developed by lack of movement about this wonderful world.

Companionship is one of the vital accessory conditions of travel. This factor must be largely regulated in accordance with idiosyncrasy. A person who is by inclination exceedingly sociable naturally shrinks from the idea of a solitary tour. But even some of the most socially genial spirits occasionally long to break loose from every conventional tie. Said a very able and busy City man not long since in our hearing: "I dearly love my family circle, and there is no happiness like that I enjoy in my own home; but when I take my little annual holiday on the Continent, I do like to go quite alone!" The reason was that this gentleman, tied all the rest of the year to his office, feels like a schoolboy let loose for the most active play when he can simply shoulder a knapsack and go climbing up mountains, or tramping over high and fatiguing passes. He would wear out those who are dearest to him by the sort of vacation he needs.

Advantage of Companionship. But fellowship in travel has its advantages and its drawbacks. It is an advantage to any tourist going forth for the first time into the great foreign field, without any knowledge of the people or the language of a strange country, if a friend can be found who is a linguist, who delights in touring holidays, and is gifted with both the traveller's instincts and with the spirit of comradeship; then the yoke is delightfully easy, and the pleasure is doubled. But it is imperative that the novice give himself to the leading of his friend. A programme—at least, a tentative one—should be agreed on beforehand, and there should be on each side a disposition to make mutual concessions by the way. We have known what should have been a most enjoyable expedition turned into an itinerating purgatory by the determination of one of the two parties to make the whole occasion, from first to last, subserve some purpose in which the other could feel no special interest. Everything had to give way to that. Where a number of people join in a party, congenial souls will unconsciously and inevitably gravitate together. This is one reason why organised and conducted parties for travel on a large scale are so popular. It is not only because facilities are arranged—though this for many people is of supreme importance—but because suitable companions are sure to be encountered, that this mode of touring is so much in vogue. If mutual temperament allows, the duet plan is a good one. Where two people are friends, who know and understand and appreciate each other, their fellowship and reciprocal help are always likely to enhance pleasure, to obviate the feeling of home-sickness, and to prevent a sensation of loneliness

The Solitary Traveller. But so much depends on individual temperament that it is dangerous to lay down rules or to give advice in any dogmatic way. One of the present writers more strongly than the other favours the lonely journey. He has experienced all kinds, and believes that, given the frame of mind which enables one to derive pleasure and profit from the common objects of a day's journey, there is no way of travel better than that of going alone; for even two friends are apt to tire each other in the course of three or four weeks' continuous companionship, than which no more crucial test of friendship can be devised. A triangular party is better than two—unless the two have been tested and tried by previous companionship—for it is well that there should be an umpire, as it were, to decide any difficulties that may arise. Husband and wife make the best couple, since they have learned the lesson of "bear and forbear" as friends seldom learn it. But perhaps the lonely journey is best when one goes afoot or awheel, the two ideal methods of foreign travel. "Now, to be properly enjoyed," says R. L. Stevenson, "a walking tour should be gone upon alone. If you go in company, or even in pairs, it is no longer a walking tour in anything but name. It is something else, and more in the nature of a picnic. Walking tours should be gone upon alone, because freedom is of the essence; because you should be able to stop and go on, and follow this way or that as the freak takes you, and because you must have your own pace, and neither tramp alongside a champion walker, nor mince in time with a girl. And then you must be open to all impressions, and let yourself take colour from what you see. You should be as a pipe for any wind to play upon." It also breeds self-reliance, independence of judgment, resource.

Pleasures of Wayfaring. Then, again, the solitary wanderer can economise if he wishes to do so; can stay where he pleases and as long as he chooses; can alter his itinerary at will; and can regulate the occupations in which he wishes to engage without fear of inconveniencing a companion. Reading and writing can be indulged in without let or hindrance; calls can be made; business can be done if there is advantage in attempting any; and either rest or extra exertion may be enjoyed individually to an extent hardly possible under the limitations imposed by company. We met a schoolmaster in the wildest solitudes of Norway, in the very heart of the grand Fille Pjeld, who was walking right across the country from Christiania to Laerdal Sören, and was carrying nothing but a rug and a knapsack. He intended to take three months for the tramp, staying as he pleased at any specially inviting spot. He had been sadly unwell at home, but the journey was putting new life into him. "I am never lonely," said he. "I get delightful little episodes of chat almost every day with strangers like yourselves." On the other hand, we recollect how, in Athens, we had long and unusually enjoyable talks with a most accomplished Belgian financier. This gentleman told how he had been three months in Greece on important business. He was entirely alone, and was accustomed to long expeditions, but had been laid up ill alone at that hotel in Athens. He had simply been left in solitude, excepting when the doctor came to see him, or the servants did whatever was necessary. The people of the place took no sympathetic interest in him whatever, and the sense of solitude had been fearful.

Husband and Wife. Of course, the ideal foreign journey is that in which husband and wife accompany each other—if both are alike fond of movement and sightseeing. Nothing in literature can be reckoned more delightful than the mutual accounts of their wanderings by Sir Samuel and Lady Baker, or Professor and Mrs. Tyndall, or Sir F. and Lady Lugard, or Mr. and Mrs. Bullock Workman, or the Duke and Duchess of Argyll (Princess Louise), or Professor and Mrs. W. M. Ramsay, or Mr. and Mrs. A. M. Mummery, or Mr. and Mrs. Theodore Bent, etc. A book lies before us which we consider one of the most extraordinary illustrations known of the special side of travel to which we are referring. It is entitled "The Collected Remarkable Travels of George Pitt, Accompanied by His Wife, Round and Over the World." Mr. and Mrs. Pitt belong to the Society of Friends. Their record shows how the world can be seen with the utmost enjoyment, on what Mr. Pitt calls "marvellous conditions of economy," by two people who are happily mated.

Family Travel. A few weeks ago a gentleman and his wife returned to England after a voyage round the world. They are unpretending, intelligent, business people—still in business, indeed—but determined not to work without knowing something of the glories of the world they live in while still able to enjoy life. They have brought home stores of pictures; have taken copious notes; are full of happiness when in conversation over their reminiscences; have made kind friends all over the world; and have spent astonishingly little considering what they have seen.

Family parties on tour, of course, involve considerable trouble and responsibility for the seniors, but these have the intense pleasure of knowing that they can in this way, as in no other, at one and the same time train young minds and impart to them indescribable enjoyment. There cannot conceivably be anything more gratifying than to watch the wonder, and often ecstasy, with which youths and maidens for the first time gaze on the view of the Jungfrau; or watch the prospect from the top of the Stelvio Pass; or look at the majestic cone of Etna; or inspect the beauties of Capri; or follow the doings of the sardine fishers at Amalfi. To minister in this way to the intellectual development and the culture of taste in boys and girls at the most impressionable period is worth considerable sacrifice.

Travelling with Specialists. Other conditions (such as those of temperament, etc., already referred to) being equal, it is specially advantageous, if possible, to secure the company of some specialist, but an expert who can convey his knowledge to the non-expert mind, and does not ride a hobby to death. On one occasion, we recollect how an expert botanist opened up a perfect world of wonders amongst Alpine flowers during an expedition which happened to be undertaken just at the best season for his observations. At another time we were for some days favoured in Italy with the fellowship of an architect who was an enthusiast in his profession, and was overjoyed to meet with sympathetic listeners to his expositions.

Ministers of religion are apt to think that there is no better idea practicable for making the most of a Continental trip than in the society of a brother minister. But we know of a minister who has for years enjoyed long pilgrimages with a Church officer who is a business expert. The former is able to give endless information on ecclesiastical affairs and history, and is considered a perfect peripatetic cyclopædia in this direction, so that a visit to a cathedral or an abbey in any country is a treat in his society. The latter is stored with knowledge on practical international affairs through his large commercial foreign dealings. Two people who are both skilled in different departments can double the profit and pleasure of a trip. We once visited Greece in company with a merchant who carries on large transactions. When we came to such places as Patras, and saw the vast heaps of currants piled on the quay waiting for shipment; when we rode that enchanting trip along the Bay of Lepanto; when we stayed among the vine-growers round Corinth; and when, on leaving Greece for Asia Minor, we went into the wonderful gardens where sultanas were ripe on the vines, it was enlightening indeed to listen to the merchant's exposition of many matters

connected with business in various commodities. We came home with stores of fresh knowledge.

But it is surprising how much information one may gather from talking with chance acquaintances. Once we had the whole interesting trade in fruit and vegetables between Brittany and England explained to us at Tréguier, where, going to visit the birthplace of Rénan, we found two English ships taking away tons of new potatoes, and got talking with the representative of the English merchants, who was staying at our hotel. People who ride hobbies are to be avoided at all costs; authors of the same class also. For instance, Mr. Percy Dearmer's "Highways and Byways in Normandy" is weighted with tiresome disquisitions on stained glass, which can only interest the specialist, and is only saved from dulness by the accuracy of its information, some good descriptive and historical passages, and Mr. Pennell's illustrations.

The Means of Travel. In these days of varied modes of locomotion, four methods of travel are in vogue. Each of these is attractive to different orders of mind; each is specially suitable for distinctive purposes, and they obviously admit of various combinations and permutations. Train, carriage, cycle, and foot must each be acknowledged to have certain preferential claims in different directions. Pedestrians and cyclists have this great advantage—that they are able to visit just what spots they wish, and as in many cases railroads and Nature in its real beauty do not nurse each other, there are countless points of attraction that are never seen by those who only travel by train. At the same time, where swift transit is desired, or considerations of physical weakness must be consulted, the railway, of course, takes the first place. The cyclist effects the completest compromise possible. He can go anywhere very quickly, and thus is most perfectly master of the situation—apart from the greater liability to accidents and breakdowns. Carriage driving is the ideal way of getting about for the valetudinarian or the elderly tourist. It is invested with peculiar delights; and for the wealthy the automobile constitutes, of course, the acme in this department. We say "for the wealthy," not because of the initial cost of the car and its fitments, but for the reason that motorists are regarded everywhere abroad as persons of longer purses than cyclists or ordinary travellers, and are apt to be imposed upon accordingly.

The Language Problem. We now approach certain difficulties which are greatly dreaded by large classes of would-be tourists. The most formidable of these is the language problem, especially as we are not a nation of linguists. The educated Russians and the Dutch far excel us here. The notion that English is practically—for the convenience of the Anglo-Saxon traveller—a universal medium, is a painful fallacy, as the tourist speedily discovers directly he ventures off the beaten Continental track. Our insular language is usually understood by some functionary or other in the chief hotels of important cities, but this is apt to be the limit. One of the most comic sides of travel has its cause in the absolute linguistic ignorance of multitudes of travellers. Two American ladies recently related to us some of their curious experiences in certain small German towns. Yankee-like, they were on a very hot day anxious to secure a water-melon. Their English was an unknown tongue to the hotel folk, so they tried by gestures to indicate that they wanted something of globular shape. A large wash-hand basin was brought, to their great astonishment, and next an open umbrella was tried, on which they were constrained to abandon their quest.

It is remarkable how very far, however, a slight smattering of French, German, or Italian will go. French is generally understood in good Italian hotels, but it is of little use in Germany, excepting in the most fashionable centres, while German and Italian are generally of no avail in France. In many parts of Switzerland, French, German, and Italian are interchangeable. It is so easy to gain a slight elementary acquaintance with any Continental language (excepting Russian, Magyar, Finnish, Basque, and Turkish) that no tourist should shun the little labour needed for a task which pays in every way. A trip in Norway or Denmark is doubly pleasant if the voyager happens to have acquired something of the common vocabulary. Norwegian is the language of both these countries, and it serves almost equally well for Sweden, the language of that country being cognate. A little Swedish will take the wayfarer nicely almost anywhere in lovely Finland. It is to be borne in mind that even little fragments and scraps of the native tongue are intensely appreciated by the people, who will generally place themselves eagerly *en rapport* with any visitor if they see he is so far sympathetic with their country and their nationality as to think it worth while to cultivate some knowledge of the language they speak.

Continental Feeding. Those who are going abroad for the first time will need the valuable hints which they can gain by consulting more experienced people as to various conditions of life in other lands. Otherwise experience may be dearly purchased. The dangers arising from insanitary surroundings were much greater of old than they are to-day. If wine is taken, it should be the native product, rather than some imported vintage. Changes of diet are inevitable in extensive travelling, but simple food will be found the safest. The average Continental table-d'hôte is excellent, as well as inexpensive. The tourist abroad must not expect to be treated to chops and steaks, or to cuts off large joints, in English fashion. The dietetic ways of John Bull are absolutely strange to all foreigners. Few people in the South of Europe ever saw a buttered slice of bread, and, for that matter, our way of eating bread is quite unknown to the ordinary American. But Continental diet has its peculiar pleasures—delicate little dishes; soups of infinite variety; compôte such as is never dreamed of

in this country; superb poultry in France, and delicious quails and bécasses further south; a continuous fruit banquet in Italy, Greece, or Turkey; luscious preparations of caviare, sterlet and sturgeon in Hungary and Russia; *pièces de résistance* of tunny or swordfish at Messina, Taormina, or Constantinople; dishes of berries like the incomparable "moltebaer" in Norway, with wonderful cream from the saeters; reindeer tongue in Finland; goose breasts in jelly, followed by pumpernickel in Germany, occur to memory as a few of the culinary attractions that are unfamiliar to the British appetite, but are likely to be truly relished by any hungry tourist as he sits down at a foreign table.

Hotel Charges. Of the charges at foreign hotels the tourist in most cases need have no fear. Excepting at the most aristocratic resorts in the height of the seasons, the charges are almost universally less than those of our own British hostelries. It is, for instance, far more expensive to stay in the Scottish Highlands than in Switzerland. Italy is cheaper still. Usually the most costly items are extra little things asked for beyond those in the cartes for meals. Invariably is it more economical to lunch or dine at table-d'hôte, for which the charge is fixed and stated. All attempts to have a cheaper meal by selecting two or three dishes will result only in having to pay as much or more than the entire table d'hôte charge for one half or less of its value. Of France especially is this true, and it applies more or less to every country on the Continent. In unsophisticated places like the little and charming cities perched in the Apennines, the towns in the east and the south of Sicily, in Corsica, in the hotels of the interior of Norway and Sweden, the fees for lodging are fabulously low.

Money. Another of the popular fallacies is that "English gold will take you anywhere in Europe." This is no more true than the companion fiction about the English tongue. We have proved its falsity too often, and to our financial loss, to allow any novice to entertain it for a moment. Even so near at hand as along the coast of Brittany we have met innkeepers who had never seen an English sovereign, and who, we ascertained beyond doubt, were not emulating the innocence of Ah Sin. Also it is important not to leave one Continental country with much money bearing the stamp of another Government in one's possession. Belgian, French, Swiss, Italian, and Greek coinage is, with some reservations, current in any of these countries, but not the paper, and we recollect our difficulty in discharging a bill at a sleepy town near the French northern frontier because we had practically nothing but Belgian paper money and English gold in our possession; yet Belgium was only a few hours' cycle ride away. In the banks of most large towns there is no difficulty in changing English money, or one's hotel-manager will often be ready to supply change; but in shops and restaurants, at railway stations, and *everywhere* in the smaller towns and villages, the money of the country should be presented. It is thus important to carry a good supply of the currency, even if one has to get what is left exchanged on returning to England.

The Custom-house. The traveller must be prepared at any moment to submit to the irksome inspection of the Custom-house officers. In Tyrol this is exceedingly tiresome, because on almost any trip in that lovely region we are crossing the borders of not less than three nationalities continually. But the "douaniers" are almost universally extremely civil if they are treated patiently and courteously; if not, they will probably resent the behaviour shown them by turning out all the belongings of the wayfarer. "Pflicht ist pflicht" (duty is duty), said an Austrian Custom-house officer to some impertinent and impatient Britishers. That was a nice little play on words! The travellers were in that case compelled to pay toll on certain articles which would otherwise have escaped notice. Spirits, scents, and articles of certain categories easily ascertained, are taxed, with, of course, cigars. Only the travellers who resent the inspection of the officers—who are merely discharging their duty—ever have cause to be annoyed by the Customs.

Clothing. One of the most prevalent mistakes of those who undertake a tour for the first time relates to clothing. It is an error to imagine that overcoats or any description of warm wrap will never be needed in a southern country. The difference of temperature at different altitudes is remarkable. Nights are often very cool in Switzerland and Italy. Especially is the weather very deceitful on the Riviera. In that delightful winter resort it is dangerous to be much in the shade in light clothing, however warm and radiant it may be in the sunshine. But many changes of clothing are not needed on an ordinary tour for either sex. With reason, the smaller quantity of apparel carried about the better. Umbrellas and macintoshes should be carried, for there is frequently a great trouble to get clothing dried. Throughout very large regions of the Continent a fire, in our kitchen or parlour sense of the word, is altogether unknown, little charcoal stoves being the only means of heating and cooking. Overheating and undue exertion have caused many a valuable life to be sacrificed on tour.

The one *sine quâ non* for the tourist is courtesy. The British and the refined Americans are cordially welcomed all over the Continent, but certain samples of Anglo-Saxondom every season do their best to render themselves obnoxious to the foreigner. We have travelled far and wide in Russia, just where Englishmen are supposed to be anything but welcomed, yet nowhere in the world have we been the subjects of greater kindness from all classes.

CHEMISTRY
4

Continued from page 402.

THE GREAT DIVISIONS OF CHEMISTRY

Organic and Inorganic Chemistry. Chemical Formulæ. The Elements, with the Atomic Weights and Symbols

By Dr. SALEEBY

Divisions of Chemistry. When we come to consider the details of chemistry we find that the whole subject may be divided into two great parts—Inorganic Chemistry and Organic Chemistry.

Those terms, though very widely employed and very useful, are open to very grave misconception. They are meant to imply that chemistry may be divided into the chemistry of bodies that are not alive on the one hand, and the chemistry of living bodies on the other hand. But before we proceed to accept these terms, we must ask ourselves how far the supposed distinction between the two kinds of chemistry is valid.

Is it the case that, when we deal with bodies that are not alive, we make the acquaintance of a certain series of substances and can discover a certain number of laws; and that when we come to deal with living bodies we find a different set of substances and a different set of laws? At one time it was thought that such a real distinction obtained, but that belief has been modified, first in one direction, then in another, until finally there remains not a single phase of it that can be sustained. There is absolutely no distinction between organic chemistry and inorganic chemistry, save merely for convenience. It used to be thought that fundamentally different substances were found in living matter, and that it had fundamentally different properties from those of non-living matter, but no chemist now maintains this belief.

Chemical Change in Living Matter. It was long held that certain compounds were produced through the agency of life, and could be produced by no other means. That belief received a severe blow in the year 1828, when it was found that a substance (urea) hitherto thought to be a result of vital activity alone, could be artificially produced in the laboratory by the chemist. The laws of chemical change in living matter are absolutely identical with those displayed in inorganic or non-living matter.

As we have said, the distinction between organic and inorganic chemistry is purely one of convenience. Therefore, in recent times it has been sought to make the distinction on rather different grounds. When it was found, for instance, that the combination of carbon and oxygen produced carbonic acid both in a fireplace and in the living body, and that the facts and laws of the combination were precisely the same in both cases, it became obvious that the absolute distinction between the chemistry of life and the chemistry of non-living matter could not be maintained. So nowadays the term organic chemistry has fallen into disfavour, and a new term has been employed, which, indeed, appears to convey no suggestion of the old one. Instead of talking of "organic chemistry," we speak now of the *chemistry of the carbon compounds*, and the subjects which were once discussed under the old name are now discussed under the new.

An Arbitrary Arrangement. It may be said that, after all, this new term is no better than the old one, for is not carbonic acid a carbon compound, and do we propose to treat it under the heading "Chemistry of the Carbon Compounds," or are we to treat it in the earlier part of our study, or in both? It is in order to note this objection that we have chosen the illustration of the union of carbon and oxygen. It demonstrates that our distinction between inorganic chemistry and the chemistry of the carbon compounds is in reality just as artificial as the old and untenable distinction between inorganic chemistry and organic chemistry. In other words, this classification, like all other classifications, is really an arbitrary arrangement made for the convenience of human thinking and without any basis in Nature, which is not a jumble of things mixed up for us to reduce to order, but is in reality a "flawless unit of fact."

If we clearly understand that there are not two chemistries, but one chemistry, and that the laws of chemistry, in so far as they are true at all, apply equally to the chemical processes in a fireplace, or a retort, or the human brain, or the leaf of a plant, or the interior of the furthest star—we may proceed to consider what, for convenience, we term *inorganic chemistry*, not forgetting that what is true of inorganic chemistry is true of all chemistry.

Elements and Compounds. We have already seen that chemistry, as distinguished from other sciences that study matter, depends for its existence upon the fact that matter is of different kinds, and obviously it becomes the first duty of the chemist to sort out all the different kinds of matter, to give them names, to find out how many they are, and the relations between them. The name that has been agreed upon to indicate the different kinds of matter is the word *element*.

There is a child's game which has taught us all that the ancients believed in the existence of four elements. Aristotle taught that there were four elementary substances—Earth, Air, Fire, and Water. Since his day the idea has undergone great elaboration and improvement. It was Robert Boyle who first attempted to use the word in a strictly scientific sense. He said that we must apply the name element to those substances which are incapable of being split up

into simpler substances. Such substances as are capable of being split up we must call *compounds*. They are compounded of certain elements; and thus every substance that can be named or imagined must be either an element or a compound. Now chemistry has lately learnt that the elements are related to one another in such a fashion as to teach us that not a single one of them is really elementary.

The simplest element we know is really a very complex compound of something still simpler. This discovery is of such tremendous importance, in theory and in practice, to the philosopher and to the man of action, that for some time past the writer has never used the word element in its chemical sense without quotation marks to indicate that the meaning usually attributed to the word cannot be sustained, and that its use is retained only for convenience. However, when we come to look up the derivation of the word, we find that it is disputed. Some etymologists think that it is really derived from a word meaning "to grow." Others think that it means a spirit or angel, and others that it means what has an independent power of motion. At any rate, we may take it that the proper meaning of the word does not necessarily convey the idea that the substance to which it is applied is incapable of being resolved into any simpler substance, and therefore, in the present section, the word element will be freely used in its chemical sense without quotation marks, it being assumed that the reader will persistently bear in mind the fact that the meaning of the word element which has been accepted since the time of Robert Boyle can no longer be maintained.

But the reader will insist that Boyle's definition of an element has broken down, and therefore he will ask: Are there any facts left that render it necessary to use any such word at all? Now, indeed, there are such facts, and they must later be considered. For the present the reader must accept the assertion, which there is no difficulty in believing, that matter can be reduced to a number of different substances, each of which is incapable of further analysis by the chemist, and which we agree to call elements.

It will be useful if the student is presented here with a list of the known elements. The following list omits not a few about which we have yet attained no certainty, but it includes the most recent discoveries, in so far as we may regard them as confirmed. Opposite the full name of each element is placed the symbol or abbreviation which is used to express it in chemical language, and next to the symbol is placed a figure which states what is called the *atomic weight* of the element. This term is considered below.

Name	Symbol	Atomic Weight	Name	Symbol	Atomic Weight	Name	Symbol	Atomic Weight
Aluminium	Al	27	Hydrogen	H	1	Ruthenium	Ru	102
Antimony (Stibium)	Sb	120	Indium	In	114	Samarium	Sm	150

The above list is as reasonably complete as can be. It doubtless contains errors. There are doubtless omissions which can be predicted, as we shall see, though no known element yet fills them. As to the atomic weights there is, of course, much uncertainty and incessant re-correction. For instance, it is found that the weights agreed upon in 1904, and known as the international atomic weights, differ slightly but very frequently from the weights given by Mendeléef in the same year. Many of our chemists spend their whole time in attempting to re-determine the usually accepted atomic weights.

Errors in Calculation. *In the course of such re-determinations it has often happened that curious but persistent errors appear, and it has often been found that these errors are really due to the intermixture with the element in question of another element hitherto unknown.* Many new elements have been discovered in this fashion, and doubtless the discrepancies between the atomic weights given by one authority and another will in many cases be explained in similar fashion. One authority has used one method and one another, and the difference in their results is due to the circumstance that the two methods involve slightly different factors, one of which may well be the intrusion of a new element which alters the result in the one case as compared with the other.

As a rule round numbers have been given, and it is a fact of great significance that in many cases the numbers are really round, but in other cases it is, of course, possible to calculate the atomic weight to several places of decimals. In these cases it becomes a question to determine how far it is worth while pursuing the calculation —that is to say, at what point the figures cease to correspond to the facts of nature and come to depend upon merely the errors which are inseparable from even the most delicate and skilful experimentation. But the reader must not fancy that these atomic weights are arbitrarily decided upon, or that much guesswork enters into their composition. Suppose that no two observers get the same result. It does not follow that we cannot obtain a result which is nearer the truth than any result obtained by any one observer. Suppose, for instance, we take the atomic weights reached by a thousand different observers, and then take the average of the thousand calculations. Plainly that result is likely to be very near the truth.

No more suitable place than this could be chosen for commenting upon the study—which has lately been reduced to a science—of the limits and the laws of experimental error, and of all the factors that enter into what is often called the *personal equation.* This study is of especial importance to the chemist, whose experiments are so delicate and whose principles depend for their discovery upon the delicacy and accuracy of countless processes of weighing and balancing.

Atomic Weights. Another point may be noted as to the atomic weights of the foregoing table. It will be noticed that the weight of hydrogen is given as 1 and the weight of oxygen as 16. Hydrogen is the lightest known element, and when tables of atomic weights first came to be constructed, it was agreed to use hydrogen as the unit and to measure the weights of all the other elements relatively to the weight of hydrogen. Near the beginning of last century it was suggested that perhaps the hydrogen atom is the true unit of matter, and that the so-called atom of oxygen really consists of 16 hydrogen atoms, carbon of 12, and so forth. This could only be assumed by simply ignoring the decimal figures following the whole numbers, on the assumption that they were due to experimental error; but we know that they were not due to such error, and the simple and attractive theory that the atoms of all the other elements are simply compounded of the atoms of hydrogen cannot be maintained.

Relative Weights. If we take the atom of hydrogen as 1, then the atom of oxygen is not 16, but 15·879. That is very well established. Suppose, however, instead of calculating all our atomic weights from the atomic weight of hydrogen as 1, we allot the number 16 to be the atomic weight of oxygen, and then calculate all other atomic weights relatively to the weight we have assigned to oxygen. Then we shall have to write down the atomic weight of hydrogen not as 1, but as 1·008, and we do not appear to gain anything from this change.

But when we come to calculate all the atomic weights on this ratio, we find that we do gain substantially by allotting the round number 16 to represent the atomic weight of oxygen. We actually find that some 20 of the atomic weights thus calculated are whole numbers even to the second decimal place, and that 17 are very nearly whole numbers. This is of course as much as to say that there is a relatively simple and close ratio between the weight of oxygen and the weight of a very large number of other elements. So striking is the degree of simplicity of this ratio, far more simple than can be accounted for by the laws of chance, that it cannot but have a meaning into which we must soon inquire.

It is often thought desirable in chemical textbooks to discuss at this stage the main facts as to the characters of the elements and the manner in which they are prepared; but in writing this section in the light of the work of the last three or four years, we shall defer the consideration of such facts as the characters of the elements, and proceed immediately to a discussion of the deeper meaning that can now be discerned in the study of such a table as we have given on the previous page.

IDEAS FOR BUILDERS AND ENGINEERS

New Projects in Building and Machinery. Difficulties to Face and Reforms to Effect. Some Inventions in the Making and Others to be Sought

By ERNEST A. BRYANT

The Engineer of the Future. The present is an interesting and important time in the history of building and engineering. Young men about to enter upon their careers may be destined to share in notable reforms which are even now taking shape. Men in whom pride of race is by no means lacking, in whose constitution pessimism holds no place, tell us that the first need towards rendering British engineering more efficient is the institution of a monster scrap-heap, upon which to throw antiquated and ineffective machinery, whose place shall be taken by appliances more in keeping with modern requirements and with the productive skill of the nation.

The engineer will, in the future, be more closely associated with the builder. The day is about to pass when bricks and mortar and huge blocks of stone play so commanding a part in the construction of great buildings. The genius which converts waste slag into a brilliant illuminant, and a by-product from coal into medicines, scents, and dyes, representing many millions of money, will be summoned to aid the contractor to construct great works cheaply and expeditiously by means not hitherto seen in this country.

Building Regulations. But there are difficulties in the way. An Act of Parliament of the greatest value to London is the London Buildings Act. It is the Act which declares how a builder shall build, and of what. Properly speaking, it applies only to the London area, but its influence is over all the land. In minor particulars, the requirements of provincial regulations may differ, but for all practical purposes the London Buildings Act is the model upon which all are framed. These Acts, though necessary and advantageous in the main, are often hindrances, restricting the architect, builder, and engineer to old methods, and barring out the introduction of the newer methods at their disposal. Hence the day of the steel-framed building, with the innumerable possibilities of ferro-concrete, or reinforced or armoured concrete, as it is also called, has yet to dawn in this country.

Our foremost builders, architects, and engineers wait with impatience for the removal of existing restrictions. Under the existing regime it is not possible to build more than one floor at a time; with the steel-framed building, half a dozen floors may be constructed simultaneously in perfect safety. The terrors of the Employers' Liability Act make it certain that the masters will not voluntarily involve risk of injury to their men; but until the existing law is modified we must continue to build upon the old plan of one floor at a time.

Steel in Buildings. Again, we have yet to look to the time when our regulations will take cognisance of the strength of steel in a building. At present the law says that if a man put a steel framework about his factory or machine shop, not only shall he build up floor by floor, one at a time, from the basement, but that he shall put into the steel-framed building just as great a thickness of brick—all the way up—as if the steel were not there. Furthermore, though reinforced concrete is stronger than brickwork, we have at present, if using it for a building, to put in a greater thickness of it than if it were brick.

Reinforced concrete, as the student will learn from other portions of the SELF-EDUCATOR, is concrete solidified about girders or rods of steel. The steel takes the tension, the concrete the compression. It is not new. Napoleon Bonaparte employed it for his fortifications; but, like many other wonderful inventions, it has had to be rediscovered. America, which carries out building operations on such a gigantic scale, employs it for some of her largest undertakings. Some of her great buildings consist—from basement to roof—entirely of this ferro-concrete. In them enormous masses of machinery are handled, and mighty cranes travel with their giant loads every hour of the day and night—conclusive evidence of the stability of the material.

Materials of the Future. Here, then, are two directions in which the builder and engineer of to-morrow may expect to turn. The uses to which reinforced concrete may be applied are beyond enumeration. For foundations of great buildings, for sub-aqueous piers and piles, for fireproof floors, for party walls, for, in fact, every kind of building in which strength and durability are demanded, steel and concrete are the materials of the future.

The growing demand for cheaper and better cottages, which arises not only in London and the big provincial cities, but also in the country villages all over the land, directs attention to an unlimited field for the future. The problem to be solved is worthy the attention of the most thoughtful. In London, at any rate, rock-bottom seems to have been reached in the cost of production. Land is so costly and materials so expensive that if a man is to build a house which is to do him credit he must charge an exorbitant rent. The further settlement of the London artisan in cottages in or about London itself seems impossible. If he must be in London, he must seek the tenement dwellings. The best of these are as yet far from ideal. They want more air; they want more sunshine; they need better systems of heating and ventilation. Here is a

task for the accomplishment of which the whole world waits. Not even the ingenious American builder has reached finality in heating and ventilation. His hot-water pipes make the air stuffy; his ventilation simply means an apartment where draughts whirl in chilling blasts.

New materials are needed for cottages outside London. Reinforced concrete may have something to do with the solution of the problem. But the builder is still seeking a permanently non-inflammable wood. He needs it for the cottage; he needs it still more for the large establishment. The authorities, rightly holding human life as more to be regarded than the pocket of the builder, insist that wood for staircases and what not shall be of oak, or some other equally hard wood. This costs three times as much as deal, which, were it rendered really non-inflammable, would answer as well.

A Cheaper Power Supply. Another of the newer tendencies in modern industry is for great city firms to establish works beyond the London radius. Subsidiary industries spring up around these new centres of work. Populations grow and need to be catered for on the spot. Cheap mechanical processes for the small man are necessary. Here occurs the opening for economical power-supply. Hitherto, the small man has had to be content with an engine driven by steam or the gas used for ordinary illuminating purposes. The latter, handy for rapid starting of small engines, has, in its old form, done good service, but may now have to be modified to conform with newer ideas. Pressure-producer gas answers well for anything over 150 h.p., but suction-producer gas is the best servant of the smaller man, who requires up to 150 h.p. The principle of this wonderful invention is explained elsewhere in the SELF-EDUCATOR. Here it suffices to say that the gas-engine, by drawing air through a fire of anthracite coal or coke, makes its own gas as it requires it. No steam-engine is required; neither boiler nor chimney. It produces neither smoke, tar, nor smell. With a generator, a vaporiser, one or two scrubbers, and a fan for starting, the apparatus is very compact and simple. It consumes on an average 1 lb. of coal per brake-horse power, which is about half the consumption of a good steam boiler, and produces 1,000 cubic feet of gas for one penny.

How a Railway Lost a Fortune. From this, the next step will be the application of the principle to the gas-engine. Probably hundreds of minds in various parts of the world are now concentrated on this fascinating problem. Many obstacles will disappear with its advent. It is certain some day to be invented—as certain as that stars whose discovery the astronomers predict years before they are seen do eventually come within the view of the telescope. Perhaps the secret has already been solved, and needs but rediscovering. Nothing is new, save application. Professor Adams, whose valuable course on Materials and Structures appears in this work, supplies in his own experience a most interesting example of this idea. As a boy, employed in the offices of a great engineering works, he designed a new funnel for railway locomotives. He showed it to a relative who was locomotive superintendent to a railway company, but nothing was done with it.

Five-and-twenty years later Mr. Adams stumbled across his boyish production. He showed it to another relative high up in the railway engineering world, and this time the plan was adopted, the funnel being placed upon the engines of the London and South Western Railway Company. The result was, that during the next seven years the Company made a saving in fuel of £60,000. Had it been employed when first thought out, twenty-five years earlier, they might have been the richer by a sum which a child can calculate. Perhaps, in the same way we shall have to rediscover an old scheme and adapt it to the turbine gas-engine. That, says the scientist, will be the climax in the career of the gas-engine. But, as we all know, there is no finality in invention.

Railway Revolutions. Railways must always afford scope for the inventive mind. The mono-rail appears to some the plan upon which progress in the future will be made. But no man need fear that one system will monopolise the world. It is perfectly safe to speculate with new contrivances for making even our present system more up to date. Scientific railway work has an immense future. In Great Britain and on the Continent, where such vast sums have been sunk in the existing systems, revolutions cannot be immediately expected, but inventors associated with firms which are building the railways of new lands have fine scope for new ideas in traction, in appliances for giving additional safety, speed, and greater comfort in travel. Incidentally, of course, bridge construction and repair come within their purview. For their purposes, as for the purposes of a thousand other enterprises, we want more highly specialised machinery for tools; new processes for high-speed steels; more modern and powerful machinery for pressed-steel car bodies for railways. The tendency here is more and more towards sub-division, and the increasing use of machinery for producing the materials required. Any new idea which enables a tool to make faster and deeper cuts adds to the common sum of production, and may mean a fortune to the man who devises it.

Expanded Metal. It is interesting to trace the unexpected directions in which a new scheme radiates. A modern production, known as expanded metal, is obtained by punching short slits in sheets of metal and stretching out the latter into a species of trellis-work. Originally designed as a substitute for wire netting in fences, it was seized upon as the very thing to reinforce concrete employed for certain purposes. The concrete sets in the interstices of the steel and forms an almost unbreakable block. For plastered walls, the expanded steel still has its future, but for the other purpose it has become vastly more important.

The last word of the electrician has not been spoken in connection with railways. Even in

the relatively unimportant matter of bell-hanging, or the fixing of other forms of alarms upon trains, he is still far from his goal. In the matter of cliff and mountain railways there remains a vast field still practically virgin soil, while our canal system appears at last likely to claim the notice which it has long deserved but been denied.

Scope for the Electrician. Mention of electricity leads necessarily to the telegraph and telephone. The telephone will become as essential a part of household equipment as a bell or a door-knocker. Already St. Martin's-le-Grand traces a movement towards the substitution of the telephone for the telegram. This tendency they expect to see vastly developed. Necessarily, then, there lies here an enormous industry in the manufacture of implements for the telephone. Every year we pay to the United States and to Sweden hundreds of thousands of pounds for telephonic apparatus. It was but yesterday, so to speak, that attention was first given to the manufacture of these things in our own country. Now, however, that the work has actually commenced in England, great possibilities open out to the inventor. Villages lying off the beaten track of the railway companies have now their telephone stations. The convenience would be enormously enhanced could defects in the apparatus be instantly repaired. At present, however, a fault may have to lie for days, until an operator, responsible for too large an area, can attend to the breakdown. We may hope for the day when the Government will see the wisdom of issuing licences to the local electricians to undertake repairs. This in itself might mean an appreciable addition to the income of the small tradesman in the country district.

Machinery for Shops. The revival in London of a long-lost pneumatic tube anciently employed to despatch mails from the General Post Office to one of the railway termini is certain to give an impetus to this method of transmission. The pneumatic tube is already largely in use in post-offices and newspaper offices. It is capable of adaptation to the requirements of many large warehouses and other business premises. The matter of shop and business fittings has not received in this country nearly so much attention as its importance merits. Artistically, many of our great business houses are nearly perfect. In point of utility, however, not much can be said of many of the most expensive items of their schemes. Every contrivance which saves labour and time in the conduct of business means additional revenue to the firm employing it. What may be termed shop-machinery is an industry of the future. Supposing that one buy a desk or cabinet for his office. Some alteration is necessary—new or different handles are required, or some other point in its brass furniture needs amendment. You cannot get that trifling alteration made without sending to Birmingham for materials.

From all directions comes the demand for new ideas. Some firms have what is called a Suggestion Scheme. Men in the employ of such firms, if they have an idea, communicate it to their manager, and if there be anything in it they are given either a separate sum, an addition to their wages, or some share in the profits resulting from its application. The plan cannot be too highly commended. The firm which is eager for ideas, and ready to put them into practice, is the firm for which the future holds its riches.

A Metal with a Future. Aluminium is a metal with a great future. So far, relatively few have concerned themselves with it. It can be made as hard as iron, though it is only a fourth the weight of silver. It does not corrode or tarnish, and in that respect has an advantage over all metals except gold. Its uses are infinite—for shipbuilding, for bicycles, for domestic utensils, even for decorative purposes. But although it was discovered nearly a century ago, it has never really had the vogue which it deserves. Difficulty of production has, of course, been a deterrent. But we have in our rivers and streams and waterfalls running to waste the very power which would so well produce this valuable metal.

Bunsen's efforts at the production of aluminium by electrolysis were not a commercial success. But the world has travelled far since then, and electrolytic methods have developed enormously. Not aluminium alone can now be produced by this process ; the uses of electrolysis are almost unlimited. And we are still only on the fringe of the knowledge which as yet is to be gained concerning this interesting process. Every year reveals some new direction in which electrolysis carries its disciples nearer to fortune and the world to industrial revolutions.

Opportunity of the Gas Companies. Competition between gas and electricity as illuminants has become so severe that the exploiters of both have to be continually on the alert for new ideas. It is surprising that they should let slip some of the best. One of the happiest ideas is a pneumatic gas-bracket. Instead of depressing a switch to turn on the electric light, one touches a button to raise or lower the light in the incandescent burner. The mechanism is simplicity itself, capable of infinite development where the electric light is not obtainable.

Mathematicians have need of more instruments ; corporations need workable schemes for the conservation of flood waters which now run riot in winter and leave the lands parched and dry in time of drought. Our cities need improved destructor furnaces ; households need developments of coal-gas for domestic purposes. There is a call for improved cooking-stoves and utensils ; laundries need machinery which will cleanse, but not tear, clothes, nor need the use of chemicals which destroy them. Owners of small machinery plants want a simple, inexpensive means of softening water. The printer is looking for a process by which he can print satisfactorily half-tone and "line" blocks on the same page without spoiling either.

To be continued

SLEEVES, AND THE MAKING OF A SKIRT

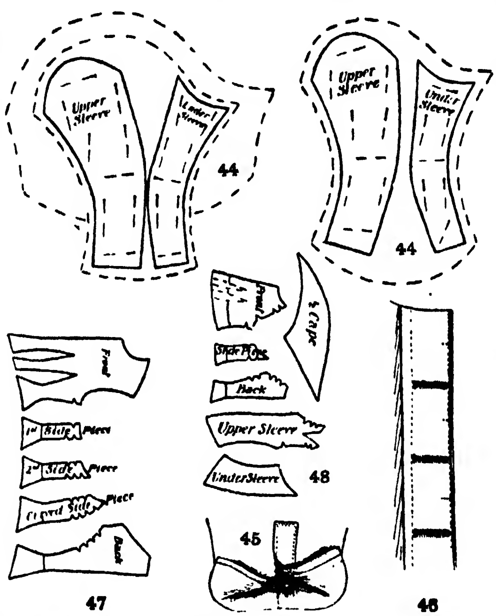
Drafting Blouse Sleeves. Making a Blouse. Bodice for Stout Figures. The Drafting and Making of Various Patterns of Skirts

Continued from page 480.

By AZELINE LEWIS

The Sleeves. So far our blouses are sleeveless, but this omission can be easily remedied by turning to the next diagram. Here we have three different shapes evolved from the coat-sleeve of our drafting—that of a gigot, or leg-of-mutton, sleeve, having been already described.

On the right-hand side of No. **44** a medium-sized bishop sleeve is depicted. Place and pin the upper and under portions of the coat-sleeve pattern in their relative positions, the space between the slope at top and cuff being regulated by the shape and size required, and cut out. On the left-hand side the method of obtaining two sleeves is shown—namely, a leg-of-mutton bishop, and a puff to the elbow. For the former, the upper and under portions of the coat-sleeve are placed farther apart at the top than in that on the right hand, and consequently closer together at the wrist. From these two examples it will be seen that it is just the space between the upper and under parts which determines the shape and size of the sleeve; the nearer together they are at the cuff part, the narrower will the sleeve be here and the fuller at the top, and the reverse, the space at the lower part, with a corresponding sweep of curve, giving the jelly-bag sleeve, which has, fortunately, just been consigned to the limbo of things past, but which may again return for aught we know.



44. LEG OF MUTTON AND PUFF AND BISHOP SLEEVES. **45.** WRIST OPENING. **46.** FALSE HEM FOR INVISIBLE BUTTONHOLES. **47.** BODICE FOR STOUT FIGURE. **48.** BODICE WITH ALTERED WAIST-LINE

The second and outer row of broken lines on the left-hand example gives the method of cutting a puff to the elbow such as that shown in *d* of the group of blouses [See last number], the cuff portion being cut to the same shape as the lower portions of the coat-sleeve. The two other shapes shown—the gigot and the medium bishop with straight cuffs—are used for the other blouses. In *b* the fulness at the wrist is just pleated over and stitched instead of being inserted in a cuff.

The Making of a Blouse. Having gone through the matter of cutting-out, we will now consider the making of a plain blouse—viz., that with the American yoke. Gather the centre of back at the top about 2 or 3 inches. Turn up the yoke edge on the wrong side, snipping selvedges to prevent puckering, and press this. Place the centre over the centre-back of blouse, then pin yoke to this at both ends, also midway between these and centre; draw up fulness to the right size, being careful not to get the gathers all in one place; tack the yoke along and machine in place, quite near the edge on the right side. Turn in and either tack or press the edges of the fronts of yoke ⅜ of an inch at least on the wrong side, and as these are on the cross, it may be as well to do so over a narrow strip of muslin to prevent stretching.

Make an inch-wide hem on the left front for a button-stand, then gather upper edges, pin each end under the corresponding ones of yoke, draw up gathers to the right size, being careful not to draw them too tight. Pin in the centre and between; arrange the gathers evenly, then tack and do the other front the same. If necessary, fit on to see that the front fulness sets well and easily, and if any alterations are required. Be careful to get both sides alike, then stitch the front yoke to blouse at the edges, and put in the facing. For this last, turn in the edges to face those of outer portion. Pin the centre-backs even over each other, pin at each end, also between, and tack across. Proceed with the fronts in the same way, then hem the facing in position, and join the under-arms by a French seam.

For the fold or pleat of right front, cut a strip about 3½ inches wide, place right side to right

edge of front, run together, press, and turn over with the centre a little outside the centre of blouse, tack down, and hem inside over the turnings. Then machine-stitch at either edge with silk. Make three or more lengthwise buttonholes in the centre of this fold, and bar well at each end, then sew the buttons on the left front to correspond, and hem lower edge; if, however, the material be rather thick flannel, it can be herring-boned instead. [See HERRING-BONING.] The waist fulness at back may be either drawn up with a "runner," or sewn to a band of waist-size, which is secured to the waist-line as far as the under-arm seam. This latter method obviates the bulkiness which is more or less inseparable with the "runner," and is certainly better for woollen goods.

The Runner. For the "runner," however, stitch a piece of tape about 4 or 5 inches in length at the centre-back of waist on the wrong side—for a casing—then work a perpendicular buttonhole at each end. Take a piece of narrow tape, long enough to go round the waist and tie in front, thread it through the casing, bring one end through the buttonhole, turn down the other end and secure firmly to the tape casing, then thread another piece of tape through from the other side, and fasten in the same way.

For the collar, if of material, turn in and tack the edges over an interlining of muslin, stitch them and secure to the neck of blouse and finish off in the same way as for bodice. If of cotton material, the collar could be interlined with a coarse linen to take the starch.

Making the Sleeves. The sleeves are joined up by a French seam, and have a wrist opening made about 2 or 2½ inches in length at centre-back. For the finishing of this, stitch a narrow fold on the upper side, make a narrow hem in the under part, and fasten off the former over the latter securely at the top [**45**]. For the cuff cut a straight piece of material 6 or 7 inches wide, fold in half, wrong side out, and stitch down each end, leaving only very narrow turnings. Turn inside out, then tack and machine-stitch once along the fold, also at each end—more if wished. Gather the wrist part of sleeve, and draw up to fit cuff. Turn down upper edge of cuff, pin to sleeve, arranging fulness evenly, then tack and machine-stitch together. Turn in the other edge, being careful to make the ends neat, and hem the inside part over the turnings. Then make buttonholes and sew on the buttons. Gather the upper edge of sleeve, pin and tack in armhole, with fulness well round shoulder, then stitch in place. Cut off the superfluous turnings and overcast neatly.

For *d* in the group of blouses, the side portions must be gathered and arranged very carefully and evenly on each side *before* tacking the back to the front at the shoulder and under-arm seams. An amateur would find it easier and safer to tack the yoke, if of thin or "stretchy" lace, to muslin or leno before arranging the side portions in place, and then cut this all away when the blouse is finished.

The back fastenings are better arranged on a false hem as shown in the diagram [**46**], but if buttonholes to show be preferred, be sure to make these *horizontal*. Hooks are also used for fastenings, but they should be of a make that will not easily come unfastened, and eyelet-holes are preferable to loops for securing them, unless the material be of a thin, loose make, when small silk loops or bars, buttonholed with silk, are best.

For the yoke of *e*, if arranged as sketched, tack the insertion on the foundation, leaving not more than ⅜ of an inch between—a trifle less is better—for the faggoting. If it is to be transparent, this is better worked on a pattern yoke of something stiff, either French canvas or brown paper, and the lace must be tacked firmly at both edges, or it will go askew in the working. As this is rounded the insertion would be better run along with fine cotton at the upper edges to draw it up to the required shape.

A Bodice for Stout Figures. Thus far our models have been built for those of normal, well-proportioned figures, but there are a vast majority who are outside these limits, and such as these usually receive scant consideration in the majority of fashion articles.

It has been already suggested that for very stout figures three side-pieces may be advisable, and in some cases three darts also. In the accompanying diagram [**47**] we have a bodice of this order, an arrangement which gives more spring and shape to each portion, and also lessens the space between each, thereby giving a more graceful effect to the bodice, the making of which has already been described.

In the next diagram [**48**] is shown a bodice with an altered waist-line—*i.e.*, shorter in front than at the back, a very usual failing in those of advanced years. The sleeves are cut and set in Raglan fashion, a method which has many advantages over the ordinary shape of armhole, particularly where there is any stiffness of the joint. The pointed cape is in addition, we think, a little smarter than the shawl usually worn, as it can be trimmed in a variety of ways. As the back would be more or less bent and rounded, the centre-back portions of bodice might be eased a trifle to the curved side-piece, but it must be remembered easing does NOT mean gathering or puckering. It may be pointed out that in this shape it is much easier to obtain a comfortable fit without any of the little pleats so often thought necessary for such figures.

DRAFTING & MAKING A SKIRT

Having learnt how to draft a bodice from measurements, the next step is the drafting and making of a plain skirt. We have chosen for this purpose a five-gored affair, of walking length, as one of the most useful skirts for both slim and stout; and, moreover, one that is capable of being easily adapted to a two, three, and seven-gored shape.

For skirt drafting, the measurements required are those of waist, hip (this is taken at the largest part of the hips), and length of front. As we have already seen, however, the perfectly

proportioned figure is rather the exception than the rule, so it may be necessary to take measurements of the back and the sides to ensure a perfectly hanging skirt, particularly in the case of stout figures, though slender ones may also need this at ention. For instance, some either sink in or are rather flat a' the back, just below the waist, a deficiency which is generally accompanied by an undue fulness of figure in front or at the hips, all of which will affect the hang of the skirt. This is of special importance in the case of skirts made either just to clear the ground, or what is known as the "trotteur" length—*i.e.*, several inches from the ground.

The measurements of the skirt in the accompanying drafting are:

Waist measure	.. ..	24 inches
Hip measure	.. ..	42 „
Length of front	.. ..	40 „

Having taken these measures, we will proceed to draft the skirt.

The Front Gore. Draw lines A to 1, the length of skirt, at the edge, so as to keep this quite straight for the fold of front.

Next draw 1 to 2, quarter of hip measure ($10\frac{1}{2}$ in.), then A to B, quarter of half waist measure, plus $\frac{1}{2}$ in. for the dart ($3\frac{1}{2}$ in. in all). Now place a tape measure on B and 2, and make 3 the length of the skirt—*i.e.*, 40 in.

B to C is $\frac{1}{2}$ in., and B to 4 measures 4 in. Curve from C to 4 for the side of front, also from 1 to 3 for the foot part of this. Lower the waist front $\frac{1}{4}$ in. from A, and then curve it up to C. Mark 5 midway between C and 3, this being of importance when putting together. [49]

Side Gore. In drafting the side and back gores, remember to draw the lines for the length of these $\frac{3}{4}$ in. or so from the edge of the paper to allow for turnings.

Make A to B half the size of waist—remember, *half* measures are taken for this—plus 2 in., which last will be taken out in the darts, and then mark C midway between A and B.

From B to D measures $\frac{3}{4}$ in.

From A to 1 is 1 in. (or a twelfth of waist measure).

C to E is a twelfth of waist measure, less $\frac{1}{2}$ in.

From 1 to F is $\frac{1}{2}$ in.

Curve from F through E to D.

F to G is $\frac{1}{4}$ of waist measure—*i.e.*, 3 in.

D to H is the same length.

Draw a line from 1 to 2 for the length of skirt (40 in.), then make 2 to 3 half of seat measure (21 in.), plus 6 in.; mark 4 midway between 2 and 3, 5 being halfway between 2 and 4, and 6 the same distance between 4 and 3.

Now place a tape measure on B, extending it to 3; draw a line and make 7 the length of skirt, then do the same from E to 4, and make I the length of skirt.

We now return to the waist, and finish the dart here. 8 and 9 are each midway between F and G, H and D. 8 to J and 9 to K are each the length of the skirt. 1 to 10 is 4 in., B to 11 the same distance.

Curve from F to 10 and from D to 11 for the sides of the gore, to shape these to the waist. Make dot L $3\frac{1}{2}$ in. from E on the line drawn from here to I; then draw lines from G and H to L for dart.

For the foot part, draw lines from 2 through J, I and K to 7. M and N are each half skirt length, that is 20 in., and correspond to 5 on front width. [50]

Back Gore. Draw line A to 1, the length of skirt, and 1 to 2, half of hip measure (21 in.). 3 is midway between 1 and 2, 4 between 1 and 3, 5 between 3 and 2. From A to B measures quarter of waist, plus $\frac{1}{2}$ in. ($3\frac{1}{2}$ in.); whilst C is midway between A and B. A and D is $\frac{1}{2}$ in. E and F are each halfway between D and C, C and B.

Now place the tape measure on B, also on 2, and make 6 the length of skirt, E to I, C to H and F to G being each the same measurements. For the foot part, draw a line from 1 to I, H and G, to 6. A to 7 is 4 in., curve from D to 7 for the side of back gore. 8 and 9 are each half of skirt length. [51]

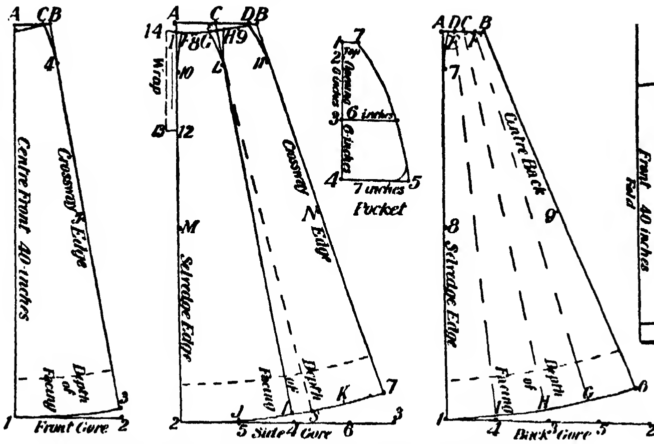
Note that the broken lines in the side gore represent the wrap for placket opening. From F to 12 is the length of placket, 12 to 13 being 2 in., 13 to E measures $\frac{1}{2}$ in. more than from F to 12, this being necessary for the curve of waist. The thick line on the wrap shows where the pocket can be inserted. This, however, is a matter for which no hard-and-fast rule can be given, as pockets can be placed in the gores, in the case of full skirts, or on the other side of the placket, to come under the front.

When the skirt is drafted, cut it out along the pencil marks, and notch the sides of the gores at the dots 4, 10, 11, and 7; also 5, M, N, and 8, so that no mistake shall be made when putting together.

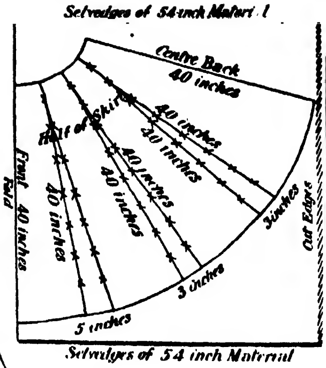
Adapting Pattern to other Shapes. Fashion is so constantly changing in the matter of skirts that we cannot possibly attempt to deal with the variations of La Mode in this respect, but will confine ourselves to showing how the more usual shapes can be evolved from the skirt just drafted. When these are done successfully, the worker should have gained sufficient knowledge to evolve any more elaborate styles that may be preferred.

The Circular or Umbrella Skirt. In the diagrams given, the portions not to be cut are marked with a line and crosses. The umbrella skirt is now a very popular shape, so we will take it first. It is cut in one piece, with a seam down the centre of back, but fashion sometimes prefers it cut in two pieces, with a seam in the centre of front as well, a method usually adopted for checked and striped goods.

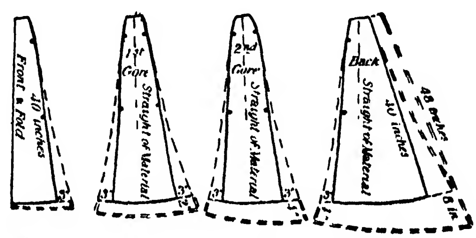
If cut in one, it is not always possible to do so from material folded in the ordinary way; but if this be opened out to its full width and then folded, it is comparatively easy. It is, however, only possible to do this when the material has no pattern or pile, as seams or joins are sometimes made on either side; and unless both are the right way of the material, the result will not be a happy one.



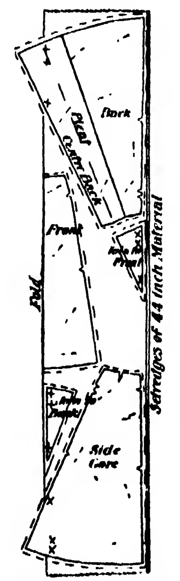
49, 50 AND 51. DRAFTING A FIVE-GORED SKIRT



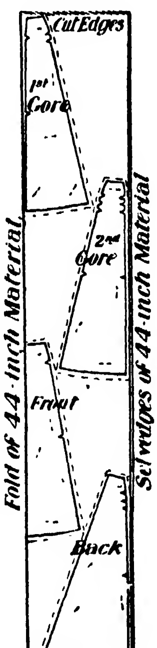
52. A CIRCULAR SKIRT



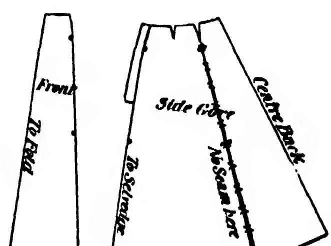
54. FLARE, OR TRAINED, SEVEN-GORED SKIRT



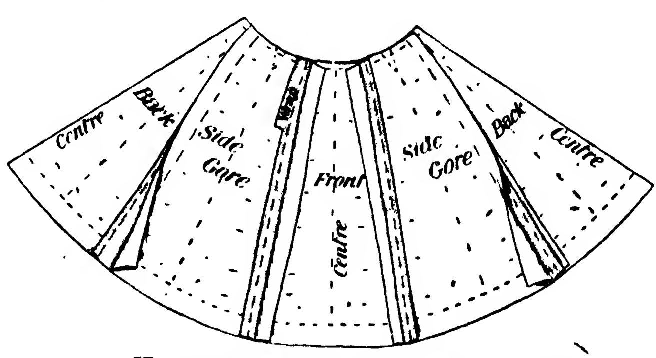
55. A FIVE-GORED SKIRT



56. A SEVEN-GORED SKIRT



53 A THREE-PIECE SKIRT



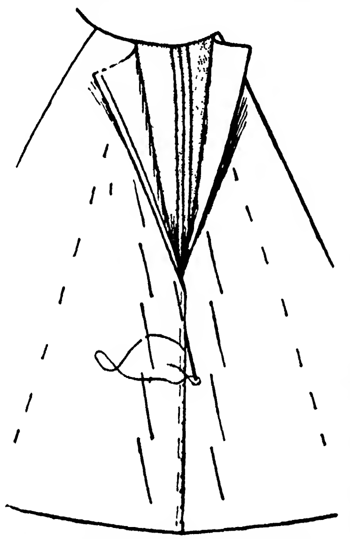
57. INSIDE OF SKIRT—READY FOR STITCHING

To convert the five-gored skirt to a circular shape, cut the side gore from I, through L, to within ½ in. of C ; this will allow it to fit closely at the waist without darts, and also give a little more spring and fulness at the lower part. If darts are required, this is not necessary. At the present moment, however, the circular skirt is very full and guileless of darts at the waist.

Having cut up the gore, open out the material to its full width, and fold over ; then lay all the gores on the material, with the centre-front to the fold, beginning at the bottom and taking care to allow for turning up. Place all the darts together, leaving a space of 3 in. or more at the bottom For a close-fitting skirt, close the darts F and C, 10 and 4 touching, which will leave 5 in. between each gore. Treat the other darts in the same manner. Pin all carefully in place before marking and cutting out. [52]

If the waist part be tucked or gathered, the darts should be placed apart. From this it will be seen that this model is capable of many modifications, and may be utilised for an ordinary morning skirt or made into an extremely stylish affair, suited to a visiting or an evening gown, when it could be trimmed in a variety of ways.

A Three-piece Skirt. This shape of skirt is also popular, and consists of a front width and two wide gores. To obtain it, place the centre-front to the fold of material, then place the side and back gores together, 7 and 11 touching, also 8 and N and 7 and 1. Mark round and cut out, excepting the portions indicated by the crosses, as in the previous diagram. The front side of gore, F to 2, must be placed to the selvedge ; and to cut this without joins the material will have to be opened out to its full width, though it would not be quite so economical as cutting from the material folded in the ordinary way and joining on small pieces at the lower edge of back. [53]



58. FELLING LINING OVER SEAMS

Converting a Five to a Seven-gored Skirt. A very graceful skirt is the seven-gored shape, particularly for stout figures, and also for a smart skirt for evening wear.

For this the following alterations are made in the side gore, so we must again refer to diagram [50].

Make S 1½ in. to the right of I, then draw a line from S to dot L—that is, just at the point of the dart, as indicated by the broken line in the diagram. Now trace from S, through L, to G at the waist, so that F to G and 2 to S now represent the first side gore. H to D and I to 7 make the second gore. When tacking together, place G to H, S and I together.

A "Flare" and Evening Skirt. From our five-gored pattern we can also evolve the "flare" skirt, either in five or seven-piece form. Our diagram shows the latter, the flare being indicated by a broken line, whilst the double line indicates the direction to be taken if a trained skirt be desired ; the length of this, of course, depending on taste and circumstances. [54] A five-gored "flare" skirt is cut in the same way.

The skirt shown in this diagram is close-fitting round the hips, but as fashion alters so much in respect to fulness, it may be necessary to cut it of ampler dimensions.

The width of the front gore is a quarter of hip measure, the two side gores quarter of hip, plus 5 in. or more, and the back, half of hip, or more, according to taste and prevailing fashion. The length, of course, will also be regulated by the same rules, as well as the flare, which may be more than the 3 in. allowed for in the diagram. When cutting out this skirt, the gores with the broken line should be placed to the straight of the material, as indicated in 54.

The Back Fulness. With respect to the fulness at the back, this is largely a matter of taste and fashion. Sometimes a sheath-like effect, guileless of any pleat at the back, is the prevailing mode ; at others a fairly full effect is preferred, which is obtained either by a box, or an inverted, pleat at the centre-back. If the former, the centre-back must be placed to a fold, as there must be no seam here. If the latter, the centre seam on the bias, as shown in the diagram [51], will be correct, but the needed amount for this can be allowed on the back of the pattern.

For stout figures, a pleat or fulness at the centre-back is always desirable, as it "takes away" from the apparent width or flatness which is so frequently the weak point.

If a gathered skirt be required, the drafting should be cut without allowing for either dart or shaping at waist part of seam—that is, from A to B in the case of each gore, plus the necessary amount for fulness, which depends on the material employed, as very thin stuff requires a good deal to look well without adding very much to the size of hips. The greater amount of fulness should be at the back part of side gore and the back gore.

Cutting out the Lining. Having traced and cut out the pattern and carefully marked the various portions indicated by the dots, we will proceed to cut out the lining.

Place the front of pattern to the fold. Trace from 1 to 3 to C, and also through 5, leaving ¾ in. on side seams, and 1 in. on the bottom for turnings. Should the material be of a loose make, 1¼ in. must be left

The front edges of side and back gores go to the selvedge If the lining is not wide enough to cut the side gore, join on pieces at the lower part of back, as shown in diagram [55]. Trace from 2 to F, through E to D, from 2 to 7, from 7 to D; also the line from I to dot L and the dart, the dart and wrap, also M and N, and leave turnings as before. Then trace the back gore.

Cutting the Facing for Foot Part. The broken lines at the bottom of the diagrams 49, 50 and 51 indicate the depth of facing, which, to set well, must be cut to the same shape as the bottom of the skirt. For the front, mark off 3 in. from the bottom, or the depth of facing required, from 1 on the fold, also in the centre and up from 3. Draw a line through these marks.

For the side gore, mark up 3 in. (or to correspond with the front) from 2, J, I, K and 7; then draw a line through marks, as explained for front. Treat the two gores in the same way; then, to save wasting the lining, trace the facing out on paper, taking care to number and mark the parts where they are to be joined.

Cutting out the Material. When the lining is cut out, proceed to arrange the various portions on the material, as shown in the diagram [55], which represents the five-gored skirt placed and pinned on 44-in. goods without any up or down, so that the back gore may be reversed, and considerable economy effected.

For faced cloth, or any material with an up and down, each gore must be placed the right way up, and no reversing is possible, as shown in diagram [56]. Velvet or velveteen will necessitate each piece being placed separately and to face the right way up of the material, in the same way as shown for bodice. [See Bodice.] Trace and mark the material in the same way as the lining, allowing the same turnings.

Basting Lining and Material. First outline the waist-line and the bottom of the skirt on the lining, also the placket opening and darts, with white cotton. Before beginning to baste, place the fold of material of front on the corresponding fold of lining, and tack the two pieces together along this line. Smooth the material carefully on both sides of the fold, also towards the top and bottom of the gore, pin along the edge, and round the gore. Use No. 40 basting-cotton, with a No. 5 or 6 needle. Begin to baste [for basting see Stitches and also Bodice] at the left-hand side of the waist, smoothing it as you go along, taking care not to stretch the bias side of the gore. Baste lining and material together with a stitch ¾ in. in length—with the needle straight from right to left—all round the gore, 1½ in. from the wheel-mark.

For the side gore, pin the centre of this to the centre wheel-mark of lining, and all round the edges, carefully smoothing before pinning; then baste down the centre and all round in the same way as for the front. Proceed with the back gore in the same way as the side gore.

Tacking the Gores Together. Place the side gore on the table, with the straight, or selvedge edge towards the worker and the crossway edge away. Now place the bias edge of the front gore to the straight edge of side gore, according to the marks or notches, taking care not to stretch the crossway edge, nor to lift it from the table when tacking. *Pin the material in the wheel-marks at the waist at top and bottom edge, also midway and several times between.*

Tack ½ in. only *in from the pins, making stitches* ½ in. in length, leaving the lining loose; then take out the pins and turn the lining back to the wheel-mark all along the gore. The left-side gore should only be tacked as far as the placket opening.

Tack the other gores to their corresponding edges in the same way, remembering that the selvedge edges will go to the bias ones, except of course, at centre-back, where the two crossway edges come together.

Stitching the Seams. The inside of the skirt should now present the appearance in diagram [57], where all but the back seam are tacked ready for machine-stitching, this being left open for the sake of clearness.

When machining the seams, keep the work well up to the needle; this is especially necessary if the material be at all loose, as a puckered, stretched, or drawn effect will be the result if the machine be allowed to drag the work. No. 60 cotton should be used for stitching the seams, but silk is preferable, and, if the latter, use either 36 or 40. Stitch up left side of front gore only as far as placket-opening.

Pressing the Seams. When all the seams are machined, remove the tacking-threads, also the white cotton tackings, from the seams, but be careful not to remove those of placket opening.

Before pressing, cut off the edges of the seams to about ½ in. Do not use water or a damp cloth, unless experiments have previously been made on a piece of the material to see whether it will stand this, as some stuffs will quite change colour if either be employed. Open the seams and with the aid of a covered roller and a *warm* iron, proceed to press them gently. It should be remembered that in dressmaking the word "pressing" is used in its literal sense; the iron should neither be pushed nor rubbed along, as in laundry work, but should be used with a firm, gentle pressure.

When the seams are well pressed, tack the straight edge of the lining ½ in. away from the seam of the skirt—the wheel-marks on the lining and material must now meet—then turn down the bias side ½ in. beyond the wheel-marks (to make up for losing in making), and tack over the straight edge. Note the *crossway*, or bias, edges of gores are felled over the straight ones. Now fell the turned-over crossway edge with a fine needle and No. 60 cotton. [58]

To prevent the waist getting stretched whilst the seams are being felled down, it is advisable to tack a piece of straight lining to the waist-line. Proceed with the back and side gores in the same manner, remembering that the other side of the skirt is tacked from top to bottom.

To be continued

NATURAL & ARTIFICIAL STONES

Including Granites, Slates, Sandstones, Marbles, Limestones, etc., the Manufacture of Artificial Stone, and the Preservation of Stone

By Professor HENRY ADAMS

ENGLAND is fortunately constituted for the study of geology. The various strata in their natural position, in horizontal layers one above the other, would occupy many miles, and the lower ones would be practically inaccessible. But in England they are, speaking generally, tilted up on the western side and down on the eastern side, all lying at an angle, so that on the east coast only recent alluvial deposits are found, but in travelling towards the west, the outcrop of the various strata is passed over until the igneous rocks are reached on the west coast.

Architecture Dependent on Geology. The architecture of a country naturally follows that form most suitable to the prevalent building material, so that where forests abound timber dwellings are the rule—as in Norway at the present time, and in England during its early history. Upon the disappearance of forests, recourse has to be had to the materials in the soil. Hence towards the east coast, where clay abounds, brick buildings are the rule; and towards the west, where stone is abundant, stone dwellings are more common.

The London Basin. In the neighbourhood of London there is a peculiar dip in the strata, taken across the bed of the Thames, forming what is called the London Basin [47]. A study of this will show how rocks and minerals that have been deposited at different periods may, in certain places, be seen and examined on the surface. It also shows why artesian wells sunk through the impervious London clay provide a large supply of water, it having travelled through the greensand from considerable distances.

Building Stones. Building stones may be classed as (*a*) hardstones, such as granite and several kinds of sandstones; and (*b*) freestones, such as Portland oolite, Bath stone, Caen stone, etc. They may also be divided into (*a*) siliceous stones, in which silica is the prominent constituent, such as Granite, Bramley Fall, and Craigleith; (*b*) argillaceous stones, in which alumina is the chief constituent, such as clay slate; (*c*) calcareous stones, in which carbonate of lime predominates, such as Kentish Rag, Portland, Bath, Caen, etc. Sandstones have the greatest fire-resisting ability; limestones decompose under heat, and clay, slate, and similar stones crack when heated.

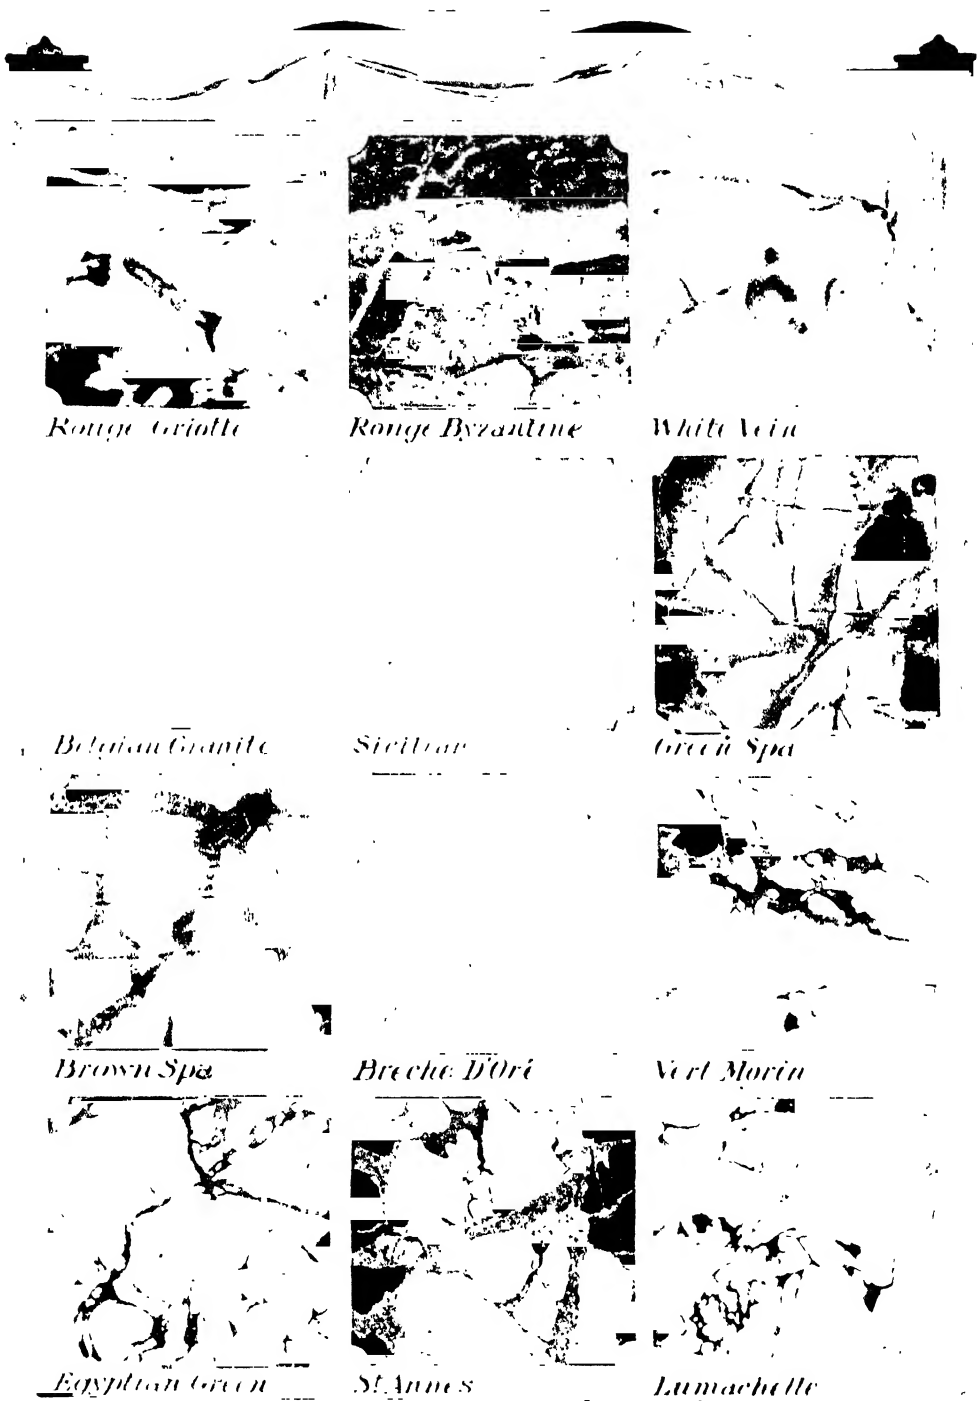
Detecting the Natural Bed. Some stones, particularly when of a laminated variety, show the natural bed at a glance, two of the faces being comparatively flat and smooth, and the others more or less in projecting portions. In other samples, stratification of coloured or crystalline particles may be observed, and when the stone contains shells the position in which they are bedded may indicate the natural bed, as they would originally be deposited horizontally. Sometimes wetting a stone helps to show up the difference in the faces and make the stratification more apparent. If the water be applied gradually, the direction in which the moisture spreads most rapidly indicates the natural bed. Under a magnifying-glass the particles composing the stone may be observed flattened in the direction of the pressure, thus showing the beds. When it cannot be detected by the eye, the mason can often tell by the feel of the grain in working it.

In considering the principal stones used in building, it will be desirable to begin with the oldest group.

Basalt. Basalt is the general name given to those igneous rocks of volcanic origin which by eruptive agencies have been forced as lava through granite and the superincumbent strata to all levels at various times. Basalts are nearly homogeneous, the component materials being finely divided and equally distributed throughout the mass, while granites consist of crystals of such size as to render the composition clearly evident on inspection. True basalt is found all over the county of Antrim in Ireland, in the Hebrides, and the North and Midland counties of England. It is of a dark green, or nearly black, colour, and so difficult to quarry and work that it is only used for road metal, paving setts, and pitchers, and the manufacture of artificial stone. It is composed of lime-felspar, augite (silicate of magnesia), olivine, and titanoferrite; when the felspar predominates, the colour is rather lighter. It generally occurs in dykes or sheets, penetrating other rocks, or lying between them or upon the surface, sometimes stratified, and at other times columnar, with six or eight sides, as in the Isle of Staffa or the Giants' Causeway. Basalt lava blocks, either rock-faced, or with drafted margins, form good plinths for heavy buildings.

Trap Rocks. Trap rocks consist of a mixture of felspar and hornblende, varying from a dense mass without apparent grain to a granular crystalline structure. The names of the varieties depend upon the district from which they come. The colours vary from greenish-grey to black. When stratified, this stone may be easily converted to paving setts, but is not suitable for use as a building stone, owing to its decomposition on exposure to the weather.

Greenstone. Greenstone is distinguished from true basalt by its containing hornblende; for example, that found at Penmaenmawr in



MARBLES OF COMMERCE, SHOWING VEINING AND COLOURING

North Wales, and at Rowley Regis in Staffordshire, known as Rowley Rag. The Penmaenmawr stone is easily split for paving setts by cutting a fine line with an axe in the direction required, and then tapping smartly with a hammer.

Whinstone. Whinstone is similar material found in various parts of Scotland. It is used as road metal.

Serpentine. Serpentine is a hydrated silicate of magnesia mixed with carbonate of lime, steatite or soap-stone, and diallage, which is a foliated variety of hornblende and dolomite. It is found in all shades of green and red, and takes its name from the mottled streaks and patches in which the components are arranged. It occurs in Galway as Connemara marble; in the Shetland Isles and North of Scotland, Anglesea, and Cornwall. It is compact in texture, but soft and easily worked, takes a fine polish, and is used for interior decorations, as it does not weather well for outdoor use in towns. The red varieties weather better than the green. They are quarried in blocks two to three feet long.

Porphyry. Porphyry is a stone of varied colours, consisting of a fine matrix with larger crystals interspersed. Felstone, or felsitic porphyry, has a base of quartz and orthoclase, known as felsite, with independent crystals of felspar. Quartziferous porphyry has a base of a granular crystalline compound of quartz and felspar, with independent crystals of quartz and felspar. It is used chiefly for road metal and paving setts, but the fawn-coloured sorts are sometimes used as building stones, although they cannot be obtained in very large blocks.

Porphyritic Granite. Porphyritic granite from Penzance and Land's End has large crystals of felspar, known as horses' teeth, and has a yellowish tint. *Shap Fell* is a porphyritic granite from Westmorland, and is of a pink, or reddish-brown colour. It takes a fine polish, and is largely used for decorative work, of which London examples are the columns at St. Pancras Station and the posts enclosing the western area of St. Paul's Cathedral.

Granite. Granite is the general term for granite and syenite and for stones of intermediate composition. It is an igneous rock of granular crystalline structure, consisting of 50 to 60 per cent. of quartz in crystals, 30 to 40 per cent. of felspar in amorphous lumps, and about 10 per cent. of mica in small detached glittering particles. The felspar is very irregular in size, and its colour gives the tone to the mass. The durability of granite depends principally upon the proportion of quartz it contains, on the regular distribution of the felspar, on the smallness of the mica grains, and upon the absence of iron in any form. The mica is the most liable to decay, but the felspar is sometimes in a state of incipient decomposition into kaolin, or porcelain clay. Potash felspar is more liable to decay than lime-and-soda felspar. There is very little waste in a granite quarry, as the larger pieces are used as building blocks, the smaller for road metal, and the chippings for the manufacture of artificial stone.

Aberdeen Granite. This granite is considered one of the best. It is a clear grey, very durable, and takes a high polish. It is extensively used for building purposes in the neighbourhood of the quarries, also for bridges and dock work. In London it is used for polished columns, pilasters, plinths, and other architectural features. It is better to have it dressed at the quarry, as it is easier to work before the quarry sap has dried out. The local men, from their experience, can also usually work it with greater facility; and as most granite quarries have machinery on the spot, those portions which can be so worked can with advantage be dressed at the quarry. The saving of freight in the reduced weight is also a consideration.

Peterhead Granite. This is a well-known variety, of a good red colour, taking a fine polish. It is largely used for constructional and decorative purposes. The pillars of the Carlton Club, London, are of Peterhead granite.

Guernsey Granite. Guernsey granite is very hard, and tends to become slippery when used for paving setts and pitchers, but is very durable. It has a close grain and bluish colour, and is generally heavier than Scotch granite.

Irish Granites. Irish granites have various shades of grey, as a rule, but that from Galway has a reddish tint, and Newry furnishes a granite of greenish colour which is more correctly a syenite.

Norway Granite. This variety, generally grey, but obtainable in other colours, is very largely used for kerbstones, for which it is preferred, as it may be obtained in long lengths.

Syenitic Granite. This granite has the addition of hornblende to the other minerals in ordinary granite. De Lank granite from Cornwall is one of the best known, and is highly appreciated from its density and light-grey colour. It is hard, compact, and durable, and was used in several works at Portland, Milford, and Devonport, as well as for Eddystone and Beachy Head lighthouses, and in Blackfriars Bridge.

Syenite. Syenite is similar in general appearance to granite, but consists of crystals of quartz, felspar, and hornblende, the latter taking the place of the mica in ordinary granite. The name is derived from Syene, in Upper Egypt, but it is also found in Leicestershire, Merionethshire, and the Channel Islands. It is generally of a dark blackish-green colour owing to the hornblende, and containing some pink, grey, or pinkish-brown crystals of felspar, according to the locality from which it is derived. It is on the whole tougher, harder, more compact, and of finer grain than ordinary granite, and of a darker colour. It is the most durable of the granite class, and will take a fine polish, but is used principally for paving setts and road metal. When the expense is not prohibitive, it may be used for exterior decoration.

Leicestershire Granite. This is a true syenite, but the colour is variable, that known as Charnwood being dark-green, Clift Hill dark-green and pink, while others are blue and pinkish-brown.

Elvan. Elvan is a fine-grained crystalline stone, composed of quartz and felspar, found in Cornwall and Devonshire; like a granite, but without mica.

Gneiss. Gneiss belongs to the metamorphic group, composed of quartz, felspar, and mica. The latter constituent occurs in layers, giving an appearance of stratification, and enabling the stone to be easily split. It is used as a building material in the bodies of walls, and also for flagging.

Mica Schist, or Mica Slate. This stone is composed of mica and quartz in thin layers, of a silvery grey, glistening colour. It is used for flagging.

Hornblendic Schist, or Hornblende Slate. This consists principally of hornblende, with a little felspar and quartz. It is tougher than mica slate, runs thicker, and is superior for flagging.

Slate. Slate is a stone formed of compressed clay, derived from the decomposition of felspar in the granite rocks washed down into ancient sea-beds, and there subjected to great pressure and heat, and the cleavage planes developed afterwards by lateral compression due to the shrinkage of the earth's crust. It is, therefore, originally an aqueous or sedimentary rock, but classed as metamorphic owing to the changes wrought in its constitution by igneous action.

The action is supposed to have been somewhat as follows: The original grains, more or less rounded, as shown in **48**, were compressed by superincumbent deposits into laminated beds [**49**], as in ordinary stratification, and then, by the great horizontal pressure due to the shrinkage of the earth's crust, the layers were forced to take a more or less vertical position [**50**]. This resulted in the original beds becoming convoluted, as shown by the wavy lines in **51**, and in cleavage planes being created, as shown by the straight inclined lines in the same figure. The upper surface being denuded by the action of the weather, glaciers, etc., does not often follow the line of the stratification.

Slates are found chiefly in North Wales, but also in Cornwall, Lancashire, and Westmorland. The blocks are sawn to various lengths, according to the size of slate required, separated into pillars [**52**], and then split along the cleavage planes to an average of $\frac{3}{16}$ in. thick. The most usual sizes are Duchesses, 24 in. by 12 in.; Countesses, 20 in. by 10 in.; Ladies, 16 in. by 10 in.; and Doubles, 13 in. by 10 in. Blue slates are obtained from Bangor, Cefn, East Cornwall, Launceston, and elsewhere. Purple slates from Carnarvon and Penrhyn; green from Elterwater, Tilberthwaite, Kirkstone, &c.; grey from Yeolmbridge and Garrybeg; red from Dinorwic. Although chiefly used for roof coverings, owing to their comparative lightness and durability when exposed to the weather, larger slabs are used for chimney-pieces, ..., shelves, steps, tanks, paving, etc., and for many other purposes in the neighbourhood of the quarries. A good slate should have a clear ring when struck with the knuckles, should be free from any earthy smell when wetted, and when stood to half its depth in water should show no perceptible rise of moisture. The conversion of a block from the quarry into roofing slates is shown in **52**.

American Slates. American slates of various colours have been introduced, but they only have one quality to recommend them—viz., cheapness in first cost.

Westmorland Slates. Westmorland slates are thicker and coarser than Welsh slates. They are not made to any special size, and are termed *ton* slates, being sold by weight instead of numbers. They are sorted out into sizes on the job, the largest being fixed at the eaves, and the courses diminished in width as the ridge is approached. They are sometimes laid like glass in a conservatory roof, with a simple lap at the ends, butting at the sides against a fillet down the centre of the rafters, and the joint covered with a twice splayed wood fillet.

Enamelled Slate. Enamelled slate is used for lavatory tops, table tops, and chimney-pieces. Cornish slate makes the best slabs, but inferior slate is generally used for enamelling. The slabs are planed and rubbed, coloured black, and placed in racks in a large oven heated to 300° F. When removed, they are coloured to imitate various marbles, and again heated, and finally polished with rottenstone.

Slatestones, or Tilestones. These are not true slates, although called slates locally. A true slate does not split along its bedding planes, but along cleavage planes, more or less at right angles to the bedding planes, while the tilestones are sandstones or limestones that split easily along their bedding planes, and thus form slabs that may be used for roofing purposes. The best known are perhaps the Colyweston slates from Stamford, in Rutlandshire, consisting of a dark-grey limestone. The blocks are split into slabs by having water thrown on them in the winter, when alternate freezing and thawing cause the splitting.

Sandstones. In sandstones the grains of quartz or silica forming the mass of the stone are indestructible, but the cementing material may be very liable to decay, as happens in the case of carbonate of lime. A dull, earthy appearance in sandstone indicates a poor quality. When the cementing material is siliceous the stone is most durable. Sandstones may be classed, according to their physical character, as liver-rock, flagstones, tilestones, and grits; or according to their composition, as micaceous, calcareous, felspathic, and metamorphic.

Shamrock Stone. This stone, which comes from Liscannor in Ireland, is a blue-grey millstone grit of two kinds, both very hard and durable. That from the top bed is used for

kerbs, setts, pitching, and building blocks for engineering purposes. That from the lower bed is slightly laminated, and can be split very truly for pavings, landings, flags, and steps. It is very durable, as it is free from carbonates.

Bristol Pennant, or Blue Pennant. This is a hard sandstone of a blue colour, very good for municipal work, such as pavings, kerbs, channelling, and pitching; also for steps, landings, caps, copings, and girder-beds.

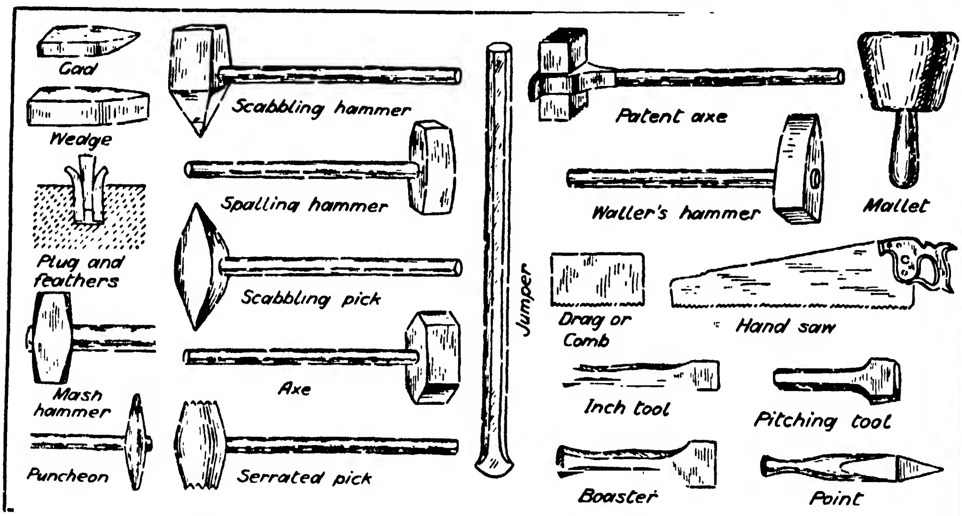
Craigleith and Hailes Stone. This is considered to be the most durable sandstone, containing only 1·1 per cent. of carbonate of lime, and 98·3 per cent. of silica. It is a silvery white or pale-grey colour, with crystalline fracture, and largely used for all purposes where strong, good weathering stone is required. It is very free from defects.

Darley Dale. Darley Dale is a white sandstone with very little carbonate of lime, but containing 1·3 per cent. of oxide of iron and in three distinct beds, the first two series being of a grey colour, and the bottom bed of a bluish tint. The stone is well adapted for building or for heavy engineering work, such as docks and bridges. It was used in the construction of Cardiff, Swansea, Gloucester, and other docks.

Closeburn Red Freestone. This variety, quarried in Dumfriesshire, has very good weathering qualities. Examined under a microscope, it is seen to consist of angular fragments of quartz, with a cementing matrix of a ferruginous silico-argillaceous character, by which they are firmly interlocked. It has a good red colour, which does not fade.

Robin Hood. Robin Hood is a greenish-grey sandstone, quarried near Wakefield, in Yorkshire. It is very durable, and is largely used for landings, staircases, and sawn slabs.

Park Spring. This is a light ferruginous brown sandstone from Farnley, near Leeds, in Yorkshire, occurring in irregular beds. Much of



TOOLS USED IN QUARRYING AND WORKING STONE

alumina. It is compact and very hard, and is extensively used for general building purposes, as it weathers well.

Abercarne. Abercarne is a blue Welsh sandstone, very similar to blue Pennant.

Bramley Fall. This is the most noted of the Yorkshire sandstones, of homogeneous structure. The original is all worked out, but good stone is still obtained from the same neighbourhood, although in thinner beds. It is much subject to iron stains. The lamination of York stone, as used for flags, is due to plates of mica running in one plane.

Scotgate Ash. This is a light-brown York stone, chiefly used for steps, landings, copings, and sinks. One of the beds is called ragstone, which is recommended for heavy engine bases and foundations.

Forest of Dean Stone. This stone, found in the coal measures of Gloucestershire, is the stone known as Park Spring comes from other quarries.

Beer. Beer is classed both as a sandstone and limestone, owing to its constituents. It is a light-brown Devonshire stone, soft when first quarried, but becoming harder by exposure.

Limestones. Limestones, when compact and crystalline, are almost free from defects. As a class, they are rather soft and absorbent, and liable to sand cracks. They vary very much in texture, from the pure crystalline structure of marble to the roe-like structure of Ketton and Bath stone, the shelly structure of Ancaster, Purbeck, and Portland, and the homogeneous structure of Kentish Rag. They are classified, according to their physical properties, as compact limestones, granular limestones, shelly limestones, and magnesian limestones.

Keinton Stone. Keinton stone is a blue lias limestone used for floors, landings, steps,

hearths, pavements, kerbs, and channeling, and is both cheap and lasting. It is also used in the manufacture of lias lime.

Kentish Rag. This is a very homogeneous stone of a blueish colour, extremely tough, so that it is not readily dressed with chisels. It is commonly used as a facing stone for churches in the style known as "polygonal ragwork." It is liable to patches of hassock, which is a soft, porous stone like compact sand. It is also liable to pockets of iron pyrites, which, if exposed to the atmosphere, oxidise and cause rust stains. Of the various beds, *Pelsea* yields large hard blocks 12 in. thick, but difficult to quarry. *Whiteland Bridge* produces blocks 12 ft. long of any width, and is very free in working. *Horsebridge* yields blocks of good stone 15 ft. long and 16 in. thick. The other beds yield only small stones fit for rubble, kerbing, and pitching.

Marbles. *Ashford* is a black Derbyshire marble used for chimney-pieces. *Berry Pomeroy* is a red and white Devonshire marble. *Carrara* is an Italian marble of a pure white, close-grained and uniform, used for statuary, headstones, and chimney-pieces. *Rouge Royal* is a French marble, red and brown veined, used for chimney-pieces and table tops. *Tullamore* is a grey Irish marble used for chimney-pieces and internal decorations. *Hopton Wood* is a fine-grained, compact stone of a warm light-grey colour. It weathers well, and is largely used for steps, paving, etc.; it will also take a good polish, and may be classed as a marble. *Purbeck Marble*, from the upper oölite beds, is of a grey colour, and is capable of taking a polish, although cavities frequently occur which have to be filled with wax. It was much used for the slender shafts in the interior of old churches, as in the Temple Church, London, and is still largely used for internal church work. The veining and colouring of the best figured marbles are shown in the frontispiece.

Oölites. This name is given to those limestones which show a distinct structure like the hard-roe of a fish. As a rule, they are bad weathering stones. *Portland Stone* is obtained from the upper parts of the oolitic series, and consists of four distinct varieties of building stone, known as *True Roach*, *Whitbed*, *Curf*, and *Basebed*, all of which are of a whitish-brown colour, weathering to a bluish tint, but of widely different structure. The section of a Portland-stone quarry is shown in **53**. The upper portion being excavated, the top cap and roach are blasted, and the whitbed and basebed are quarried by wedges and levers. True roach may be distinguished from the other varieties by the peculiar fossil it contains, known as the "Portland screw" [**54**]. This stone is tough, strong, weathers well, and is particularly good for resisting the action of water, for which reason it has been largely used for breakwaters, dock and sea walls, etc. Whitbed is, perhaps, the most valuable building stone in the Portland series. It weathers admirably, is easily dressed to a smooth surface, and will take a fine arris, and is therefore suitable for the best class of ashlar work. Curf, or bastard roach, resembles true roach very closely, but is inferior in almost every respect. It is largely used in the locality of the quarry, and is suitable for foundations and backing walls. Basebed is almost identical with whitbed in appearance, but is softer, and not such a good weathering stone; it is well adapted for the finest class of internal work and carving.

Ancaster. Ancaster is a cream-coloured compact, and fine-grained oölite, but is found both white and brown. The white is a hard, close-grained stone, with small hard shells apparent. It works very much like Bath stone, and weathers well. A number of the Lincolnshire churches are built of this stone, and it is used locally for building work generally, but in London its principal use is for door and window dressings.

Bath Stone. Bath stone is the name applied to the stone found in the Great, or Bath oölitic formation. It is obtained from many different quarries, of which Box Ground, Corsham, and Coombe Down are among the best. Box Ground is the best weathering stone, and is largely used for dressings, carved, and moulded work. Corsham, when fine-grained, is used for sculpture and mouldings, but that known as "corngrit" Corsham is very hard, and especially suitable for engine-beds, landings, etc.

Caen. Caen is a fine oölite found in Normandy, and largely imported into England. It weathers badly, and is unsuitable for external work, but it is well adapted for internal carving, and is much used for internal decorative work.

Chilmark. This, also known as *Wardour* stone, and in London as *Tisbury*, is a light greenish-grey to yellowish-brown oölite. It is largely used for building work generally, but is specially suitable for steps, pavings, and road metal, also for heavy engineering work, and any position exposed to wet and hard wear; the Pinney beds for door and window dressings, moulded string courses, cornices, etc.; Trough bed for steps, and Wardour Garden bed for internal moulded arches where great strength is required.

Doulting Stone. This is a shelly, granular oölite, the colour of which varies from cream to a light brown. It is very uniform in texture, durable, free working, and is largely used for general building purposes.

Edithweston Freestone. This stone is similar to Ketton stone, and from an adjacent quarry. It is of a fine, even texture and good colour, easily worked with a fine arris, hardens on exposure to the weather, and withstands London smoke.

Ham Hill. Ham Hill is a light yellowish-brown stone, bright when first quarried, but the colour soon tones down. The beds vary considerably in quality, but the best is very durable and strong, weathers well, and is used for facings and dressings.

Ketton. Ketton is a very durable oölitic stone, of a creamy-pink colour, called roestone by masons. It is suitable for dressings, plinths, stairs, etc., and was used in the recent parts of Peterborough and Ely Cathedrals, and at St. Pancras Station. The ragstone beds are white, cemented with highly crystallised carbonate of lime.

Painswick. Painswick is a cream-coloured limestone from the upper oölite, of very uniform grain. It is suitable for internal staircases, and was used in the construction of the Houses of Parliament.

Seacombe. Seacombe is a light-grey to light-brown oölite from the Purbeck beds. The whitbed from this quarry is a very good stone, of even colour, strong, and very durable under wear, so that it is an admirable stone for stairs. It is also used for kerbing and for dock walls.

Dolomites. Dolomites are those magnesian limestones which have an atom of carbonate of lime for each atom of carbonate of magnesia, giving a result equivalent to an alloy in metals. *Bolsover Moor* is a light yellowish-brown magnesian limestone. This stone was at first selected for the Houses of Parliament, but the quantity required was more than the quarry was capable of supplying. It is a durable building stone, and is also largely used for paving. *Roche Abbey* is a whitish-cream stone which weathers dark, and in lines according to the beds. It is, however, used for general building purposes. *Mansfield (yellow)* is generally classed as a limestone, as half its bulk consists of carbonate of lime, but some Mansfield contains a much larger quantity, and is on that account not such a good weathering stone. *Mansfield (red)* is classed as a siliceous dolomite; it is a ruddy brown, and loses some of its colour on exposure, and is a fairly good weathering stone. *Mansfield (white)* is a similar stone, of a greyish-white colour, used for steps and landings. Both these varieties, red and white, are sometimes classed as sandstones.

Artificial Stone. Artificial stone is a manufactured article intended to be used as a substitute for natural stone. There are many different kinds, passing under distinctive names, but they may be classed under three groups: Ordinary, or simple cement concretes; hardened cement concretes; and chemical stones. Simple concretes are mostly composed of granite aggregate, with Portland cement as the matrix, and they have the advantage of either being laid *in situ* or cast in moulds to the true form required. Some of the best known simple concretes made are: Stuart's Granolithic, Ward's Synthetic Stone, Globe Granite, and Basaltine Stone, the aggregate of the last-mentioned differing from the others in that it consists of basalt chippings, while trass is mixed with the cement. Of those concretes which are subjected to the hardening processes, Victoria Stone, Imperial Stone, Indurated Stone, and Empire Stone, are perhaps the best known.

Victoria Stone. Victoria stone consists of an aggregate of crushed Leicestershire granite After the aggregate has been well washed, three parts are thoroughly mixed with one of Portland cement in a dry state, and the water then carefully added, to prevent washing out the fine cement. As soon as mixed, and before any setting takes place, the mixture is put into the moulds, care being taken to fill up all the corners in order to obtain fine arrises. When filled, the moulds are allowed to remain until the concrete has sufficiently set, the fastenings are then released, and the moulds, which are made in pieces, can then be readily detached. The slabs are next placed side by side in a tank containing sufficient silicate of soda solution to cover them, and they are left there for about 14 days. They are then stacked in the storeyard to season, and are used in the order of their age. Victoria stone is mostly used for paving slabs, but is also cast for steps, balustrades, etc.

Imperial Stone. Imperial stone is very similar to Victoria stone, the chief differences being that the slabs are subjected to steam during setting, which enables the moulds to be removed in one day; they are placed in the silicate tanks for only three days, and are stacked for six months before use. Imperial stone pipes are made in a similar manner to the slabs, the only difference being that crushed flint is used for the aggregate in the place of granite.

Ford's Silicate of Limestone. This is the best known of the chemical stones. It is made of fine sand (silica) and chalk lime in the proportions of about 94 per cent. silica to about 6 per cent. lime, mixed and rammed dry into a perforated steel box mould. The air is then extracted from the box, and boiling water forced in under pressure, which slakes the lime and then escapes through the holes. Afterwards, to ensure the thorough slaking of the lime and its combination with the silica, superheated steam is forced in under a pressure of 120 lb. per square inch. The resulting stone resembles a sandstone, and the entire operation of manufacture only takes about eight hours. *Chance's Artificial Stone* is made by melting Rowley Rag basalt and casting it in moulds to the shape required. *Rust's Vitrified Marble* consists of a mixture of glass and sand fused together and run into moulds.

Preservation of Stone. *Fluate* is a solution of fluate of magnesia, obtained by dissolving crystals in soft water applied to Bath and other soft limestones, converting them into a substance identical with fluor spar, which is insoluble, and therefore practically imperishable. For non-calcareous stones, a solution of lime is first used upon which the fluate can act.

Szerelmey's Stone Liquid. This is a soluble glass, which is painted on the surface, and is slowly absorbed, penetrating the surface and forming a waterproof layer impervious to moisture. It is transparent, but can be coloured to any shade desired.

Painting the stone is sometimes done, but is not desirable, as it changes the colour and hides the natural grain, giving an artificial appearance. It also imprisons the moisture in the stone, and increases the risk of fracture by frost. Paints do not adhere well to stone, and, becoming oxidised by the action of the air, have to be periodically renewed

To be continued

A SYNOPSIS OF THE GEOLOGY OF THE CHIEF KINDS OF STONE

To understand the formation and relative geological position of the various stones, it is necessary to present a synopsis of the whole. Different writers adopt various classifications. The principal divisions are shown in this table.

Epoch.			System.	Group.	Character.	Contents.
Cainozoic	Tertiary	Aqueous or Sedimentary	Post Tertiary	In progress and recent	Alluvial deposits. Peat mosses. Coral reefs. Raised beaches.	Plants and animals of existing species.
			Tertiary.	Pleistocene	Fossiliferous clays and sands. Boulder or drift formation.	Plants and animals extinct but not widely different. Birds. Mammalia of existing orders. Foraminifera. Megatherium.
				Pliocene	Mammaliferous clays.	
				Meiocene	Red crag. Coralline crag.	
				Eocene	Fluvio-marine beds I. of W. Bagshot sands. London clay. Bognor beds. Plastic clay.	
Mesozoic	Secondary		Cretaceous	Chalk	Upper soft white. Lower hard, dark, few flints. Chalk marl. Tottenhoe stone.	Plants and animals, chiefly marine; now extinct. Ammonites. Belemnites. Teeth. Sponges. Corals. Coprolites. Iguanodon.
				Greensand	Upper soft or hard. Gault. Lower various. Kentish Rag.	
			Oölitic	Wealden	Weald clay. Hastings sands. Purbeck beds. Limestones.	Plants and animals of families now extinct. Hugereptilia. Palms. Coniferæ. Trigonia. Ammonites. Belemnites. Nautilus. Icthyosaurus. Plesiosaurus.
				Oolite	Upper—Portland stone. Kimmeridge clay. Middle—Coral rag. Oxford clay. Lower—Cornbrash. Fuller's earth.	
				Lias	Upper—Bituminous and alum shale. Lower—Dark limestones. Ironstones. Jet. Lignite.	
			New Red Sandstone	Trias	Upper—Variegated marls. Gypsum. Rock-salt. Variegated sandstones. Corsehill, Grimshill, and Runcorn stones.	Plants and animals not abundant. Families extinct. Palms. Pines. Small bony fish.
Palæozoic			Carboniferous	Permian	Middle—Laminated limestone. Gypseous marl. Magnesian limestone. Marl slates. Lower—Red sandstone on coal.	
				Coal measures	Coal.	Plants and animals abundant. Excess of tropical vegetation. Tree ferns. Equisetums. Marine shells and zoophytes. Encrinites. Terebratula.
				Millstone grit	Fireclay. Ironstone.	
				Mountain limestone	Carboniferous limestone.	
				Lower coal measures	Carboniferous slates.	
			Old Red Sandstone	Yellow sandstones	Fine-grained stone. Scotch pebbles.	Plants few and imperfect. Fishes abundant. Other animals rare. Ganoid, placoid and ctenoid fish. Small reptiles.
				Red conglomerates	Coarse red conglomerate. Red sandstone.	
				Grey fissile sandstones	Grey micaceous and flaggy sandstones.	
			Silurian	Upper Silurian	Ludlow tilestones. Wenlock limestones.	Trilobites. Graptolites. Serpulites. Encrinites. Terebratula. Orthoceris.
				Lower Silurian	Llandeilo rock. Shelly limestone. Freestones.	Eozöon.
Azoic	Transition		Metamorphic	Clay Slate	Roofing slates and slabs.	No Fossils.
				Gneiss and Mica Schist	All hard crystalline rocks.	No Fossils.
	Primary	Igneous	Igneous	Granites and Basalts	Granite. Syenite. Whinstone. Greenstone.	No Fossils.

POETRY OF THE ELIZABETHAN AGE

I. The Lyric Poets. Being a Short Study of Sidney and Spenser, and a Review of the Lesser Writers to the End of the Sixteenth Century

By J. A. HAMMERTON

WHEN we turn our attention to the poetry of the Elizabethan age, it is as though we were looking with unskilled eyes upon a starry heaven, so bewildering and so brilliant are the names that glitter in the literary firmament of that wonderful age—Shakespeare, the " bright particular star." With the awakening of the English nation to a new and grander perception of national patriotism, the dusky clouds of mediævalism had been suddenly dispersed by the bright sun of a new day.

It is indeed hard to resist the temptation which besets every writer on the Elizabethans to let rhetoric displace criticism, to decorate one's chronicle with " purple patches." But here the necessity to condense is so imperative that we must content ourselves by dealing very briefly with most of the poets who now call for attention ; and, as in almost every case it will be necessary for the reader to make direct acquaintance with their work, there is the less need for biographical or critical detail. This may be thought an unprecedented method to adopt, but we are prepared to defend it on the ground that in a practical guide to English Literature it is more necessary to deal at some length with those writers who, while sufficiently important from the historical point of view, are not urged upon the reader for his personal study, than with those whose works must be read.

The New Era. Of course, there was nothing miraculous in the outburst of poetry which heralded and accompanied the Elizabethan age ; the dawn of the new era did not come so suddenly as the hyperbole of the impassioned historian would suggest. If from the time of Chaucer the genius and imagination of the country had languished, scholarship, at least, had ripened ; and, as we have heard, the mediæval age did not pass away without leaving a legacy to the age that followed, since the English language had assumed, in the poetry of Wyatt and Surrey, a greater perfection of form than it had hitherto possessed, and it was now to be used by writers imbued with loftier idealism than that of the age of chivalry and old romance. But for some little time yet we would naturally expect to find the older notions of life still actuating writers who, chronologically, are to be reckoned Elizabethans. This is true in some measure of Spenser and his friend and patron, Sidney, both of whom were born some four years before the accession of Elizabeth.

SIR PHILIP SIDNEY

Sir Philip Sidney. Although the figure of SIR PHILIP SIDNEY (b. 1554 ; d. 1586) is one of the most familiar in literary history, it is not unreasonable to suggest that this is due as much to his remarkable qualities as a man as to his literary gifts. Indeed, we do not purpose dwelling at any length on Sidney's poetry, for he will merit more consideration when we come to the study of English prose. Wyatt and Surrey could write sonnets as good as his, but he was the first to write the prose of art. We notice, for instance, that the late Francis Turner Palgrave, an unerring judge, could find only one little love ditty of Sidney's to include in his " Golden Treasury of English Songs and Lyrics." None the less, Sidney was a poet of no mean parts, somewhat affected, it is true, but destined to live in several of his sonnets, such as that beginning, " With how sad steps, O Moon, thou climb'st the skies," and another, " Come sleep, O sleep, the certain knot of peace." But so much good poetry has been written since the days when Sidney was deemed by his admiring contemporaries one of the foremost literary men in England that readers of to-day need not fear the charge of philistinism if they are content merely to make his acquaintance in a volume of selections.

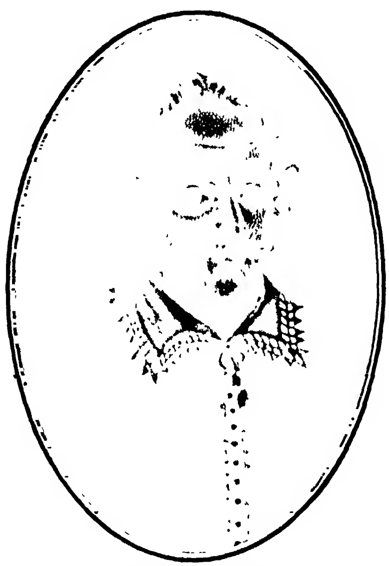
About the Sonnet. We print on the next page one of the sonnets above-mentioned to illustrate at once a good example of Elizabethan verse and the reason why it falls short of perfection. It is part of our plan, as we proceed with our studies, thus to give specimens of each new form of verse when it comes up for consideration.

"With how sad steps, O Moon, thou climb'st the skies,
How silently, and with how wan a face!
What! may it be, that even in heavenly place,
That busy Archer his sharp arrows tries?
Sure if that long-with-love-acquainted eyes
Can judge of love, thou feel'st a lover's case;
I read it in thy looks; thy languish't grace,
To me that feel the like, thy state descries.

Then, even of fellowship, O Moon, tell me,
Is constant love deem'd there but want of wit?
Are beauties there as proud as here they be?
Do they above love to be lov'd, and yet
Those lovers scorn whom that love doth possess?
Do they call virtue there ungratefulness?"

A careful reading of these verses will show that the poet has not risen superior to the exigencies of rhyme, for in the last line sense is subordinated to sound, the question being not whether virtue is there called ungratefulness, but whether ungratefulness is there called virtue. If we transpose the two words the line is intolerable, having neither rhythm nor rhyme. As it stands it has both, but the sense is obscured. The strict form of the sonnet as it was brought to perfection by the Italians — Petrarch, Tasso, and Dante—gave two rhymes only in the first eight lines or "octave" arranged as above, and two only in the concluding six lines, or "sestette," where Sidney has used three, a change of thought being expressed in the second division of the little poem. Neither Wyatt nor Surrey observed these rules strictly, and innumerable arrangements of the rhymes have been adopted, but a sonnet must never have more or less than 14 lines, and in this narrow space many a masterpiece of poetry has been composed.

Edmund Spenser. Sidney's friend, EDMUND SPENSER (b. 1552; d. 1598), was a poetical star of much greater magnitude. Indeed, Spenser is esteemed by many the finest of English poets before Shakespeare, though his great contemporary, the unhappy Christopher Marlowe, was to exercise far more influence over the greatest of all poets. Remembering the point of view we are endeavouring to maintain, it is difficult to decide how we are to regard the poetry of Spenser. As far as possible we are striving to repress mere personal inclination in dealing with each writer; but we are constrained to confess ourselves among those who have found it a tedious task to read "The Faëry Queen," the most celebrated of Spenser's poems, and consequently hesitate to urge it upon others. When Pope was only 12 years old he read it "with infinite delight," and Southey confesses to having read it thirty times over; but it is doubtful if the enthusiasm of these eminent admirers of the poet is alone sufficient to induce the ordinary reader to bear Spenser company through the six books of "The Faëry Queen." In the plan of the work we still find that characteristic of mediæval literature, a set scheme of stories told for some given purpose, as in the "Decameron" and "The Canterbury Tales." The Fairy Queen is supposed to be holding her annual feast, of 12 days' duration, and on those 12 days 12 different complaints are submitted to her. To redress the wrongs thus brought to her knowledge she commissions 12 knights, each of whom is noted for a certain virtue, and his doings are celebrated throughout a whole book. But, in addition to such heroes as the Knight of the Red Cross (Holiness), Sir Guyon (Temperance), and the lady-knight Britomartis (Chastity), there is the superlative figure of Prince Arthur, in whom all knightly virtues are combined, and who, appearing in every book, is designed as the general hero in quest of Gloriana, or Glory.



EDMUND SPENSER

The Spenser Stanza. It has been considered by good critics that the verse of "The Faëry Queen" was an ill choice on the part of Spenser, who, taking the stanza of eight decasyllabic lines, added a ninth, two syllables longer than the others, thus unduly drawing out the metrical movement and handicapping himself in the choice of rhymes, in which the English language is by no means rich. But many of our finest poets have used the same stanza with perfect effect, as in Burns's "The Cotter's Saturday Night." We give an example of the "Spenser stanza":

"A gentle knight was pricking on the plain,
Yclad in mighty arms and silver shield,
Wherein old dints of deep wounds did remain,
The cruel marks of many a bloody field;
Yet arms till that time did he never wield:
His angry steed did chide his foaming bit,
As much disdaining to the curb to yield:
Full jolly knight he seem'd, and fair did sit,
As one for knightly jousts and fierce encounters fit."

The last line is called an Alexandrine, as it is of that measure of verse first used in early French romantic poems on Alexander the Great. Pope criticised it in his well-known couplet:

" A needless Alexandrine ends the song,
That like | a wound | ed snake | drags its | slow length | along."

Spenser's Place among the Poets. But there can be no manner of doubt as to the eminent place of Spenser among the English poets (if we except such untempered praise as Dryden gave him), for he is an obvious master of epic poetry, his invention inexhaustible, the rhythm of his verse the very perfection of poetic form, his imagination so rich and sensuous that Campbell aptly called him "the Rubens of English poetry." Despite all this, and the fact that he is Milton's acknowledged master, it is true that he is not, on the whole, a poet for the general reader; and, let the critics say what they may about the critical shortcomings of Macaulay and Hume, there is more honesty in the statement of the latter than in the affected enthusiasm of many Spenserites when he writes: "The tediousness of continued allegory, and that, too, seldom striking or ingenious, has also contributed to render 'The Faery Queen' peculiarly tiresome; not to mention the too great frequency of its descriptions and the languor of its stanza. Upon the whole, Spenser maintains his place upon the shelves among our English classics; but he is seldom seen on the table." Macaulay, too, is very human when he complains that "we become sick of the cardinal virtues and deadly sins, and long for the society of plain men and women." Spenser has been called "the poet's poet," which means that to get the best from him the reader himself must be of so poetic a temperament that "the linked sweetness long drawn out" of his poetry does not cloy, but rather whets and stimulates the mental appetite. Still, Spenser is a poet with whom the ordinary reader should at least make acquaintance, as some knowledge of his writings is essential to the proper appreciation of Elizabethan literature. His first great work, "The Shepherd's Calendar," a tuneful but joyless and affected pastoral poem, with little of the warm humanity we find in Chaucer, is to be regarded as the opening pæan of that mighty chorus which we call the Elizabethan poetry.

His Life. Spenser was born in London of a poor, but honourable family, some five or six years before the accession of Elizabeth in 1558. Educated at the Merchant Taylors' School and Cambridge University, he early won the friendship of Sidney, to whom he dedicated the "Calendar," and it was through the influence of his friend that he received, in 1580, an official appointment in Ireland, where the remainder of his short life was passed, for the most part, in a state of prosperity. In 1590 the first three books of "The Faery Queen" were published, and brought him great fame. Six years elapsed before the other three and a fragment of the seventh were printed, and three years later, a fugitive from the rebel Irish who had sacked and burned Kilcolman Castle in County Cork, which for more than 10 years he had occupied under Royal favour, we hear of his death at a tavern in King's Street, Westminster—"for lacke of bread," said Ben Jonson, despite all his fame.

Raleigh and Others. Sir Walter Raleigh (b. 1552; d. 1618) is only incidentally a poet. He belonged to an age when every man of note seems to have had some literary talent, and his verse is graceful, free from the more pronounced affectations of the period, but of no extraordinary quality. More noteworthy are his prose writings.

Sir John Harrington (b. 1561; d. 1612), the translator of Ariosto, the Italian poet, need only be mentioned; none but specialists in the period will care to acquaint themselves with his work. And the same may be said of Edward Fairfax (b. about 1580; d. 1635), though all scholars who can speak with authority are agreed that his translation of Torquato Tasso's "Recovery of Jerusalem" is admirable, and much superior to Harrington's rendering of "Orlando Furioso."

Michael Drayton. A Warwickshire man and a friend of Shakespeare, who entertained him and Ben Jonson at Stratford a few weeks before his death, Michael Drayton (b. 1563; d. 1631) was a lyric and descriptive poet of very unusual qualities. He was not a great poet, though certain of his contemporaries entertained the most extravagant estimate of his merits. His chief work was conceived and carried out on a plan which made it hopeless of continued popularity. It was called "The Polyolbion," and may be described as a topographical account of England, displaying wonderful learning, but utterly mistaken in its medium, which should have been prose. It contains many quick and glowing descriptions of natural objects, but some of its passages read like catalogues of birds and beasts, thus:

" To Philomel the next, the linnet we prefer;
And by that warbling bird, the woodlark place we then,
The red-sparrow, the nope, the redbreast, and the wren.
The yellow-pate, which though she hurt the blooming tree,
Yet scarce hath any bird a finer pipe than she.
And of these chaunting fowls, the goldfinch not behind,
That hath so many sorts descending from her kind."

Our quotation is given not only to show Drayton's manner, but to illustrate at greater length a metre which we have already noted in connection with Spenser's stanza. That is the iambic hexameter, or Alexandrine, first used in English by Robert of Gloucester in the latter part of the thirteenth century, and adopted by Drayton in the "Polyolbion" for the first time in modern English. Drayton is seen to better advantage in the "Barons' Wars," a long poem, which, though uninteresting on the whole, abounds in passages of great spirit. In short,

he is a poet worthy of some attention, even from those who are not making a special study of the period.

Sonneteers and Allegorists. WILLIAM DRUMMOND (b. 1585; d. 1649), of Hawthornden, near Edinburgh, the friend of Drayton and of Ben Jonson, the latter of whom visited him in 1618–19—which occasion Drummond turned to literary profit by making his "Notes" of Jonson's conversation; a very interesting chapter of literary history—was one of the most accomplished minor poets of his age, examples of his sonnets being found in most anthologies. SAMUEL DANIEL (b. 1562; d. 1619), whom Jonson described as "a good, honest man, but no poet," wrote many beautiful sonnets greatly admired by Drummond. JOHN DONNE (b. 1573; d. 1631) was the greatest preacher of his day, and a poet of the "metaphysical" school, of which, indeed, he was the chief. His "Life" is one of Izaak Walton's masterpieces. Donne's poems do not possess any great interest for the general reader. His chief characteristic is extravagant imagery, which even in purely amatory verse is offensive, but when invoking the Most High comes little short of blasphemy. Thus, in his "Hymn to Christ," written "at the author's last going into Germany," and opening with several grotesquely inappropriate conceits, he goes on in this strain:

"I sacrifice this island unto Thee,
And all, whom I love here, and who love me;
When I have put this flood 'twixt them and me,
Put thou Thy blood betwixt my sins and Thee.
As the tree's sap doth seek the root below
In winter, in my winter now I go
Where none but Thee, th' eternal Root
Of true love, I may know."

This is surely an example of the vilest taste.

GEORGE WITHER (b. 1588; d. 1667) was the most prolific writer of the time, and his work is very unequal, so that the curious way in which it has suffered neglect and revival is not surprising. Dryden was by no means unfair when he wrote of him:

"He fagotted his notions as they fell,
And if they rhym'd and rattled, all was well."

But he will always be remembered, if only for that exquisite lyric beginning:

"Shall I, wasting in despair,
Die because a woman's fair?"

THOMAS CAMPION (b. 1540; d. 1623), poet, critic, and musician; ROBERT HERRICK (b. 1591; d. 1674)—it is curious to note, by the way, that the lyric poets were all longer lived than the dramatists of the same period—one of the sweetest singers in our language, whose "Hesperides" is a collection of unrivalled lyrics; FRANCIS QUARLES (b. 1592; d. 1644), immensely popular in his own day and after as a writer of religious poems, whose "Emblems, Divine and Moral," are still worthy of attention; and GEORGE HERBERT (b. 1593; d. 1633), like Quarles, one of the least objectionable of Dr. Donne's school of metaphysical or allegorical writers, and a better than his master, were the only other lyric poets born before the close of the sixteenth century with whose works the ordinary reader need concern himself. We have space to note the names only of Thomas Watson, Phineas and Giles Fletcher, William Browne, Sir John Davies, and Thomas Carew, "that delectable versifier," among the many other minor poets born in the sixteenth century.

We have not followed the usual plan of dividing the Elizabethan age into two periods, but have deemed it more convenient for the progress of our study to thus review at once the poets who are epic, as Spenser; narrative, as Drayton; or lyric, as Sidney; reserving the dramatic writers for separate consideration. Naturally, some of the dramatists wrote lyrical verse also—Ben Jonson's "Drink to me only with thine eyes," for example, being one of the most exquisite songs in our language—but we must regard them as essentially dramatic poets. Perhaps our arrangement is somewhat arbitrary, since there was no great distinction between the lyric poets of the second half of the sixteenth and the first half of the seventeenth centuries, and there was necessarily much overlapping of writers; but it serves at least to give us some idea of the poets of the lesser order immediately preceding, contemporary with, and following Shakespeare and the Elizabethan dramatists

Books to Read. The ordinary reader may be content to study all the poets we have mentioned in volumes of "specimens." There is no reason why he should set himself the task —for such it would be in a very real sense—of studying all their works, or, indeed, all the works of any one of them, as a very fair conception of their respective merits and their united influence on the literature of our country can be obtained by reading some of their longer poems and a selection of their minor pieces. We give below a list of books, several of which may be used for this purpose; there is abundance of such works published at low prices.

EDITIONS OF THE POETS

"The Spenser Anthology," edited by Professor Edward Arber, and published by Mr. Henry Frowde at 2s. 6d., gives an admirable selection from the chief poets between 1548 and 1591.

"The Canterbury Poets" Series (Scott, 1s. each) contains volumes of selections from Spenser, Herrick, and Herbert.

Spenser's Works in Globe Series (Macmillan, 3s. 6d.).

Drayton's "The Barons' Wars" was last published in Morley's Universal Library, at 1s.

The Lyric Poets Series (Dent, 2s. 6d. net each) contains volumes of selections from Sidney, Spenser, Herrick, and Campion.

"The Golden Treasury of English Songs and Lyrics" (Harmsworth Library, 1s. net) is indispensable to the student of poetry.

BRACED STRUCTURES

The Warren Girder. Means of Ascertaining Stability of Walls and Dams. Crane Jibs and Roof Trusses in Practice

By JOSEPH G. HORNER

Calculations for a Warren Girder. Our next example [38—40] is a Warren girder, with 56 ft. span, subjected to loads imposed at intervals of 8 ft. on the upper boom. The angle of the diagonals is 45°, the depth of the girder is 4 ft. 6 in.

Lay out the frame diagram as in 38, making its depth 4 ft., this being the approximate depth of the frame measured between the boom centres; mark off the vertical loads, and the reactions at the supports, as shown, then letter in accordance with Bow's notation, as already explained—*i.e.*, place a letter in each space between the external loads, and also one in each internal space. Note that the end vertical members being in simple compression do not enter into the diagram; also that there is no load on the end horizontal members, the final load being carried to the ends by the members LK and XK.

Load Diagram. Construct the load diagram to as large a scale as possible [39], marking off the vertical loads AB, BC, CD, DE, EF, FG, GH, and HJ, proportionate to the tons 4, 8, 8, 8, 8, 8, 8, 4, and closing it with the reactions AK and JK. Then set off the horizontal member BL until it intersects KL. Lay down the diagonal LM till it cuts KM, and so on with each diagonal and horizontal in turn. Note that members QR and RS have no load, and are consequently termed redundant members—that is, they are not theoretically necessary to the girder-frame, but are put in for convenience of manufacture, to give mechanical support to the lower boom, and for the sake of appearance.

The loads may now be scaled off, and the various sections determined. The maximum boom load occurs in ER, QK, and SK, and scales 96 tons. The area required in the bottom, or tension boom at, say, 6 tons of stress per square inch $= \frac{96}{9} = 16$ square inches, whilst the area required in the top, or compression boom at, say, 5 tons per square inch $= \frac{96}{5} = 19{\cdot}2$ square inches. These sections may be proportioned thus:

	Net area.	Gross area.
2 angles 5 in. × 5 × ½ in. =	8·7 sq. in.	9·5 sq. in.
2 plates 14 in. × ⅜ in. =	9·3 „	10·5 „
Total.. ..	18·0 „	20·0 „

Net Area. The net area allows for rivet holes cut through the section, one ⅞ in. hole in the angle bar, and two ⅞ in. holes in the plate. A single ¾ in. plate might be used in place of the two ⅜ in. ones, but it would require a very long cover-plate where jointed. Dividing the thickness between two plates also gives the option of leaving one plate off where the boom load falls to a sufficiently low value.

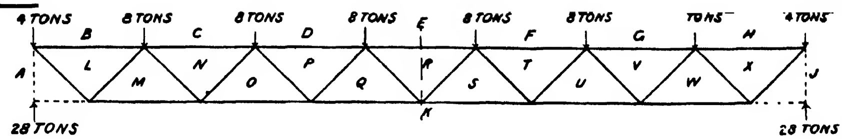
Covering Plates. In a girder of this length it is not convenient to obtain the boom sections in one length. Joints must therefore be designed and arranged, and the joint covers must have an equal area with the members which they cover. The flange-plate cover can be the same section as the flange plate—viz., 14 × ⅜ in., but the angle cover, having to lie in the hollow of the main angle, must be narrower in width by the thickness of the main angle. In this case a 4½ in. × 4½ in. × ⅝ in. angle will meet the conditions, and will give a net area of 9·5 sq. in., which is slightly in excess of what is required.

The length of a cover depends upon the number and pitch of rivets used. In the flange plate, 13 rivets, ⅞ in. diameter, will be necessary at 5 tons per square inch in shear; and, at 4 in. pitch, this works out to be a plate 4 ft. 7 in. long; in the angles 11 rivets, ⅞ in. diameter, will be found necessary, involving a length of 3 ft. 11 in. for the covering bar.

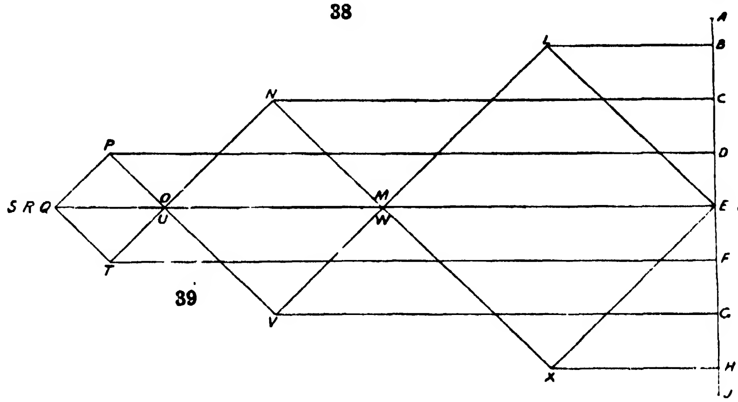
If desired, the outer flange plates could be left off when reaching bays CN, GV, MK, and WK, when the boom load drops to a quantity which a single flange plate and the angles can carry. It is, however, not usual to do this in small girders, as the level of the boom is thereby broken, and where superimposed girders occur, packings must be used to restore the level.

The maximum tie load occurs in LK and XK, and scales 34 tons. The area required at 6 tons per square inch is $\frac{34}{6} = 5{\cdot}7$ sq. in.; two 6 in. × ⅝ in. flat bars, with allowance made for a ⅞ in. rivet hole in each, gives 6·5 sq. in. area. The attachment at each end is by rivets in double shear, a ⅝ in. plate being sandwiched between the two tie bars and between the two main angles. The number of rivets required at 5 tons per square inch is eight.

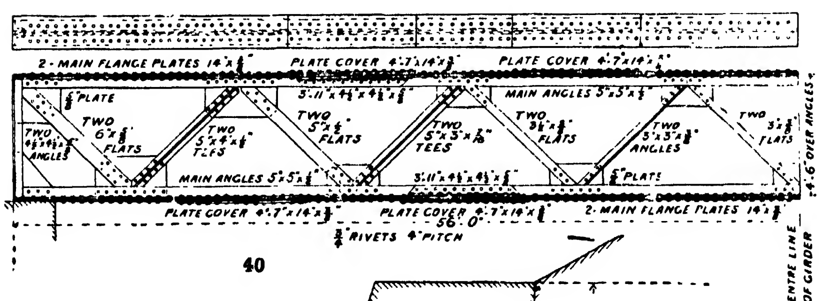
The maximum strut load occurs in LM and WX, and scales 34 tons. The free length of the strut may be taken at 4 ft., and the minimum width, say, 4 in.; the ratio of depth to length is then $\frac{48}{4} = 12$ to 1. Using Gordon's formula for columns, having both ends fixed, this ratio gives a safe load of 4 tons per square inch, with a factor of safety of 5, then the area required $= \frac{34}{4} = 8{\cdot}5$ sq. in., which will be met by the gross area of two 5 in. × 4 in. × ½ in. tee bars, the riveted connection being the same as for the tie bar, the load being identical.



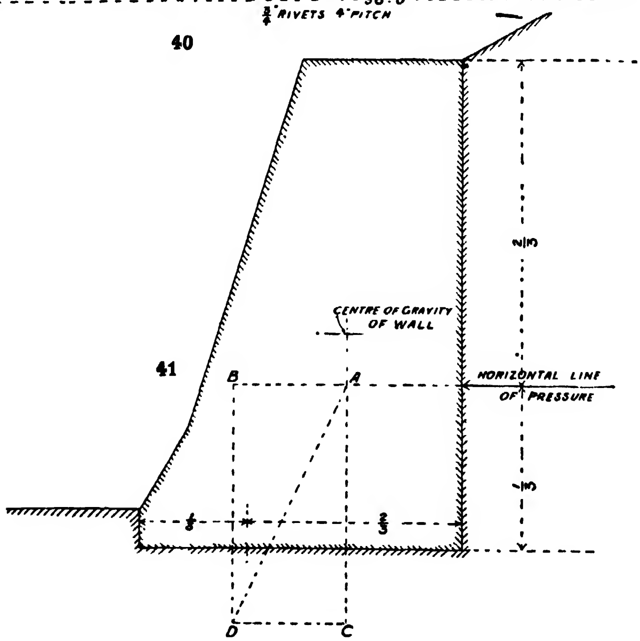
38



39



40



41

STRESSES IN A WARREN GIRDER AND A DAM

Bearing Area. In designing riveted joints it is necessary to see that the rivets have sufficient bearing area as well as shearing area. For ordinary girder work an allowance of 10 tons per square inch is usual. This consideration frequently decides the thickness of the gusset plate. In the case in hand there are eight $\frac{3}{4}$ in. rivets in a $\frac{5}{8}$ in. plate, giving a total bearing area of $8 \times \frac{3}{4} \times \frac{5}{8}$ in. $\times\ 3\frac{3}{4}$ sq. in., a bearing stress of $\frac{34}{3{\cdot}75} = 9$ tons per square inch.

The remainder of the struts and ties are now designed to suit the loads that they have to sustain, and the drawing [**40**] is completed in accordance therewith.

We shall return to these examples immediately after having shown the application of force diagrams to a dam.

Dams. The parallelogram of forces is used to ascertain the stability of retaining walls, dams, etc. **41** illustrates the application. A section of the wall is drawn to a convenient scale, and its centre of gravity marked thereon. Drop a vertical line from the centre of gravity until it intersects the "horizontal line of pressure," marked off at one-third of the height of the wall. From this point (marked A) lay off the amount of the pressure in a line from A to B, then drop another line vertically from A to C equal in amount to the weight of the wall. These pressures are usually taken in units per lineal foot of wall. The parallelogram is then completed from C to D, and from D to B, and the resulting thrust is found upon joining the diagonal A — D. This line must, to ensure stability, pass well inside the base of the wall. If it pass outside the base the equilibrium is unstable. As a matter of fact, conditions in practice are so arranged that this line cuts the base within a point at not less than one-third of its length.

Examples from Practice. In the illustrations which have been given of crane framings, roofs, and framed girders, we have excellent examples of the remarks made in Article 2 on the applications of certain materials in certain ways.

The members in cranes are too numerous and varied to be taken in full detail here, but we may offer remarks on some of the more important of them.

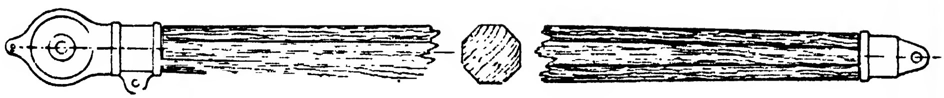
Referring to the crane framings in Article 3, we saw that while the jib is a compression member, the tie rods and the chain are subjected to simple tension. It is not quite correct to say that the jib is in compression absolutely. That is true only so long as it is not subjected to such excessive strain as would tend to flexure, and calculations on the strength of jibs are invariably made on this least favourable basis. That is, they are treated as long columns, which in case of fracture would fail by bending and not by crushing; and this is, in fact, what does happen, for when a jib fails, as it sometimes does, it becomes bent, and thus crippled.

Examples. But in order to prevent risk of such an event happening under proper conditions of working, long jibs are seldom made of parallel sections, but in other forms. They are *bellied*—that is, built of double parabolic form, the bases of two parabolas meeting at the middle of the jib. This design is used in light and heavy cranes alike. But while timber [**42**] is often used in the former, steel bracing [**43**] is adopted in the latter. The best examples of both of these jibs are found in the derrick cranes and wharf cranes. [It will be understood that though the jibs here shown are drawn as lying horizontally, for convenience of illustration, they stand at an angle of 45°, less or more, on their cranes.] The bellied form will be recognised as that of a beam loaded in the centre, and deepened there accordingly. But there is this difference, that while a beam is deepened in one direction only—that of its depth—the jib is enlarged depthwise, sideways, and diagonally, because the bending stresses come upon it in all directions in lifting, and in slewing sideways.

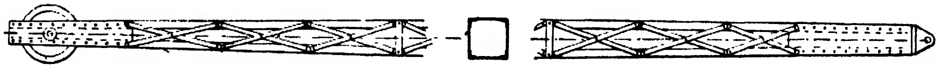
Alternatively, jibs are made of tapered outlines, the base or foot being considerably wider than the top end; or, in many cases, the tapered form is combined with the bellied, so resembling the tapering column having entasis. These outlines are also imparted to jibs made of timber [**44**] and of steel [**45**]. The latter occur in several designs, either solid plated, as in small cranes almost solely; or variously built up, and braced so as to lessen weight. In some of the heaviest cranes the jib has a large amount of tapering in both directions, perpendicularly as well as laterally, so much so, that the cross section of the framing at the foot becomes nearly square. This is also done to obtain great strength with comparatively little material, and such jibs have a very skeleton-like aspect, which seems hardly strong enough to sustain the loads of 40 or 50 tons which they carry safely. In many cranes the jibs are horizontal, instead of raking, like those shown in the illustrations. This form is introduced into cranes which have a travelling jenny, or a crab running in and out to different radii, resembling in this respect the traveller girders [**46** and **47**]. They are seldom solid plated, never in the large cranes, but are lattice braced. The design of such members in recent practice becomes more skeleton-like in appearance, being particularly noticeable in the long-armed cranes of American and German design, but they are nevertheless of ample strength for their duty.

Disposition of Materials. A timber jib [**42** and **44**] must of necessity be plain and solid. If in one piece, it is generally made octagonal in cross section [**42**]; or, if formed of two members, of rectangular section [**44**]; and it is sawn or adzed and planed to the tapering outlines. But the steel jib occurs, as already remarked, in many forms, and therein lies one of the numerous advantages that steel offers over timber for constructive purposes, and which we shall illustrate by practical examples throughout this course.

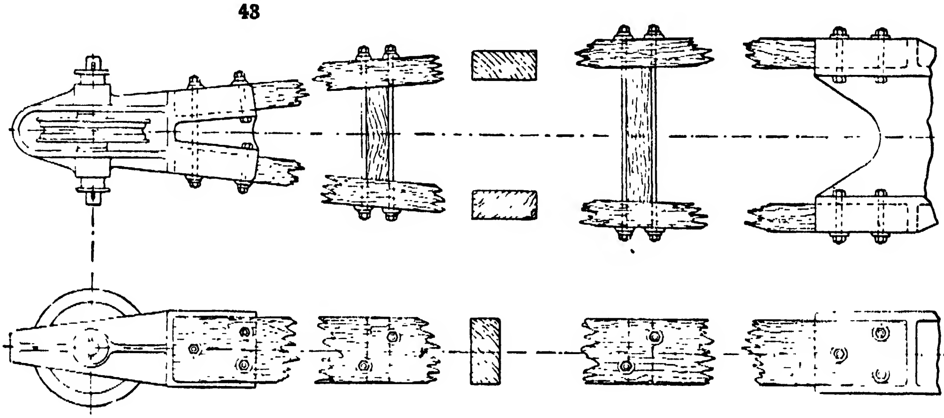
Take any of the shapes in which steel is rolled, and note their behaviour individually. Plates and bars are flexible, bending and falling about in all directions, destitute of a trace of rigidity



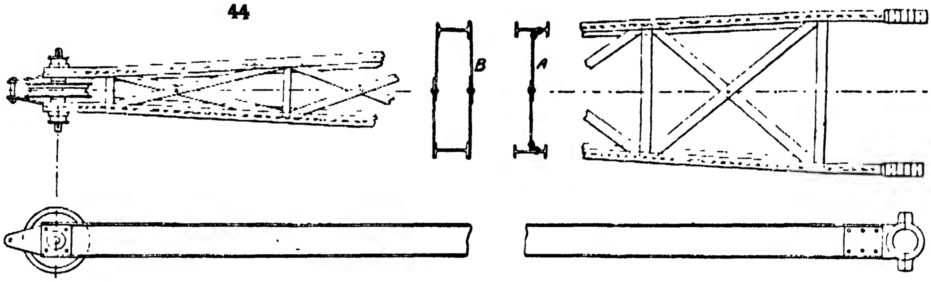
42



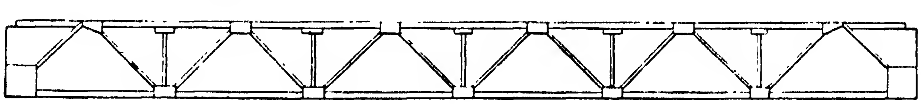
43



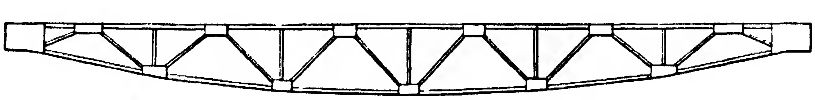
44



45



46

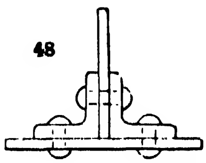


47

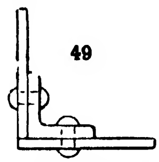
EXAMPLES OF CRANE JIBS AND TRAVELLER GIRDERS FROM PRACTICE

to withstand bending stresses. Actually, the thicknesses of single plates and bars in some girder-like structures is not much in excess of that of stout millboard; while by comparison with the dimensions of the entire structure they seem almost as thin as cardboard. But these can be so built up, as the bridge members are built up in the Warren [**40**] and other girders, as to render some elements helpful to others by affording them ample stiffness, which assistance is mutual.

The simple case of two thin bars or plates set at right angles makes a rigid combination [**48** and **49**]. This device is carried out in several designs, not only in built-up or plated work, but in what are termed rolled sections, as angles [**50**], tees [**51**], channels [**52** and **53**], joists, or H sections [**54** and **55**], and others. These give the designer



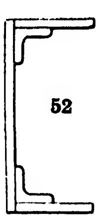
48



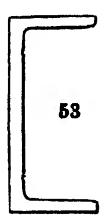
49

the means of obtaining maximum strength with minimum weight and expense.

No work of this kind is solid or cubical like timber is, but it has either a sectional form which embodies the web and flange type, as at A—the section of the jib shown in **45**—or the box type B also in **43**. The latter may be either plated, or open webbed—termed *lattice braced*, as shown. The bounding outlines of these structures are generally rectangular. But the point is that the metal is mostly massed outside, and the interior is entirely hollow, or it is webbed, and that is where the neutral axis of no strain lies. And thus it comes about that materials which in their elementary sections appear to be the least suited to



52

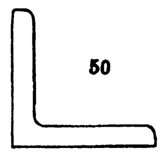


53

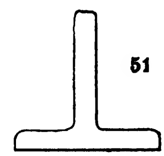
withstand compression or bending stresses are rendered as rigid as timber or cast iron, besides being much stronger and better qualified than these to resist stresses that tend to pull asunder or to bend.

The writer remembers old cranes in which jibs of cast iron were actually used, because adapted to resist compressive stresses. But at that time wrought iron was used only to a slight extent in large rolled sections, and the science of braced structures was not then understood as it is to-day.

Cast-iron Fittings. Before we leave the jibs we must point out illustrations of the union of two kinds of materials in one member—namely, mild steel and cast iron, a combination alluded to in the second article. Many jibs must have some castings fitted to serve as attachments to parts of the crane adjacent, and to carry pin bearings. The thickness of the steel plate (from $\frac{1}{4}$ to $\frac{1}{2}$ in.) does not always afford sufficient bearing surface for fastenings or pins, and therefore cast-iron fittings are attached at the foot and head, and sometimes elsewhere, depending on the design. Such fittings, being in compression, are therefore, apart from convenience in manufacture, very properly made of cast iron. Examples of these are seen in **42**, **43**, **44**, and **45**, a few only out of many designs easily obtainable by casting, but very difficult and costly to produce by forging or plating. In some cases the castings fulfil the purpose of rigid ties to the end of the otherwise unsustained plated work.



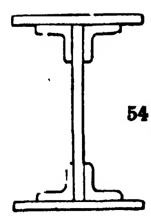
50



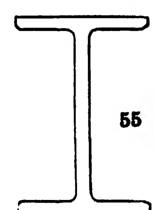
51

The chain pulleys of the jibs [**42** to **45**] are subjected only to compression, and are therefore of cast iron. Their pins are in shear, or more often combined shear and bending, and these, therefore, are made in mild steel.

Tension Rods. Turning to the tie-rods [**56**], which are subjected wholly to tension, several things have to be considered. There is not only the rod itself, but its method of attachment. It is absolutely essential that the material must not only be strong, but tough, and capable of stretching. Practically only two materials fulfil these conditions—wrought iron and mild steel. The former has a strength equal to about 22 tons per square inch, the latter equal to 28



54



55

or 30 tons. The first will stretch from 7 to 9 per cent. in a length of 10 in. previous to fracture; the second from 20 to 25 per cent. in the same length.

It is hardly necessary to point out how valuable is this property of stretching considerably before fracture in structures that are subjected to severe tension. Cast iron snaps without giving the slightest previous warning, which bars its use in tension elements, unless an enormous factor of safety is allowed.

A tie-rod is subjected to severe stresses, due to the sudden surging and jerking of loads, and therefore a high factor of safety is essential, from eight to ten in excess of the actual stress that would snap the rod by a steady pull, such as

would be imparted at the testing machine. And, of course, the work being divided between two rods—except in some very small cranes—the cross section of each rod is one-half that required for the pull allowed for.

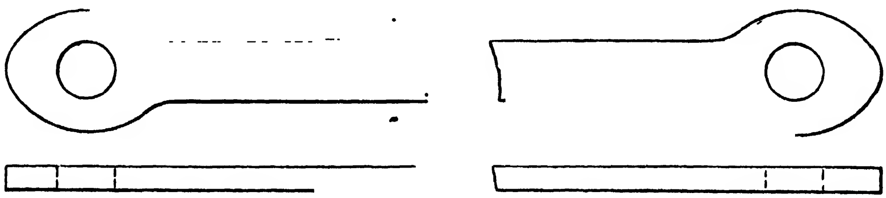
The Fastening of Rods. An important detail is that the rods should be as strong at the location of the attachment as they are throughout their parallel length. They are attached either by eyes or screws. The metal in the eyes being in direct tension, its total cross section [**56**] must be at least equal to that of the body of the rods. Generally, it is made a little in excess, for security. And, to prevent risk of the metal being torn out at the end, it is generally elongated, which explains why tie-rod eyes are usually of elliptical rather than circular form [**56**].

When rods with screwed ends are attached, the diameter of the screw-thread must be greater than that of the rod [**57**], because if screwed on the same size, the root of the thread will be smaller than the rod, and fracture would certainly take place through the bottom of the threads. This explains the reason for the swelled screwed ends seen on such rods.

Chains. It is necessary that the other main tension member in a crane—the chain—should be flexible; but with this exception similar conditions have to be fulfilled as in the rigid tension-rods. High ductility, a high factor of safety, and secure and strong attachments have to be ensured. Its strength is, of course, equal to that given by the two transverse sections of the iron in the links. As every link is closed by welding, wrought iron is used for chains rather than mild steel, because welds in the latter are not so reliable as those in iron. Chain links are strained if bent over pulleys of small diameter, they also deteriorate much in service, suffering from fatigue. Their strength can be restored by annealing. But these evils explain why the smaller and more flexible wire-rope is being extensively used in preference to the more rigid chain links. The strain in chain and ropes is alike throughout—that is, the fact of passing over a pulley only alters the direction of motion, it does not alter the stress.

Chains, or wire ropes, are frequently used instead of rigid tie-rods for derricking cranes, or lengths of chain and rigid tie-rod are linked together to form one tension member.

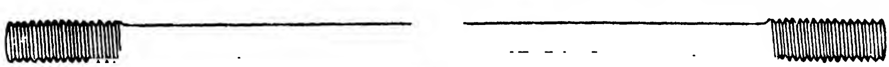
Roof Trusses. Passing from the crane diagrams to those of roof trusses [37], illustrated in the last article, we find that similar devices are embodied. The tension members are composed of flat bars only, because, being in simple tension, the strength of the cross section alone has to be considered. That is, a cross section of, say, $2\frac{1}{2}$ in. × $\frac{5}{16}$ in. has been calculated to withstand the purely pulling stress to which the member will be subjected, plus the factor of safety. There is no question of bending in these tension members, so that the flat bars do not require stiffening. Though flexible in themselves, the stress imposed maintains them in a taut condition always.



56

But now note the compression members. These are formed of rolled tees, or T sections. In heavy work they are built up of flats and angles [**48** and **49**], for reasons to be noticed presently. But the point is that, being subject to compression, such members must be capable of resisting bending stresses, as in the crane jibs now illustrated, due to their great excess of length over section. Actually, therefore, they are not strictly compressive members, and if their strength were calculated as such they would fail by bending. They behave as long columns pivoted at the ends. They are, therefore, beams, the webs of which offer resistance to flexure in directions at right angles with each other. The student, looking at a steel roof, can always distinguish the tensile from the compressive members by observing the differences in their cross sections.

Wide Utilities of the Foregoing. In structures a thousand changes are rung on these simple elementary designs, derived from flat bars variously arranged. The rolled section is simply a cheap method of obtaining what is got at more expensively by building up with bars and angles. But it is necessary to adopt the latter in heavy structures for a reason already given—namely, the lessening of weight.



57

The strength of beams increases directly as the *thickness* of the web, but as the square of the *depth*. Weight is therefore lessened by lessening thickness, and strength is increased by adding to the depth. A lighter but stronger structure can therefore be obtained by riveting two thin bars at right angles with angle irons than by using a rolled section.

Reduction to Lowest Terms. Comparison of Fractions. Addition, Subtraction and Multiplication. Examples

By HERBERT J. ALLPORT

EXAMPLES 9

1. Which of the following numbers are prime? 587, 745, 1073, 997.
2. Find the H.C.F. of (i) 165, 341, and 1302; (ii) 19769 and 36181.
3. Find the L.C.M. of (i) 18, 21, 24, 30, 36, 49; (ii) 1581 and 1887; (iii) 2520, 3315, and 5265.
4. Find the least number of lb. Avoirdupois which can be expressed as an exact number of lb. Troy.
5. Find the least number which, when divided by 42, 63 or 81, always leaves remainder 40.
6. A number of pencils can be tied into bundles of 17; but if they are tied in bundles of 8 or of 9, there is one pencil left over in each case. Find the least number of pencils.
7. Four bells ring simultaneously, and afterwards at intervals of 2, 3, 5 and 9 seconds respectively. How long will it be before they all ring together again?
8. From a heap of silver coins, all of the same sort, which weighs 38·875 kilogrammes, another heap weighing 2·605 kilogrammes is taken. Find the greatest possible weight of a single coin.
9. Two men, the lengths of whose strides are 30 and 33 inches respectively, start walking together at the same rate. How often will they be in step in walking a mile?

FRACTIONS

69. An *integer*, or *whole* number, is a number which consists of a collection of complete units.

A *fraction* is a quantity less than the unit. We have already seen (Art. 29), how quantities less than the unit can be expressed in the decimal notation. When so expressed, they are called *decimal fractions*.

70. We shall now consider another method of expressing fractions. Suppose that any unit is divided into 7 equal parts. Each of these parts is called one-seventh, and is denoted by $\frac{1}{7}$; two of the parts make two-sevenths, or $\frac{2}{7}$; three of the parts make three-sevenths, or $\frac{3}{7}$, and so on.

Thus, we see that a fraction is expressed by two numbers, written one above the other and separated by a line. The lower number shows the number of equal parts into which the unit is divided. Since it gives a *name* to the parts, it is called the *Denominator*. The upper number is called the *Numerator*, since it tells us the *number* of equal parts taken to form the fraction.

Fractions expressed in the above manner, such as $\frac{5}{9}$, $\frac{11}{43}$, $\frac{51}{8}$, are called *Vulgar—i.e., Common Fractions.*

71. A *Proper Fraction—i.e.*, a quantity which, in accordance with our definition, is *part* of a unit, will evidently have its numerator less than its denominator.

If, after dividing the unit into any particular number of equal parts, say 15, we take more than 14 of such parts, say 17, we obtain a quantity equal to seventeen fifteenths of the unit, or $\frac{17}{15}$. Such a quantity, which must evidently be not less than the unit, is called an *improper* fraction. Thus, in an improper fraction, the numerator is not less than the denominator.

72. A *mixed number* is the sum of a whole number and a fraction.

Thus, the sum of 4 and $\frac{5}{8}$ is a mixed number. It is written $4\frac{5}{8}$.

A mixed number can always be expressed as an improper fraction.

Example. Reduce $5\frac{4}{9}$ to an improper fraction.

Each unit of the 5 contains 9 ninths.

$\therefore$ 5 units contain $5 \times 9 = 45$ ninths.

Thus $$5\frac{4}{9} = \frac{5 \times 9 + 4}{9} = \frac{49}{9} \quad \textit{Ans.}$$

Again, an improper fraction is converted into a mixed number by dividing the numerator by the denominator. The quotient will be the whole number, and the remainder will be the numerator of the proper fraction.

Example. Express $\frac{43}{5}$ as a mixed number.

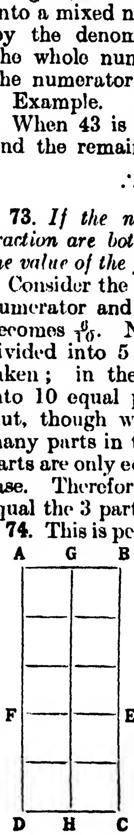
When 43 is divided by 5, the quotient is 8, and the remainder 3.

$$\therefore \frac{43}{5} = 8\frac{3}{5} \quad \textit{Ans.}$$

73. *If the numerator and denominator of a fraction are both multiplied by the same number the value of the fraction is not altered.*

Consider the fraction $\frac{3}{5}$. If we multiply both numerator and denominator by 2, the fraction becomes $\frac{6}{10}$. Now, in the fraction $\frac{3}{5}$, the unit is divided into 5 equal parts and 3 of these are taken; in the fraction $\frac{6}{10}$ the unit is divided into 10 equal parts and 6 of them are taken. But, though we divide the unit into twice as many parts in the second case, yet two of these parts are only equal to one of the parts in the first case. Therefore, the 6 parts in the second case equal the 3 parts in the first—*i.e.*, $\frac{3}{5} = \frac{6}{10}$.

74. This is perhaps made plainer by a diagram.



Let A B C D represent the unit. Divide this into 5 equal parts by drawing lines parallel to A B. Then A B E F, consisting of 3 of these strips, will represent $\frac{3}{5}$ of the unit.

Now divide A B C D into 10 equal parts by drawing a line parallel to A D. Then A B E F contains 6 of these parts, and therefore represents $\frac{6}{10}$ of

the unit. Hence, since A B E F represents both $\frac{3}{5}$ and $\frac{6}{10}$, it follows that $\frac{3}{5} = \frac{6}{10}$.

75. We have shown that $\frac{6}{10}$ and $\frac{3}{5}$ are equal.

Now, $\frac{3}{5}$ is obtained from $\frac{6}{10}$ by *dividing* both numerator and denominator by 2. Hence, the statement in Art. **73** is also true if we substitute "divided" for "multiplied." Therefore, the numerator and denominator of any fraction may always be divided by any common factor that they contain.

When we have divided out (or *cancelled*), all the common factors of the numerator and denominator, the fraction is said to be ***in its lowest terms***.

76. Reduction to Lowest Terms. In finding the common factors of the numerator and denominator the rules given in Art. **56** should be applied. When, however, common factors cannot easily be seen, it is better to find at once their H.C.F. by the ordinary rule.

Example 1. Reduce $\frac{5115}{11880}$ to its lowest terms.

Here $\frac{5115}{11880} = \frac{1705}{3960}$ (dividing numerator and denominator by 3),

$= \frac{341}{792}$ (dividing by 5),

$= \frac{31}{72}$ (dividing by 11).

Now, 31 is a prime number, and it does not divide 72,

$\therefore \frac{31}{72}$ is in its lowest terms.

Example 2. Reduce $\frac{1582}{10057}$ to its lowest terms.

By trial, 2, 3, 5, 7, 11, 13 are none of them common factors, so we find the H.C.F.

2	1582	10057	6
4	452	565	1
	...	113	

The H.C.F. is 113. Divide numerator and denominator by 113. The quotients are 14 and 89,

$\therefore \frac{1582}{10057} = \frac{14}{89}$ *Ans.*

H.C.F. working can be more compactly arranged than by the method in Art. **60**. Here, the first remainder is 565. We now divide this into 1582, writing the quotient, 2, on the left. Remainder is 452. Divide this into 565, putting the quotient on the right; and so on.

77. Any fraction can be expressed with a denominator which is any given multiple of its original denominator.

Example 1. $\frac{3}{4}$ can be expressed with denominator 7 × 4.

Thus $\frac{3}{4} = \frac{7 \times 3}{7 \times 4} = \frac{21}{28}$; for the value of the fraction is not altered when we multiply both numerator and denominator by 7.

It is now clear that any number of fractions can be expressed as fractions with a denominator which is some *common* multiple of the original denominators. It is generally most convenient to use the *least* common multiple.

Example 2. Reduce $\frac{3}{7}$, $\frac{5}{14}$, $\frac{8}{21}$ to a common denominator.

The L.C.M. of 7, 14, 21 is 42. Therefore, we express each fraction as a fraction with denominator 42.

Thus $\frac{3}{7} = \frac{3 \times 6}{7 \times 6} = \frac{18}{42}$,

$\frac{5}{14} = \frac{5 \times 3}{14 \times 3} = \frac{15}{42}$,

$\frac{8}{21} = \frac{8 \times 2}{21 \times 2} = \frac{16}{42}$.

The multiplier for each fraction is, of course, found by dividing its denominator into the common denominator 42.

78. Comparison of Fractions. When we have reduced any given fractions to a common denominator, we see at once that the one with the largest numerator is the greatest fraction. For instance, in Ex. **2** of the last article, the three fractions were found equivalent to $\frac{18}{42}$, $\frac{15}{42}$, and $\frac{16}{42}$. But $\frac{18}{42}$ is greater than either $\frac{15}{42}$ or $\frac{16}{42}$—*i.e.*, $\frac{3}{7}$ is the greatest of the given fractions.

Example. Arrange in ascending order of magnitude,

$\frac{13}{15}, \frac{11}{14}, \frac{31}{35}, \frac{17}{21}$.

Find L.C.M. of denominators:

3	15, 14, 35, 21
7	5, 14, 35, 7
	2, 5

L.C.M. = 3 × 7 × 2 × 5 = 210.

$\frac{13}{15} = \frac{13 \times 14}{15 \times 14} = \frac{182}{210}$; $\frac{11}{14} = \frac{11 \times 15}{14 \times 15} = \frac{165}{210}$;

$\frac{31}{35} = \frac{31 \times 6}{35 \times 6} = \frac{186}{210}$; $\frac{17}{21} = \frac{17 \times 10}{21 \times 10} = \frac{170}{210}$.

Therefore, the fractions in ascending order are

$\frac{165}{210}, \frac{170}{210}, \frac{182}{210}, \frac{186}{210}$;

or, $\frac{11}{14}, \frac{17}{21}, \frac{13}{15}, \frac{31}{35}$ *Ans.*

79. We can also compare the magnitude of fractions by reducing them to a common *numerator*, in which case the fraction with the *least* denominator is the greatest fraction.

Example. Which is greater, $\frac{3}{7}$ or $\frac{2}{5}$.

Here, L.C.M. of the numerators is 6,

and $\frac{3}{7} = \frac{3 \times 2}{7 \times 2} = \frac{6}{14}$,

$\frac{2}{5} = \frac{2 \times 3}{5 \times 3} = \frac{6}{15}$;

$\therefore \frac{6}{14}$, *i.e.*, $\frac{3}{7}$, is the greater fraction.

80. Addition of Fractions. If two or more fractions have the same denominator, their sum is obtained by adding the numerators.

Thus, $\frac{1}{7} + \frac{4}{7} + \frac{5}{7} = \frac{1+4+5}{7} = \frac{10}{7} = 1\frac{3}{7}$.

If the fractions have different denominators, we must first express them as equivalent fractions with the same denominator. (Art. **77**).

Example 1. Find the value of

$$\frac{1}{9} + \frac{3}{7} + \frac{5}{21} + \frac{2}{3}.$$

The L.C.M. is 63. The several denominators, when divided into 63, give 7, 9, 3, 21 respectively, for quotients. Therefore, we multiply the numerators and denominators of the fractions by 7, 9, 3, 21, and add the numerators to obtain the required sum. The result must be reduced to a mixed number, or to lower terms, if necessary.

The work is arranged thus:

$$\frac{1}{9}+\frac{3}{7}+\frac{5}{21}+\frac{2}{3},$$
$$=\frac{7+27+15+42}{63}$$
$$=\frac{91}{63}=1\frac{28}{63}=\underline{1\frac{4}{9}\ \textit{Ans.}}$$

In adding mixed numbers, first add the whole numbers, then the fractions, finally adding the two results.

Example 2. Add together $3\frac{1}{8}+\frac{7}{24}+7\frac{11}{15}+4\frac{3}{20}$.

Given expression

$$=3+7+4+\frac{1}{8}+\frac{7}{24}+\frac{11}{15}+\frac{3}{20},$$
$$=14+\frac{15+35+88+18}{120},$$
$$=14+\frac{156}{120}=14+1\frac{36}{120}=\underline{15\frac{3}{10}\ \textit{Ans.}}$$

81. Subtraction of Fractions. The principle is the same as in addition. Reduce the fractions, if they have different denominators, to a common denominator, and then take the difference of the numerators. In the case of mixed numbers, subtract the whole numbers and the fractions separately.

Example 1. Take $4\frac{5}{21}$ from $6\frac{3}{7}$.

$$6\frac{3}{7}-4\frac{5}{21}=6-4+\frac{3}{7}-\frac{5}{21},$$
$$=2+\frac{9-5}{21},$$
$$=2+\frac{4}{21}=\underline{2\frac{4}{21}\ \textit{Ans.}}$$

If the fractional part of the number to be subtracted be greater than the fractional part of the other number, we proceed as follows:

Example 2. From $7\frac{4}{15}$ take $4\frac{11}{25}$.

$$7\frac{4}{15}-4\frac{11}{25}=7-4+\frac{4}{15}-\frac{11}{25},$$
$$=3+\frac{20-33}{75},$$
$$=2+\frac{75+20-33}{75},$$
$$=2+\frac{62}{75}=\underline{2\frac{62}{75}\ \textit{Ans.}}$$

Example 3. Simplify $3\frac{2}{9}+4\frac{5}{7}-5\frac{13}{21}+\frac{2}{35}-1\frac{14}{15}$.

Given expression

$$=3+4-5-1+\frac{2}{9}+\frac{5}{7}-\frac{13}{21}+\frac{2}{35}-\frac{14}{15},$$
$$=1+\frac{70+225-195+18-294}{315}$$
$$=1+\frac{313-489}{315},^{*}$$
$$\frac{628-489}{315}=\frac{139}{315}\ \underline{\textit{Ans.}}$$

82. Multiplication of Fractions. (i.) When the multiplier is a whole number. This, as in the case of whole numbers (Art. 15), means that we have to find the *sum* of a given number of repetitions of the fraction.

* Obtained by adding all the numerators with + before them, and then all those with − before them.

Example 1.

$$\frac{7}{9}\times 4 \text{ means } \frac{7}{9}+\frac{7}{9}+\frac{7}{9}+\frac{7}{9},\ \textit{i.e.,}\ \frac{28}{9};$$

or

$$\frac{7\times 4}{9}.$$

Hence, *to multiply a fraction by a whole number, simply multiply the numerator by that number.*

Since the multiplier thus becomes a factor of the numerator, we *cancel* (Art. 75) any common factors contained in the multiplier and the denominator; and this may be done *before* we perform the actual multiplication. Thus:

Example 2. Multiply $\frac{19}{46}$ by 69.

$$\frac{19}{46}\times 69=\frac{19\times 69}{46}=\frac{19\times 3}{2}\ \text{(cancelling 23)},$$
$$=\frac{57}{2}=\underline{28\frac{1}{2}\ \textit{Ans.}}$$

It follows, that, if the multiplier be itself a factor of the denominator, we may, *to multiply a fraction by a whole number, divide the denominator by that number.*

(ii.) When the multiplier is a fraction.

In performing the operation 7×9, it is plain that we do to 7 what we do to a unit to obtain 9. Similarly, $\frac{3}{5}\times\frac{4}{11}$ may be looked upon as doing to $\frac{3}{5}$ what we do to the unit to obtain $\frac{4}{11}$.

Now, to obtain $\frac{4}{11}$ from the unit, we must divide the unit into 11 equal parts and take 4 of them.

Therefore, to find the value of $\frac{3}{5}\times\frac{4}{11}$ we must divide $\frac{3}{5}$ into 11 equal parts and take 4 of them.

But $\frac{3}{5}=\frac{33}{55}$ (Art. 73) $=\frac{3}{55}\times 11$ (Art. 82, i), so that, the eleventh part of $\frac{3}{5}$ is $\frac{3}{55}$; and, if we take 4 of these parts, we get $\frac{3}{55}\times 4$, or $\frac{12}{55}$.

Thus, $\frac{3}{5}\times\frac{4}{11}=\frac{12}{55}$. Now $12=3\times 4$, and $55=5\times 11$.

Hence we have the following rule: *To multiply two fractions together, multiply the numerators for a new numerator and the denominators for a new denominator.*

As in Ex. 2 the work is shortened if we cancel common factors from the numerators and denominators.

Example 3. Multiply $\frac{22}{91}$ by $\frac{13}{77}$.

$$\text{The product}=\frac{\overset{2}{\cancel{22}}\times\cancel{13}}{\underset{7}{\cancel{91}}\times\underset{7}{\cancel{77}}}=\underline{\frac{2}{49}\ \textit{Ans.}}$$

Here, the 22 of the numerator and the 77 of the denominator contain a common factor, 11. Therefore, we cross out the 22 and write 2 above it, and cross out the 77 and write 7 under it. Similarly, we cancel the factor 13 from 13 and 91. There is now 2 left for numerator and 7×7 for denominator.

To multiply more than two fractions together, we proceed in the same way.

In multiplication of fractions, mixed numbers must first be expressed as improper fractions.

Example 4. Simplify $5\frac{1}{7}\times\frac{11}{27}\times 1\frac{11}{24}$.

$$\text{Given expression}=\frac{\overset{\cancel{4}}{\cancel{36}}}{\cancel{7}}\times\frac{11}{\underset{9}{\cancel{27}}}\times\frac{\overset{5}{\cancel{35}}}{\underset{2}{\cancel{24}}},$$
$$=\frac{55}{18}=\underline{3\frac{1}{18}\ \textit{Ans.}}$$

To be continued

THE THREE LAWS OF MOTION

Newton's Laws—continued. **Their operation as manifested in the Sun, the Omnibus, and the Cricket Ball. Interplay of Nature's Laws. Equilibrium**

By DR. C. W. SALEEBY

We cannot leave the first law of motion without inquiring whether there is any known case of perpetual motion—the words being used in their legitimate but ignored sense—or of anything that closely approaches it. In our search for such a case we must leave all cases of motion through a thick resisting medium, and must therefore abandon all cases of motion on the earth. Similarly, even the top revolving in a perfect vacuum (if that could be obtained) would not satisfy us, for the top has to be supported upon something, and this introduces friction.

The Motion of the Earth. But if we take the earth itself, we have a moving object which is not supported upon anything, and which moves through—what? If it moved through *nothing*, we should have to believe that its movement must be an instance of perpetual motion. For ages this planet "has gone cycling on according to the fixed laws of gravity"—to quote from the famous last paragraph of Darwin's "Origin of Species"—and since there is no such thing as a tendency to stop, but rather a tendency to go on unless stopped, why should it not so go "cycling on" for ever, there being nothing to stop it?

But to this we must answer that though the earth (including, of course, its atmosphere, which, fortunately for us, it does not leave behind) meets with very little resistance, yet it is moving through a medium which is called the *ether*. We use the ether as a symbol for fineness of texture and for tenuity (the opposite of density), as when those who believe in them speak of ghosts as of "ethereal texture"; but however tenuous the ether, yet it *exists*, and must offer some resistance to the earth's movement.

This is a subject now engaging the attention of the astronomical physicists. Further, it has lately been proved that light and all the radiations in the ether that are comparable with light, though they happen to be invisible to us, exercise a pressure or force upon the earth which must be slowly affecting its onward motion.

The Rotation of the Earth. But the reader may be inclined to suggest that, though the earth may meet with external force of opposition in its movement of translation, it must at any rate be free to exhibit perpetual motion and illustrate Newton's first law, in so far as its movement of rotation is concerned. Must it not go spinning for ever, even though its movement round the sun should be arrested? Is not the earth like a top which spins not only in a vacuum, but without friction, since it is without material support?

The answer to this is that even the rotation of the earth does not furnish us with the case of perpetual motion that we seek, for, apart from any friction between the rotating earth and the ether, Professor George Darwin (the son of Charles Darwin and President of the British Association in 1905) has proved that the friction of the tides acts as a brake upon the rotation of the earth; so that this rotation is becoming slower, and thus the day is lengthening by about 22 seconds in every century. This may sound very little, but consider the difference it will mean in, say, 100,000 years.

The Force in a Moving Body. Further we must note that the discovery of the pressure of light makes necessary a very curious practical addition to the first law of motion. Indeed, this law is never illustrated in actual practice, not because the law is not true, but because of the occurrence of factors of complication. The law declares that a moving body will move in a straight line with a constant velocity for ever unless it be acted upon by some external force.

But we are actually now compelled to declare that the law must be restated, for we find that the moving body contains within itself a force which tends to stop it. The tendency to stop, to which we have so often pointed as at a superstition, has some correspondence to fact, after all, though this correspondence is very different from that commonly supposed. Take, for instance, the sun, or any body radiating light, heat, or any form of ethereal radiation. This category probably includes all bodies whatever, whether in the earth or in the heavens, and certainly it includes the cricket-ball, which we have considered; but we will choose the sun as most convenient for our purpose.

The Sun Moving through Space. As the sun moves through space, with his family, he radiates light and heat in all directions, and it has been proved that this light and heat exercise actual pressure, as we shall see in a later section. But when we consider the case of the sun, or any moving radiant body, we see that he tends to "catch up" the waves which he sends in front of him, whilst those he sends out from behind him increase their distance from him with additional speed, due to the fact that he is moving away in the opposite direction from them. Hence the waves of radiation are packed close in front of the sun and thinned out behind him; and it follows that the *radiation-pressure* is greater in front than behind. Therefore the sun, in virtue of a force which he himself produces, *tends to stop*. The reader will not be confused; he will not regard this as a "tendency to stop" without there being something to do the stopping. If it were so, the first law of motion, and the conservation of energy, would be nonsense. But it is a remark-

able discovery that the first law of motion can never apply to existing things, but only to an imaginary state of affairs, since its action must always be compromised by the action of the remarkable law, in virtue of which every moving body that produces ethereal radiations (that is to say, so far as we can judge, every moving body at all) actually produces in its surroundings such conditions of external force as tend to bring about its own arrest. The first law of motion is no more to be regarded as untrue on this account than the law of gravitation is to be accounted untrue because the earth does not instantly rush into the sun. Each law is true, as a statement of what would and must occur, if no other law had to be recognised.

Interplay of Nature's Laws. The actual facts of Nature are due to the interplay of innumerable laws, and it is our business both to recognise the interplay and to disentangle the various laws if we can. Of such disentangling the discovery of the first law of motion is a great example—an example all the greater and all the more important because, so far as we know, there is in Nature no case whatever of the uncomplicated action of this law. Observe the word uncomplicated. The law is true everywhere and at all times, even though no obvious illustration of its truth can be furnished; otherwise it is not a law of Nature. In a famous controversy, Charles Kingsley, the great divine, declared that he defied and nullified the law of gravitation by his will, when he held an object in his hand, and prevented it from falling. He did nothing of the sort. The law of gravitation was strictly observed, and was expressed in the weight or pressure of the object in Kingsley's hand. Similarly, the first law of motion is as surely in action when a cricket-ball stops rolling as it would be if the cricket-ball, in the absence of friction or external resistance, went on moving for ever.

Everyday Illustrations. We may conclude our consideration of the first law of motion by one or two illustrations of its action in daily life. We shall look not at the conventional illustrations, but at others which are more vivid.

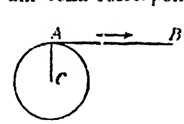
For instance, let us suppose that a man is standing on the top of a 'bus, when the conductor gives the signal to start. Everyone knows that the passenger is liable to fall backward. Why? He is in a state of rest, and in order to move forward a force must be applied to him. If his boots were so smooth, and the top of the 'bus so smooth, and his weight so negligible that friction played no part, the passenger would simply slide—not fall—backward along the top of the 'bus. But in virtue of friction, the force exercised by the horses or the motor is communicated to him. The first part of his body to be impressed by the external force is the lower, which moves forward, leaving behind the upper portion, which, deprived of support, falls vertically downward behind the advancing legs. That is to say, the passenger falls backward.

But suppose the passenger be riding in a hansom and the horse falls. As everyone knows, he lands on the horse's back. Why? Because, in virtue of the first law of motion, his body continues to move forward, though the seat which supported it happens to stop. If the earth lost its powers of gravitation, and the air had no resistance, the passenger would be propelled in a sitting position through space for ever, free of charge.

Jumping off a 'Bus. Other illustrations are furnished by the modes of jumping off a 'bus. Assume that the step of the 'bus is at the back, instead of the side. The wise passenger may step off such a 'bus on to one foot, and stand upon it without needing even to put down the other —if he will attend to the first law of motion. As he leaves the 'bus, his whole body is in forward motion at the speed possessed by the 'bus. The foot which touches the ground is arrested by friction. If the passenger's body be vertical when he steps off, the upper part of his body, continuing to move forward in accordance with the law, will inevitably be overbalanced, unless he rapidly advances the free leg to save himself. But he can perform the feat named, if he steps off the 'bus with the upper part of his body inclined so far backward that he would fall backward were the 'bus stationary. For, if the 'bus be moving, his whole body is moving. The lower part is arrested, the upper continues to move forward, and, if properly inclined backward at the moment when the foot touched the ground, will be arrested just when it has travelled so far forward as to be immediately above the already arrested leg.

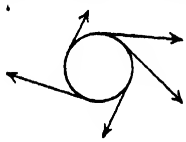
Similarly, it is easy to step from a rapidly moving 'bus, with the face turned backward, if one remembers to fall in the direction of the face as one steps off. The upper part of the body travels onward—instead of falling on one's face, one is left standing upright.

Tangential Motion. The law also explains the fashion in which rain-drops may be whisked off an umbrella by rotating the handle. If this be done very slowly, the force of cohesion between the drops and the silk is enough to keep them in their place. But as soon as the umbrella is rotated fast enough, the force of cohesion fails, and the moment the drop ceases to be in actual contact with the umbrella it obeys the first law of motion, and moves not in a circle but in a straight line; it *flies off at a tangent*. This has become a phrase of common speech, but it is strictly true. At any given moment, each rain-drop is moving in a direction which may be represented by a tangent to the circle to which the edge of the umbrella corresponds.

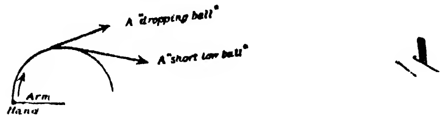


We remember that a tangent (literally a *thing touching*) is a line which touches the circumference of a circle, and is at right angles to that radius of the circle which is drawn from the point of contact. Observe that, in virtue of the first law of motion, the departing drops do not continue to move in circles, but in straight lines. The

accompanying figure represents their course, each line being a tangent to the circle at the point where cohesion failed to control the motion of a drop. Compare a "St. Catherine's wheel."



For a last illustration we may return to cricket. The ball leaving the hand of an over-hand bowler flies off at a tangent from the circle which his arm describes. Hence the path of the ball is determined by the earth's gravitation and the moment when the ball leaves the hand. The higher the ball's flight, the earlier did it leave the bowler's hand.



The bowler who has no control over "pitch" is one who cannot control the moment at which he lets the ball go from his hand, and thus cannot determine the tangent which it follows. It need hardly be said that, were there no force of gravitation and of aerial resistance complicating the action of the first law of motion, the high "dropping" ball of the diagram would never drop, but would travel in the straight line represented by the tangent at constant speed for ever. It would be a unique case of six "wides" for "lost ball"!

The Second Law of Motion. We must now pass to the consideration of the *second law of motion.* This may be stated in many different forms, but perhaps as intelligible as any is the following: Change of *momentum* is proportional to the impressed force, and takes place in the direction in which the force acts.

Before we go any further it is necessary to know the meaning of the word momentum. It is practically equivalent to quantity of motion, so that the law might be changed so as to read: Change of quantity of motion is proportional, etc. What, then, do we mean by quantity of motion? The term is to be strictly defined: The quantity of motion of any body is proportional to its mass and its velocity taken together. If we use a capital "M" to signify momentum, a small "m" to signify mass, and a small "v" to signify velocity, we may frame the formula

$$M = mv.$$

But we must have a little more definition yet. Hitherto we have used the words speed and velocity indifferently, but from this moment we must employ the word velocity with its strict technical meaning. In physics *velocity* is taken to mean speed—that is to say, rate of motion *plus the statement of the direction of the motion.* Velocity is therefore speed plus direction; thus we see that

Momentum equals mass and velocity, or equals mass and speed and direction.

We are now in a position to read the second law of motion with full comprehension.

It means that the change in the quantity of motion of a moving body, and in the direction of its motion, is strictly determined by the quantity and the direction of the force which causes it. In this law is included the principle discovered by Galileo—whom we have already described as the father of dynamics—the principle of the independence of two or more forces that may act on a body. It is true that the body moves only in one direction at one time, though acted upon by fifty forces, yet each of these forces determines the momentum of the body in its own measure, as Galileo showed.

Composition and Resolution of Forces. It is from this second law of motion that we are able to deduce the means of compounding and resolving forces. By the *composition* and *resolution of forces* we mean respectively the estimation of the net result, so to speak, of the action of a number of forces—and the discovery and identification of a number of forces of which only the net result can immediately be observed. A problem in the composition of forces, for instance, would be the determination of a future position of a planet at a given moment by means of our knowledge of the various forces that are acting upon it. A problem in the resolution of forces would be the discovery of the various forces that determine the actual observed motions of a planet.

So far, then, we may say that whilst the first law gave us a definition of force, the idea of inertia and the means of measuring time, the second law gives us the key to the composition and resolution of forces. It gives us the key also to the measurement of force and to the measurement of mass, and it also enables us to study the motion of a particle—that is to say, the ideal motion of a unit of matter.

A Falling Stone on a Moving Ship. Perhaps the simplest illustration of the first assertion of the second law of motion is the case of a stone dropped from the mast of a moving ship. As everyone knows, the stone will fall at the bottom of the mast, just as it would if the ship were not moving, yet during the time that the stone fell the ship may have advanced many feet upon her journey. The first law of motion teaches us that the falling stone must retain in falling the motion which it had when it was attached to the ship, and the second law teaches us that the external force of gravitation acts independently upon the whole, ship and stone together, with exactly the same result, whether both are moving or both are at rest.

Another illustration is furnished by a cricket ball. If to practise catching you run rapidly forward, throwing up the ball at intervals, you know, by experience, that it is not necessary to throw the ball forward, as you might at first expect; you throw the ball vertically upwards as you run, yet it comes down again into your hand, though your body has travelled a long distance forward in the interval. The curved course of the ball in its flight through the air is

deducible from the first and second laws of motion.

How Neptune was Discovered. A most conspicuous instance of the truth of these laws was furnished by the discovery of the planet Neptune, which was, of course, unknown to Newton. Newton had furnished the astronomers with the law of gravitation and with the laws of motion, yet when they came to study the actual observed movements of the planet Uranus (also unknown to Newton) they found that these movements did not tally with what the laws would have led them to predict. They assumed, however, the truth of these laws, and set to work to discover the nature of another force unknown to them which must be acting in order to cause the anomalous movements of the planet they were watching.

Two astromoners, one in Cambridge and one in Paris, each quite ignorant of the other's work or calculations, set themselves this task. Each independently declared that, if the laws of motion and gravitation were true, there must be, at a certain spot in the heavens, a certain mass of matter hitherto unknown to astronomers; the presence of such a mass of matter in such a place would account, they said, for the perturbations in the movements of Uranus, assuming the truth of the laws of motion. When the telescope was turned to the point indicated, the planet which we now call Neptune was discovered.

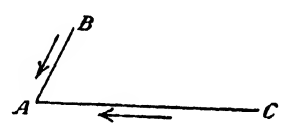
Measurement of Force and Mass. We have already stated the possibilities which are afforded us by the second law of motion, and we must make a further brief reference to them. It enables us, we have said, to measure force, for by this law a uniform force may be measured by observing the momentum which it produces in a given time. Thus the unit of force will be that force which produces a unit of acceleration when acting on unit mass. This may be expressed symbolically as $F = ma$. Similarly, it will be readily seen that we have also a means of measuring mass, since mass, force, and acceleration are now seen, in virtue of the second law of motion, to be quantities which have a constant connection with one another.

As we can measure a force by measuring the amount of acceleration which it imparts to a known mass, so we can also measure mass by estimating the acceleration imparted to it by a known force. It will be readily understood that the second law of motion is capable of almost indefinite discussions and illustration, because of the high complexity of the ideas which it contains. Here, therefore, we will merely discuss two points which it raises. And first as to the familiar theory of the *parallelogram of forces.*

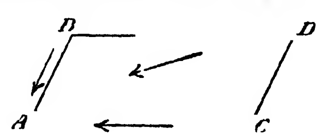
The Parallelogram of Forces. This phrase at first means nothing at all, for by a parallelogram we understand a figure or diagram on a piece of paper, whereas by a force we mean something which seems to have no relation to such a diagram. But when we speak of the parallelogram of forces, we assume—and it ought to be clear that we do assume—a symbolic way of representing forces. We find that forces and velocities and accelerations can all be perfectly represented by straight lines. Of a straight line it may be said that it has magnitude, inasmuch as it may be longer or shorter, and direction; and of these two ideas our ideas of force, acceleration, and velocity are compounded.

Hence we draw a straight line, making its length or magnitude to represent (1) in case of velocity the speed or rate of motion, (2) in the case of acceleration the number of units of velocity added per unit of time, and (3) in the case of force the magnitude of the force which, as we have already seen, is strictly proportional to the acceleration it imparts to any given mass; whilst the direction of the line indicates the direction of the motion which is implied in each case. Hence two straight lines, passing through a point, can give us a complete symbolic representation of two forces acting on any mass at that point, the length of each line being proportional to the acceleration which the symbolised force would impart to the mass, and its direction representing the direction of the force.

Now we find that from these two lines we may construct a parallelogram, if we represent the two forces by two lines which meet at the point in question. For instance, in the accompanying diagram, BA and CA represent two forces acting on a given mass at the point A—represent these forces both as to magnitude and direction.



Let us now complete the parallelogram, thus:



If now we draw the diagonal DA, it indicates exactly, both in magnitude and in direction, the resultant motion of the mass in virtue of the *composition* of the two forces BA and CA.

Similarly, we have the theories of the *parallelogram of velocities* and the *parallelogram of accelerations.*

We may state in technical language the theory which we have seen illustrated above by saying: *If two forces acting at a point be represented in magnitude and in direction by the sides of a parallelogram which meet in that point, the diagonal through that point represents the resulting force both in magnitude and in direction*

The Parallelogram in Practice. The simplest case and the most frequently illustrated of the parallelogram of forces is where the two forces are acting at right angles

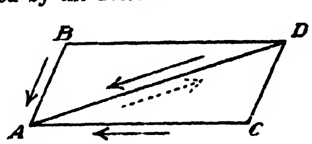
to one another. Everyone who has sailed a boat has a practical, if not a theoretical, acquaintance with the parallelogram of forces. Or take the case of a cross-Channel swimmer, whom the current is bearing in one direction, whilst his own muscles are bearing him at right angles to it. If the magnitude of the two forces, the force of the current and the force of his muscles, be represented by straight lines in the way we have seen, and then a parallelogram be constructed, the diagonal of that parallelogram will represent the actual course the swimmer's body will take.

The second topic raised by the second law of motion is most readily brought to the mind by the illustration of the various forms of lever. But before we can consider the lever, or, indeed, any of the problems of equilibrium, or of what is called *statics*—viz., the discussion of rest brought about by the balance of forces, we must devote some attention to the *third law of motion*, which is also involved.

The Third Law of Motion. This law may be said to assert that the mutual actions of any two bodies are always equal and oppositely directed, or that to every action there is an equal and opposite reaction. This exceedingly important law may be extended so as to have a much wider meaning, which Newton at any rate suspected. Thus we may say that the activity of an agent or the rate at which it does work is equal to the counter-activity of the resistance. We are here close to the proposition, which must later be discussed at length, of the *conservation of energy*.

Now let us consider again the general question of statics, that branch of dynamics which is concerned with the balance of forces. The chief problem of statics, we may say, is to discover the precise manner in which the combination of a number of forces acting on a body—each of which is in itself the cause of motion—shall produce not any kind of motion, but *equilibrium*, or *rest*.

Now, in the last diagram we saw that two forces, represented by the lines BA and CA, tended to produce a motion which can be represented both in magnitude and direction by the line DA; whence the proposition of the parallelogram of forces enables us to assert that equilibrium, or rest, will be attained if to the two forces BA and CA there is opposed a single force, to be represented in magnitude by the line DA and in direction by that line, save that it acts not from D to A, but from A to D, as indicated by the dotted arrow.



Hence the result of the interaction of three forces represented by BA, CA, and AD will be rest. This is perhaps as simple a problem in statics as we can name.

The Triangle of Forces. Now we may go further and show that, since BD is equal to AC, the fact of rest, or equilibrium, may be represented in our diagram by a closed figure—in this case a triangle, AB, BD, DA. This is what is known as the *triangle of forces*, and it is capable of great extension. It can be proved that if any number of forces acting at a point can be represented in magnitude and in direction by the sides of a closed figure taken in order, the net result of the action of all these forces will be rest—or, in other words, these forces will be in equilibrium. The triangle of forces is thus a special case of the *polygon of forces*, a polygon here being taken to mean any closed figure bounded by a number of straight lines—literally, it means many angles.

If only two forces act on a body, it is evident that rest or equilibrium will result only when the two forces act at one point, when they are equal in magnitude and opposite in direction. If the forces are not acting at one point, a new problem arises—viz., the problem of a motion of a system of particles as compared with the much simpler problem of the motion of a single particle.

What we mean by Equilibrium. By equilibrium we mean that state of balance among the forces or sets of forces acting on a body in virtue of which there is no resulting tendency for the body to change its state, *whether of rest or of motion*. Statics is precisely the study of forces in such equilibrium.

The first point to note is that we must not confuse equilibrium with rest. Whenever there is rest there is certainly equilibrium. A book lying on the table is at rest, because there is equilibrium amongst the forces which tend to pull it towards the earth and the forces by which it is sustained, but this is only one kind of equilibrium or stability. We may call it *static stability*, meaning that the body is stable, in a state of rest. But, on the other hand there may as certainly be equilibrium or stability where there is motion. This we call a moving equilibrium, or a case of *kinetic stability*. Whenever a body or a system of bodies tends to remain or be stable in a steady state of motion, we have an instance of a moving equilibrium, or kinetic stability; hence equilibrium does not necessarily mean rest, but is compatible with steady motion.

A vehicle drawn along at constant speed, in virtue of the continued action of the forces that tend to drag it on and the forces that tend to hold it back, the resultant of the two sets of forces being constant, as is proved by the constant motion of the vehicle, is as truly in a state of equilibrium or kinetic stability as it is when it comes to rest.

For many decades of the nineteenth century it was believed that the solar system is an instance of a moving equilibrium—furnishes a case of kinetic stability; but it is now known that other internal forces besides those recognised by the great French mathematicians who were contemporary with Napoleon are at work in the solar system, and that, therefore, it does not furnish a case of kinetic stability.

THE OCEANS OF THE WORLD

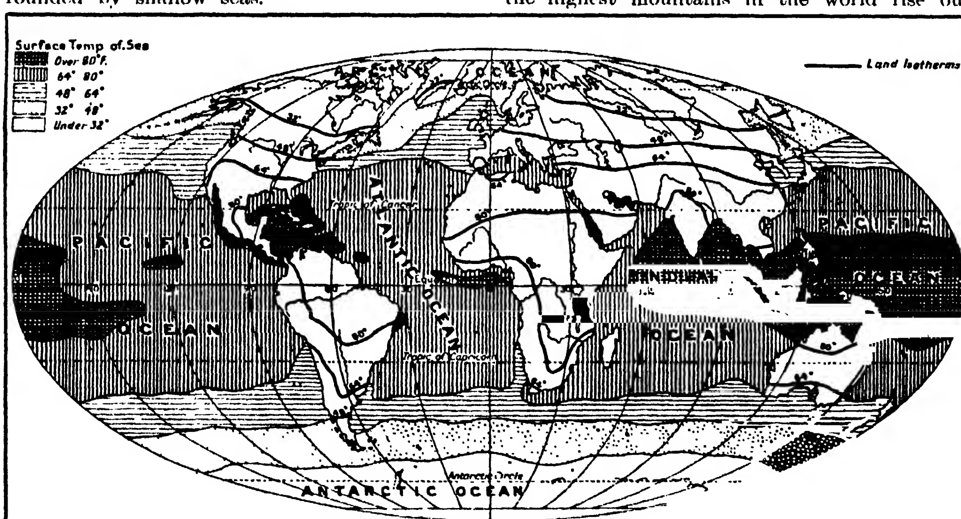
The Water Cycle. The Rivers and the Sea. Chemistry of Sea Water. Tides and their Movements. Currents. Coral Islands

By Dr. A. J. HERBERTSON and F. D. HERBERTSON, B.A.

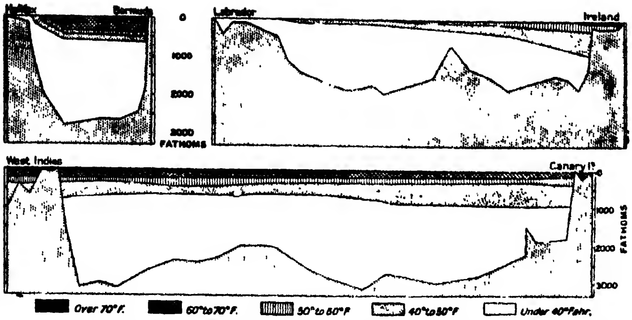
Deep and Shallow Seas. The seas over the continental shelf are everywhere shallow. The continental shelf is very broad in the northern part of the Pacific, where, if the sea sank 600 ft., North America would be joined to Asia by an isthmus over 1,000 miles wide. A broad continental shelf, covered by shallow seas, extends along the Atlantic shores of the New World. The broad continental shelf of North-west Europe is covered by the shallow North Sea, leading to the shallow Baltic Sea. A broad continental shelf, on which lie the East Indies, borders the Pacific shores of Asia. A similar broadening of the continental shelf connects Australia with New Guinea on the north and Tasmania on the south. All these lands are immediately surrounded by shallow seas.

40. THE CIRCULATION OF WATER
The arrows show the water rising in the form of invisible vapour from the sea, then, passing into cloud, it forms and descends as rain on the mountain tops, being thence carried by the river to the sea

Beyond the continental shelf the ocean varies greatly in depth. Its greatest depths, as we have seen, may be compared roughly with the greatest elevation of the lithosphere. The principal deeps are found along both margins of the Pacific. The deepest are the Japan, or Tuscarora Deeps, off the north-east of Japan; the Marianne Deeps (the deepest in the world, over 13,500 ft.), off the Marianne Islands, between Japan and New Guinea; and the Kermadec (over 30,000 ft.) and Tonga Deeps, off islands of the same name lying to the north-east of New Zealand. These are all on the eastern margin of the Pacific. On the western margin great depths occur off the Aleutian Islands of North America, and off the coast of Chile, where almost the highest mountains in the world rise out



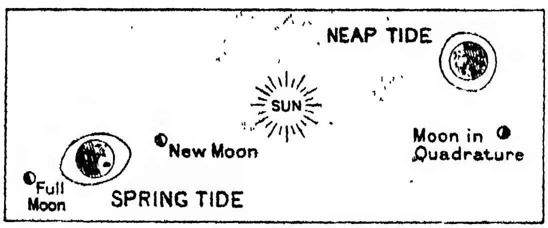
41. TEMPERATURE OF THE OCEAN
The warmer the water, the deeper the tint



42. SECTIONS OF THE NORTH ATLANTIC OCEAN SHOWING TEMPERATURE AT DIFFERENT DEPTHS
The darker the tint the warmer the water

of almost the deepest seas. In the Atlantic the greatest depths are north of Porto Rico (28,000 ft.). On the eastern margin of the Indian Ocean is the Sunda, or Java Deep, off Java (under 20,000 ft.).

The oceans receive the waters of innumerable rivers. This constant gain, however, is counterbalanced by the loss due to evaporation, which goes on all over the surface of the ocean, with an intensity varying with the atmospheric conditions [40]. We have already investigated the process in our examination of rain. The moisture absorbed by the atmosphere takes part in the great rhythm of water circulation already described, and, falling at last as rain, is ultimately restored by rivers to the ocean, to start once more on its cycle of change.



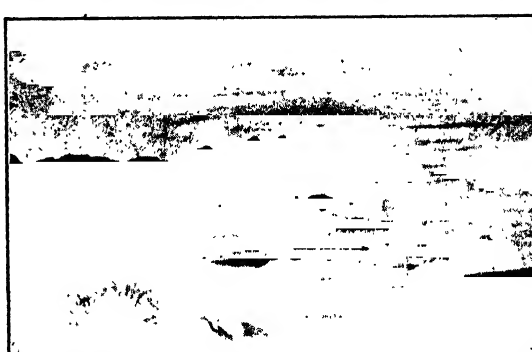
43. HIGHEST AND LOWEST TIDES

The Chemistry of Sea Water. Rivers, in passing over the surface of the land, become more or less heavily charged with chemical substances, which they carry into the ocean. These are left behind in evaporation, and their presence renders the ocean brackish. Of chemical substances present in the ocean the most abundant is common salt, which, if spread out over the land, would form a layer many feet thick. Only a small part of this is brought down by rivers. The origin of the rest is an unsolved problem. Sea water, being thus heavily charged with chemical matter in solution, is heavier than fresh, and one can, therefore, float in it more easily, as every bather knows.

The salinity of sea water varies in different parts of the world and at different depths. The surface waters are saltest where evaporation is most rapid, and rainfall least—that is, in the dry parts of the hot belts. The cold Polar waters, where evaporation is slowest, are least salt on the surface. Inland seas, like the Mediterranean and Red Seas, which receive few rivers, are exceedingly salt.

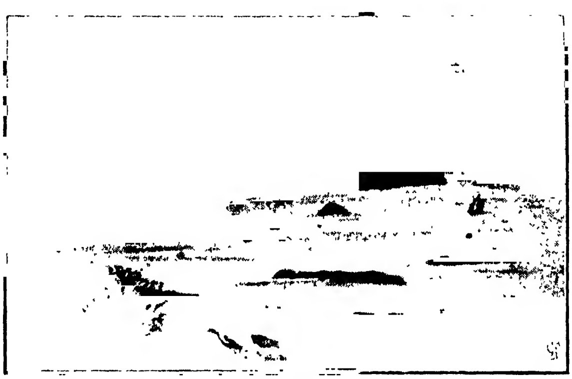
Temperature of the Ocean. A great part of the sun's rays are reflected back from the surface of the ocean, causing the glare so familiar to those who look at the sunlit sea. The rays which are not reflected off heat the upper layers, which become heavier through evaporation and consequently sink, heating the layers below by the movement of their heated particles. This heating action, though it penetrates much deeper than in the case of land, reaches to no great depth. In the hot zone the surface temperature of the ocean is about 70° F. [47], but half a mile below the surface it is only 38° F., or but a few degrees above freezing point [41]. Enclosed seas like the Mediterranean and Red Seas, lying wholly in warm latitudes, have a much higher temperature. The surface temperature of the Red Sea and the Persian Gulf may be as high as 90° F. The great oceans, which extend through all the climatic zones, have a great range of surface temperature [42]. In the Polar oceans the surface temperature is about 38° F., which may probably be taken as the average temperature of the ocean.

How the Moon Attracts the Sea. The tides are periodical risings and fallings of



44. EFFECT OF THE SUN ON TIDES
Spring tide. Low water about 6 p.m.

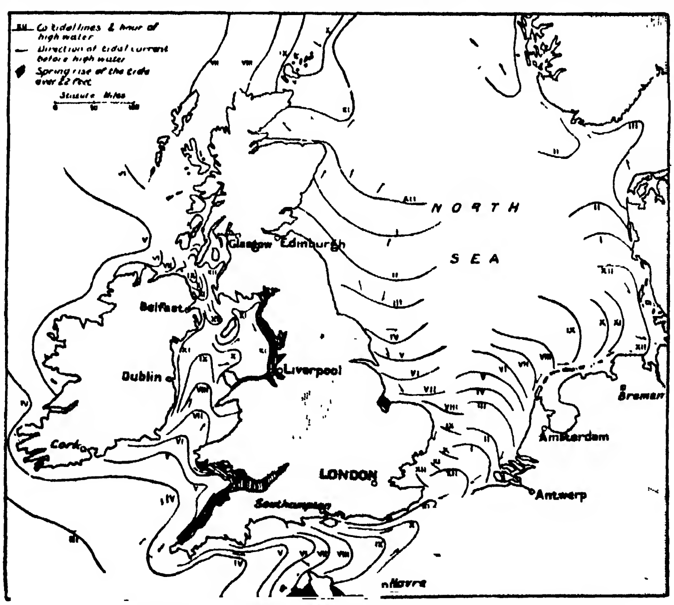
the waters of the ocean which take place twice daily. Students who are not familiar with advanced mathematics must be content to accept the statement that they are caused by the attraction of the moon, which is distant less than a quarter-million miles. The moon's attraction acts on sea and land alike, along the line passing through the centres of both earth and moon. Along this line both water and land are, as it were, pulled towards the moon, causing a heaping up of water on the side of the earth nearest to the moon, and a similar heaping up of water on the side furthest from the moon owing to the land being pulled towards the moon. These facts, which really belong to the study of astronomy, physics, and mathematics [which see], cannot well be more simply stated than in this form. The student who does not thoroughly understand them will do so as he advances in the course of ASTRONOMY. All that the student of geography needs to bear in mind is that the moon's attraction does, in the manner roughly described, gather the waters of the earth into a double wave, with one crest on the side nearest to the moon, and the other crest on the opposite side [43]. As the earth rotates, this double wave moves round the earth, retaining its relation to the moon and the crests and troughs alternately producing high and low tide. Thus there are two high and two low tides daily, at intervals of rather more than twelve hours, or half a lunar day.



45. SPRING TIDE. HIGH WATER AT MIDNIGHT
Spring tides always occur at full or new moon

The Meeting of the Tides. The attraction of the sun similarly tends to cause tides, but in a much less degree, owing to its enormous distance [44]. When the sun and the moon act in the same line, which happens at new and full moon [See ASTRONOMY], the highest, or spring tides occur. The lowest, or neap tides, are when sun and moon attract in different directions and partially neutralise each other [45]. This happens when the moon is one quarter or three-quarters full.

Owing to the different distribution of sea and land, and the varying relief and depth of the sea bottom, which causes different degrees of friction in different parts of the ocean, the tides on different shores are by no means uniform. As the ocean becomes shallower towards the shore the waters become heaped up, often forming tides of great height. This is particularly the case when the tidal wave is forced up an estuary or other narrow opening. The incoming tide then advances like a wall of water. Such high tides, or bores, are seen on a huge scale in the Bay of Fundy in Nova Scotia, and in Hangchou Bay in China. On a smaller scale they occur in the Severn, where the tide rises 40 or 50 ft. at Bristol, in the Seine, and other European rivers.

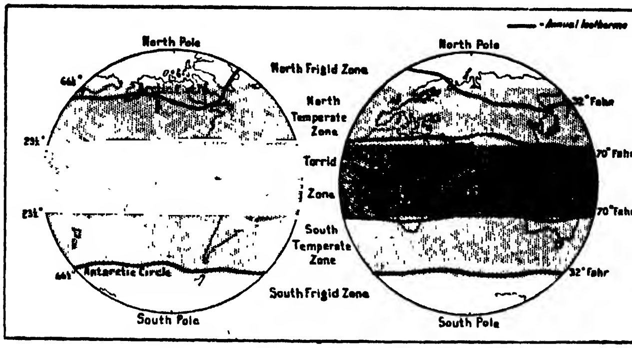


46. PROGRESS OF THE TIDES ROUND THE BRITISH COASTS

Where the tide enters an enclosed sea various modifications occur. Thus the Atlantic tides enter the North Sea both round the south of England, through the Strait of Dover, and round the north of Scotland [46]. The crests of two tidal waves meet at the Thames estuary, causing very

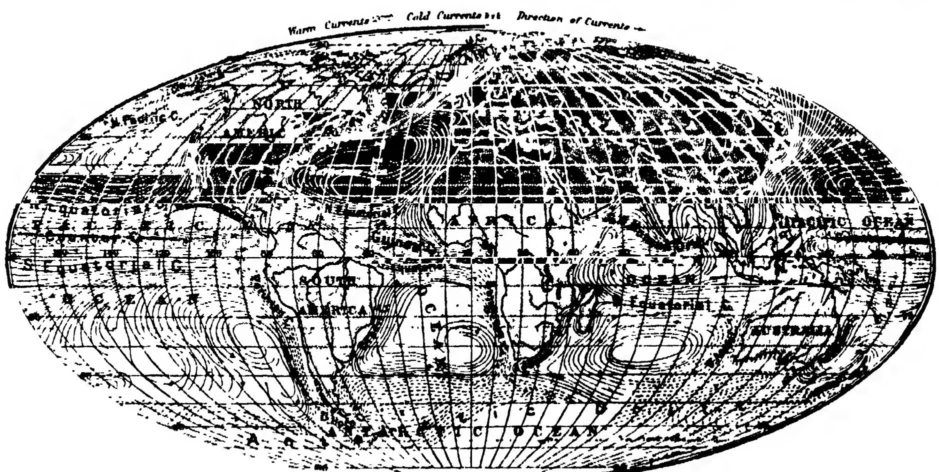
high tides, which add greatly to the advantages of London as a port. On the opposite side of the North Sea there are places where the trough of one tide neutralises the crest of the other, causing no tide to be felt. In the Mediterranean, which is practically landlocked, the tidal wave is stopped by a sort of natural breakwater, and practically no tide is felt beyond the Strait of Gibraltar.

For the student of geography tides are mainly important for their influence on commerce, which will be considered when we reach the commercial side of geography.



47. THE ZONES

Surface of the Ocean. The surface currents of the ocean are caused by the prevailing winds which have already been described. These tend to pile up the waters on the lee side of the ocean and to suck up water from lower depths on the windward side. Thus the windward side is cooled by the rising of the cooler lower waters to the surface and the leeward side is warmed by the inflowing of the surface waters, except where the set of the surface currents is towards the Equator. Currents, being caused by winds, share in the seasonal variations already noticed.



48. OCEAN CURRENTS

In every ocean the surface waters are impelled slowly in great eddies, moving, in the northern hemisphere, with the hands of a watch, and in the southern hemisphere in the reverse direction. The centre of the eddies lies in mid ocean, about lat. 30°—that is, in the high pressure area formed in the horse-latitudes. On the equatorial side of these eddies the currents move west, driven by the trade winds; on the Polar side they move east, driven by the westerly winds; while on the east side they are drawn towards the Equator, and on the western side towards the Pole, in the circling eddy already mentioned [48]. In the southern hemisphere, where there is a vast continuous belt of unbroken ocean, the east-flowing currents unite to form a circum-polar eddy. Round the Equator the distribution of sea and land prevents the development of a similar circum-equatorial eddy, encircling the world, and breaks it up into the separate eddies just referred to.

The Atlantic Currents. The Atlantic is S-shaped, and this causes surface water from the southern hemisphere to be forced westwards towards the north-east coast of Brazil, where it divides, the northern branch passing into the northern hemisphere along the Guianan coast, both inside and outside the American Mediterranean. This current is, of course, a warm one. Further north that branch which passes outside the West Indies is reinforced by a warm current from the Gulf of Mexico, and the united current, known as the Gulf Stream, moves first as a perceptible surface

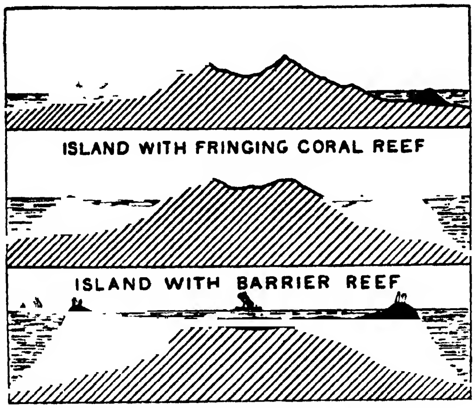
stream of warmer water, which gradually becomes less and less marked, after which it is called the North Atlantic or Gulf Stream Drift When this current reaches the latitudes of the westerly winds it is carried east towards the Old World, where it flows out partly to the south-east, forming the Canary current, and partly to the north-east by the wide passage between Greenland and Europe. This warm drift serves to keep the ports of Western Europe ice-free in winter even in the north of Norway.

There are two cold currents from the Arctic, by Davis Strait and East Greenland, the former reinforced by upwelling water, forming what is called the *cold wall*, off the United States coast.

Pacific and Indian Ocean. In the Pacific Ocean similar currents are modified by the circular configuration of that ocean. There is no great transference of warm water from the southern hemisphere north across the equator, and no great north-east current penetrating to high latitudes. The warm north and north-east current, known as the Kuro Siwo in Japanese waters, is similar to the Gulf Stream, but the almost unbroken barrier of land to the north prevents it from penetrating to Arctic waters. The northern part of the current turns north and north-west, off the coast of British Columbia, and keeps the north-east ports of the Pacific ice-free.

In the Indian Ocean the land is continuous north of the tropic of Cancer, and the winds blow inwards as monsoons in summer and outwards in winter. India juts out and breaks the ocean into two divisions, in both of which the waters circle clockwise in summer and in the reverse direction in winter.

Where winds blow steadily off the land they carry the surface waters before them, and these are generally replaced by colder water from below. Such cold upwellings occur off the West Coast of Africa and in similar latitudes in the Pacific.



49. CORAL ISLANDS

Where an inland sea like the Mediterranean or Red Sea is hot, and subject to great evaporation without many rivers to replace it, a surface current flows into it from the ocean. Inland seas, like the Baltic and Black Seas, which receive many rivers, may have a surface current outwards [48]. New land is formed beneath the ocean by the accumulation of sediment brought down by rivers, and is gradually pressed into a hard, solid form by the weight of the upper layers. The rate of formation is most rapid near the shore, but may continue hundreds of miles out to sea, according to the size of the rivers and the set of the currents. By a similar process the limy skeletons of minute sea creatures gradually form the rock we call chalk. [See page 7.] The chalk districts of Britain must in some distant age have been beneath the level of the sea.

Coral Islands. Coral islands are found almost exclusively in the tropics. The living coral polyp is a beautiful creature, the soft, fleshy, living parts of which resemble minute flowers.

Coral formations are of two kinds, *reefs* and *atolls* [49] The former may be either *fringing reefs*, occurring in the shallow seas close to land, or *barrier reefs*. Barrier reefs occur at a distance from the shore, where there is a channel of shallow water. They surround many islands in the Pacific, and are often broken by gaps opposite the mouths of rivers. The finest example is the Great Barrier Reef, which stretches for 1,200 miles along the north-eastern coast of Australia, at a distance of from 20 to 100 miles from coast [50]. Atolls are circular reefs, often rising from great depths. Inside the reefs are lagoons of transparent green water, fringed with white coral rock and sand. The coral polyp dies at sea-level. All purely coral islands, therefore, are low. The waves break off and heap up blocks of coral, which are gradually reduced to brilliant white sand, forming an island on which wind-transported seeds take root

Group 10 **ELECTRICITY** 4 Continued from page 467	# ELECTROMAGNETISM. **Forces with which Magnets Pull. Magnetic Curves. Typical Forms of Electromagnets. Lifting Magnets used in the Workshop**

By Professor SILVANUS P. THOMPSON

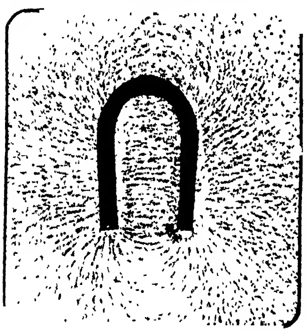
Properties of the Magnet. Every schoolboy knows that a magnet will pick up a bit of iron and stick to it, and that it will not attract silver, gold, copper, tin, lead, or such substances as glass, wood, stone, porcelain, paper, nor any animal or vegetable products. Every schoolboy also knows that a magnet, or a magnetised piece of steel will, if poised or hung so that it can turn, point towards the north. Anything that possesses these two properties is a *magnet.*

It is found that magnets can be made either of lodestone—a hard, black oxide of iron found in Sweden, Arkansas, and Spain—or of some kind of hard iron or steel. They can also be made of the metals cobalt and nickel, which resemble iron. No other metals are magnetic to any appreciable degree. The magnetism of magnets is found apparently to exist chiefly at the ends, or *poles* ; the other parts of the magnet show scarcely any magnetic property on the surface. The oldest magnets were natural lodestones. To magnetise pieces of steel, it suffices to rub them upon the pole of a powerful magnet. If the steel is hard, it will retain a good proportion of the magnetism so imparted to it. If the steel or iron be soft, it will retain little or none, particularly if the piece be short in shape.

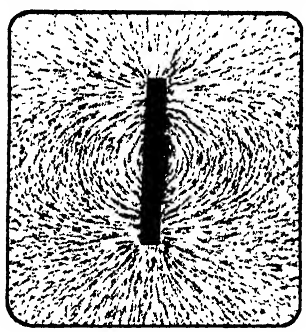
Those who want further information on the simple properties of magnets or of the magnetic compass should refer to the articles thereon in PHYSICS. We can here deal only with a few points that lead towards the industrial applications.

Experiments with Magnets. Procure a small horseshoe-shaped steel magnet, also a bar magnet, and a few bits of iron—as, for example, nails. Procure also some clean iron filings. The iron filings may be oily and dirty as they come from the workshop bench. They can be cleaned by stirring them well about in hot soapy water, and afterwards washing in clean water, after which they should be drained dry on a cloth or on blotting-paper. They should also be sifted through a pepper-box or a piece of coarse muslin, the finest filings only being kept for use.

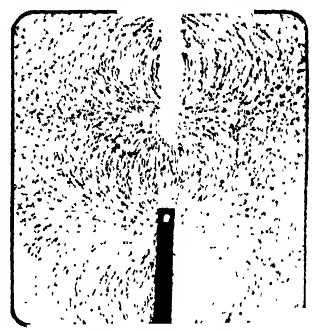
If a magnet be plunged into iron filings they are found to adhere in tufts. These tufts are chiefly on the ends, or polar regions, of the magnet. If a tuft be examined, it is found that each hair in the tuft consists of a lot of filings which have arranged themselves as in a chain, and adhere together, the end of one filing to the end of the next. If the tuft be pulled off the magnet it falls at once to dust again. Put the magnet with its pole or poles upwards, under a card or under a china plate, and put a few filings on the plate. The filings will stand up in tufts over the place where the magnet is, and if the magnet be moved the tufts of filings will follow it.



16. CURVES OF HORSESHOE MAGNET



17. CURVES OF BAR MAGNET



18. CURVES BETWEEN TWO POLES

Another experiment is to hang a nail to the pole of a magnet, then to hang a second nail to the bottom end of the first, and a third nail to the second, and so on, so that they hang in a chain. Each bit of iron, in fact, becomes a magnet while it is under the influence of the larger magnet, and will adhere to other bits of iron.

Filing Figures—Magnetic Curves. As the attractive force of a magnet is exerted more by some parts of it than by others, we shall explore the distribution of these forces by the aid of iron filings. The chains or filaments into which the filings gather themselves under the influence of the magnet tend to take definite directions. But when these chains, or filaments, hang from the pole of a magnet or stand upon its surface, their own weight

prevents them from assuming their full development. To observe them properly, arrangements must be made to relieve them of their weight. This is done very simply, by laying the magnet down upon a table, then laying over it a flat, thin sheet of cardboard, or a sheet of thin glass, upon whi h the iron filings are sprinkled as uniformly as possible, using as a sprinkler a pepper-box or a bottle with gauze over the mouth.

When a thin sprinkling of filings has thus been obtained, the sheet of card or glass should be gently tapped at the corner with a pencil or with the finger, when the filings will be seen to rearrange themselves in beautiful patterns or figures, thus exhibiting to the eye the forms of the magnetic curves. Fig. 16 gives, in photographic reproduction, the curves of a horseshoe magnet, and 17 those of a bar magnet.

Causes of Magnetic Curves. Now, the real point of interest of these filing figures is that they map out visibly to the eye the paths of forces that would otherwise be invisible; and the mechanical forces which magnet-poles exert on one another are actually exhibited and depicted by these magnetic curves. This relation will be better understood if we take a case in which the mechanical relations are already known. It is one of the oldest known facts about magnets that if the north pole—by which we mean the pole that points northwards if the magnet is hung up, or floated, free to turn—of one magnet be placed near to the south pole of another magnet, they tend to run together mechanically, as if they attracted one another.

In reality, as we shall better understand hereafter, they are pulled or urged towards one another by something that is going on in the space in between, and the older writers, who did not know about this intervening action in space, thought that they attracted one another. To investigate the action, lay down two bar magnets on the table with the north pole of one near the south pole of the other, as in 18, interposing, if need be, a small bit of wood to keep them from running together. Then place over them a sheet of card and observe the filing figure. It will resemble that shown in 18, in which we see that the magnetic curves form a series of arching lines which start from the surface of one magnet and run across the space to the surface of the other.

Magnetic Lines—Magnetic Field. The interpretation of these lines is that wherever we find them crossing any part of space there is a mechanical tension of pull exerted across that space, the direction of the tension being along the lines. In fact, the mechanical forces are such as would be exerted if the magnetic lines of the pattern could be regarded as threads of some stretched elastic substance, tending to shorten themselves. In reality, these filing curves map out stresses in the intervening medium. These stresses really exist in the neighbourhood of the pole of a magnet, but we cannot *see* them until their existence is revealed thus by the sprinkled filings.

Now, these stresses in the medium that occupies the space between magnet poles exist, whether we sprinkle filings about in order to explore them or whether we do not. We must therefore conceive of the space in any magnetic region near or between the poles of a magnet as being always full of invisible magnetic lines, which run in the directions of the forces, and of which the chains of filings are a crude representation.

We can explore these lines in several other ways, one of which is to take a small compass-needle and place it in the part of space we wish to explore, when it will at once turn and point along the direction of the magnetic lines, setting itself, in fact, at a tangent to the magnetic curve that passes invisibly through its centre. Any region of space across which in this way the magnetic lines are invisibly passing is called a *magnetic field*. Near the pole, or between the poles, of powerful magnets, where the magnetic forces are strong, the field is described as being very *intense*, the lines being numerous and close together. The whole number of lines that proceed out of any magnet pole is called *the magnetic flux* from that pole.

Flux-densities. The lines really come up through the metal, passing right through the magnet itself. The region or part of the surface where magnetic lines emerge from the magnet into the air is called its north pole. From this pole they spread out in diverging or radiating directions, then arch round in curves and re-enter the magnet at the other region, which is called the south pole. Where the lines are very close together, and the magnetic tension along them is strong, the flux is said to be *dense*. The term *flux-density* is used to denote the number of lines per unit of area crossing any surface placed squarely across their path. It is, for example, quite common in dynamo-electric machines to find in the gap that lies between the magnet poles and the adjacent surface of the armature a flux-density of 50,000 lines per square inch. For the definition of the magnetic line the reader must refer to the article on magnetism in PHYSICS, or to some book on magnetic units.

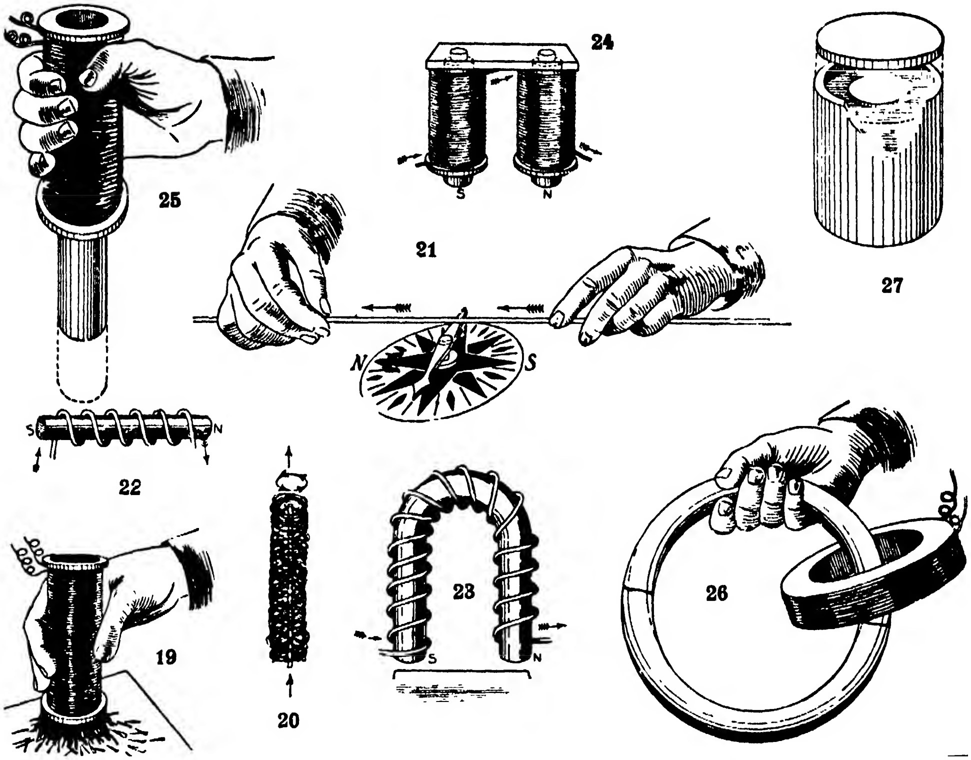
As the magnetic lines run through the bodies of magnets and masses of iron more readily than through air, it follows that in magnet cores we often find very high flux-densities. In fact, cast iron can readily be magnetised up to a flux-density of about 45,000 lines to the square inch, while soft wrought iron and mild steel can easily be magnetised up to a flux-density of 100,000 lines to the square inch. The symbol **B** is in general use to denote a flux-density—that is, the number of lines per unit of area.

Magnetic Pull and Flux-density. The mutual pull between two flat magnet poles is related to the flux-density in the space between them, and depends also on their area. It is found by experiment that if different flux-densities are tried, the pull increases as the square of the flux-density. Suppose that in any given case there is a small flux-density, and a small pull, then, if we can get double the flux-density, the pull will be found to have increased fourfold; and if we treble the flux-density, the pull will have increased ninefold. In fact, the pull

between two flat magnet poles that are near together can be calculated by the formula:

$$P = B^2 \times A \div 72{,}134{,}000,$$

where P is the pull in pounds' weight, B the flux-density in lines per square inch, and A the area of surface of each of the flat poles in square inches. For example, if we have two magnets, each of which has a pole of area 2 sq. in., and if the flux-density between them be 25,000 lines per square inch, the pull which they exert on one another will be $25{,}000 \times 25{,}000 \times 2 \div 72{,}134{,}000$; or, working out the sum, we find it will be 17·3 lb. The difficulty in using such calculations is to find out how much B is going to be.



DIFFERENT FORMS OF ELECTROMAGNETS AND THEIR ACTION

Magnetic Action of an Electric Current. All the preceding paragraphs of this article have been about magnetism only. Not one word has been said about electricity or electric currents. If electricity had never been discovered, all that precedes about the properties of magnets and magnetic lines would still be true, for magnetism was discovered centuries before the electric current was known. And yet, as we must now learn, electric currents can be made to act as magnets.

For this purpose we must construct a special coil of wire. Suppose we procure 100 ft. of copper wire, of the size known as No. 18 standard wire-gauge. It must not be bare wire, but insulated by being overspun with cotton, to prevent the spires of the coil from coming into contact, and the weight of it will be about 1 lb.

Let us prepare, as a core on which to wind it, a wooden, rod-like, small, round ruler, ½ in. in diameter, and a little over 4 in. long. We shall need two discs, or cheeks, to be fastened on, so as to leave 4 in. length of winding space. A bit of brass tube with brass cheeks soldered on 4 in. apart will do even better, but if metal is thus used the winding space should be lined with paper before beginning the winding.

If we wind this wire on such a prepared bobbin, we shall find that we shall get about 65 turns of wire in the first layer, and if we go on winding layers, there will be length enough of the wire for about six layers. The ends must be secured from unwrapping, and cleaned up so that they can be connected to a suitable battery.

Now, such a coil of copper wire has of itself no magnetic properties at all. If we try it, it will not pick up a single iron nail, nor act on a compass-needle. But if we connect its ends to a battery so that a current flows along the wire,

and goes therefore circulating round and round the core, we shall find, if we try it while the current is on, that it is quite a powerful magnet, and will pick up nails or tinned tacks, as depicted in 19. Directly, however, that we break the circuit and stop the current from circulating, the coil will cease to act as a magnet.

Electricity in Circulation. This experiment has taught us a new fact—*electricity in circulation is magnetism.* For here, without having any steel, iron, or lodestone, we have got a magnet that will attract bits of iron, and by a little experimenting we can easily prove that the coil has two poles, one at each end, and that one end is a north pole, which will attract the south pole of a compass, while the other is a south pole, which will attract the north pole of a compass. The coil is of copper wire. But it is not the copper that does the attracting; it is the electric current in the coil, for the attraction stops when the current stops. And if we had made our coil of silver or gold wire instead of copper it would have worked just as well.

Before we go on, let us give a thought to the amount of circulation of current in the coil. If we have used only one cell to generate current we shall have had but a weak current—perhaps less than half an ampere. If we have used one good Fuller's cell, we shall probably have had at least 1½ amperes. If we use a battery of half a dozen Fuller's cells in series, we shall have a bigger current, perhaps 6 or 7 amperes. Of course, if we want to ascertain how much current our battery is sending through the coil we must use a proper *amperemeter*. [See How to Generate a Current, p. 291.]

The stronger the current the more powerful will the magnetism of the coil be. Now examine the coil to see how many turns of wire there are on it. If there are 6 layers of 65 turns per layer, the total number of turns will be 390. Therefore, the current, whether weak or strong, has to go 390 times round the core before it leaves the coil. Suppose we had been able to get a current of 7 amperes from our battery. Then, 7 amperes going 390 times round will produce exactly the same magnetic effect as 1 ampere going 2,730 times round, or, in electricians' language, producing a circulation of 2,730 *ampere-turns*. One ampere-turn means 1 ampere going round once. To ascertain the number of ampere-turns in any magnetising coil we have to count the number of turns, and observe the number of amperes, and then multiply the two numbers together.

Magnetic Field of a Current. We shall naturally inquire whether or a single turn of an electric circuit has any magnetic properties, or whether a straight wire along which a current is being conducted will act magnetically. A straight wire will act in this manner. If a strong current is sent along a piece of bare copper wire, and the wire is laid down upon iron filings, it is found that some of them will adhere to the wire, not end-wise in tufts as they do to a magnet pole, but sideways, clinging on tangentially. And if a compass-needle is brought near a vertical wire that carries a current, it is acted on.

This action is, however, neither an attraction nor a repulsion, for the needle always tries to set itself square to the wire, pointing neither to it, nor from it, nor yet along it, but presenting its flank to the wire. The wire carrying a current is, in fact, surrounded by a magnetic fluid of its own, a field in which the lines are concentric circles around the wire, somewhat as in 20, constituting a sort of invisible magnetic whirl surrounding the current. If a current be carried, either in one wire or in a number of wires constituting an open coil, over or under a compass-needle, the needle at once turns to point across the direction of the wires. If a current runs from south to north over the compass-needle, the needle is deflected, as in 21, to the west. If it runs from north to south over the needle, the needle is deflected to the east. This deflection of a compass-needle by the current in a neighbouring conductor is the earliest discovery in electromagnetism, having been made in 1820 by Oersted. It is the fundamental principle of the *galvanometer*.

The Electromagnet. It was in 1825 that the most important departure was made in the invention of the electromagnet by William Sturgeon. Arago had, indeed, investigated the magnetic action of coils or spirals of wire when traversed by a current, and had found that he could magnetise steel compass-needles by inserting them into the inside of the coil, and then pulling them out again. But it was left to William Sturgeon to show that if a coil of insulated copper wire be wound upon a rod of soft iron, the combination acts as a powerful magnet when an electric current is sent through the coil.

This new kind of magnet differed from the older permanent magnets of steel, and from lodestones, in the following most important respects. First, it was more powerful relatively to its size. Secondly, its magnetism was under control, for it became a magnet only when the current was turned on, and ceased to be a magnet—and therefore dropped its load—as soon as the current was turned off. Thirdly, it could be controlled from a distance, for the switch or key by which, when required, the circuit was made or broken, might be anywhere in the circuit—might be at a distance of many feet, or even miles, away from the magnet itself. Figs. 22 and 23 are pictures of simple electromagnets such as Sturgeon produced.

Forms of Electromagnets. Some electromagnets are straight bars, and others are bent into horseshoe form like 23. A more common form—the form largely used in electric bells—is that shown in 24, in which the "horseshoe" is made of two short iron rods, or *cores*, fitted into a crosspiece of iron called the *yoke*. The advantage of this shape is that the coil can be separately wound upon two wooden bobbins, in a winding lathe, and these bobbins are then slipped upon the cores, and the wires joined up to make electrically one continuous coil.

We have suggested above experiments with a coil 4 in. long, wound on a brass tube or a wooden rod. The brass tube is preferable, because we can now introduce inside the brass tube a rod of iron projecting out at both ends,

when it will be found, on turning on the current to circulate around the coil, that the iron rod becomes a very powerful magnet. In fact, the electromagnet thus made by the iron core surrounded by the copper-wire coil will be immensely more powerful as a magnet than the copper-wire coil was without the iron core.

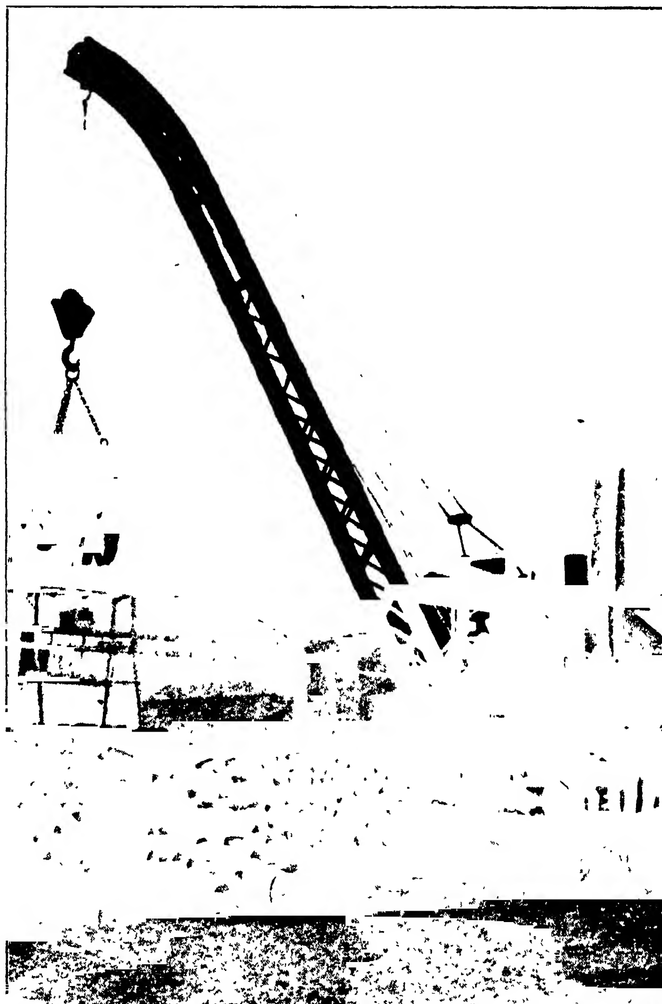
If in this form of apparatus the iron core is small enough to slip freely into the inside of the coil, it will be observed that, if the current is turned on at a moment when the iron core is inserted partly into the coil, the coil will suck the iron core into the interior. If the coil is fixed vertically, as in **25**, over a table, and the iron core is made to stand on the table, with its upper end within the mouth of the coil, then on turning on the current the iron core will be drawn up. On switching off the current, the core falls down again.

Experiment with an Iron Ring. For this experiment is required a ring, such as any blacksmith can forge, of soft iron—the softer the better—about 10 in. in diameter. It should be cut into two equal halves, and the ends faced off flat. There is also needed a coil of insulated copper wire, which should consist of a large number of turns, tied with string to hold them together, or coiled together, the coil being, say, 5 or 6 in. in diameter.

Let the two halves of the ring be put together, as in **26**, so that the iron ring is interlinked with the copper-wire coil, and let the current from a battery be now sent around the coil. This current, because it circulates around the iron, will magnetise it, and the two halves of the ring will attract one another with enormous force. In fact, if the iron has a cross section of as much as 1 sq. in. only, and the coil carries a decently strong current, it will be practically impossible for two people to pull the two halves of the ring apart. But if the current is turned off, at once the lower part of the iron ring will drop off.

Tractive Force of Electromagnets. The pull of an electromagnet upon a flat piece of iron in contact with its polar surface can be calculated by the formula given above, and as the flux-density at the polar contact surface of a soft iron pole can easily be raised to the value $B = 100{,}000$ lines per square inch, it follows by calculation from the formula that the tractive force of the electromagnet may be reckoned at about 140 lb. per square inch of contact surface. Thus, an electromagnet to lift 1 ton will require about 15 sq. in. of contact surface. Of course, there must be a sufficient circulation of current. To give this flux-density to soft iron, when there are no gaps in the magnetic circuit, the circulation to be provided by the magnetising coil must be about 80 ampere-turns for each inch length of iron core to be magnetised.

In this ring experiment, if the mean diameter of the ring be 10 in., the total length along the iron will be about $31\frac{1}{2}$ in., and 80 times $31\frac{1}{2}$ is 2,520. We need, therefore, a circulation of 2,520 ampere-turns. If our battery can give us, say, 6 amperes, we shall need a coil of $2{,}520 \div 6 = 420$ turns. For then, 6 amperes going 420 times round, will be a circulation of 2,520



28. CRANE EQUIPPED WITH MAGNET TO LIFT PIG-IRON

ampere-turns, as required. With such a magnetising force the flux-density will be about 100,000 lines per square inch, giving a pull of 140 lb. per square inch of contact. And if each of the two surfaces has 1 sq. in. of area, the total force with which the one half of the ring is drawn to the other will be about 280 lb.

In all this it will be realised that to magnetise the iron the electric current never goes into the iron at all—it merely circulates around outside it.

If in any apparatus the pieces of iron that come into play do not fit together into a closed shape—if, in other words, there is a gap, or gaps, in the magnetic circuit—then a much larger amount of electric circulation is needed to excite the magnetisation, since air, or any non-magnetic material, has a much lower conductivity for the magnetic lines than is possessed by iron. Any electromagnet that is intended to pull at an armature which is separated from its poles by a wide air gap must, therefore, be so designed that a relatively much greater quantity of copper wire can be wound on its core.

Lifting Magnets. In the industries advantage is taken of the great tractive forces of electromagnets by designing special forms, as *lifting magnets*, for handling heavy billets of iron, steel plates, and ingots. A simple form of lifting electromagnet suitable for holding on tight to flat plates or blocks of iron is that depicted in **27**, consisting of a central iron core with an external iron jacket. In the cylindrical channel between core and jacket the exciting coil is embedded. The author possesses a small lifting magnet of this type, weighing 1·7 lb. only, and having just 2 sq. in. of surface at the working face. The exciting coil weighs only 5½ oz., yet this magnet will hold on to an iron block with a force of about 340 lb. when the current is on.

Fig. **28** depicts a much larger lifting magnet, in use by the Lackawanna Steel Company, of Buffalo, New York. A magnet such as this can be made to pick up a load of several tons at a time. Control is by switches, which turn the exciting current on and off.

Electromagnets for Attracting at a Distance. We have seen that if there is a gap between the iron and the poles of the magnet a much larger amount of electric circulation will be needed to excite the magnetisation than is the case where the iron is in contact with the magnet. The reason of this is that air is a poor conductor for the magnetic flux, because if there be an air-gap in the path of the flux, the amount of that flux will be greatly reduced, and hence the pull will be greatly reduced thereby.

But there are innumerable cases in which electromagnets are required to pull at an iron armature that is not in contact with the poles—cases, in fact, in which the electromagnet is employed to produce a movement of some part, as in an electric bell, or as in a Morse telegraph sounder.

Now, as a rule, the form of magnet that is suitable for the purpose of sticking on tight—as a lifting magnet—is not suitable for this other purpose of acting at a distance across an air-gap to produce movement. For if the magnetic flux must be forced to cross this gap, with a sufficient density of the flux to produce a fair pull, there must be provided a much greater circulation of current—more ampere-turns—than would have sufficed to excite the magnetism in a magnetic circuit without gaps. Now, if more ampere-turns are to be provided, it follows that the bobbins, or coils, must have more turns of wire, and therefore must either be of greater diameter, or larger. They are indeed usually larger, and therefore the magnet cores on which the bobbins are fixed must be longer. Any electromagnet which is intended to pull at an armature which is separated from its poles by a wide air-gap must, therefore, be designed so that a relatively much larger quantity of copper wire can be wound on its cores. This accounts for the telegraphers' rule that an electromagnet intended to reach out into space must itself have long limbs. On the other hand, an electromagnet intended merely to stick on tight to its load may be made of very short limbs of large cross-section. As a very rough rule, it may be stated that for every inch of length that a magnet is required to reach across the air to its armature, its own limbs must be a foot long.

Any electromagnet intended to be operated with very small currents ought to be wired with a coil of many turns of fine wire.

Electromagnets for Long Lines. In the cases where electromagnets are needed for use in sending signals through long lines—over distances of many miles—it is obvious that strong currents cannot be used, because to carry a strong current a thick wire would be necessary as the conducting line, and the cost of the copper would be excessive. Therefore, any electromagnets that are to be operated through long lines must be wound with many turns of fine wire. As an example, the coils inside telephone receivers and in telegraphic relays are always wound with fine wire, so as to get many turns upon the bobbin.

Current Density in Electromagnet Coils. To carry a current of 1 ampere, a moderately thin wire will suffice. A No. 20 standard wire-gauge, the diameter of which is 0.036 in., will, without overheating, carry more than 1 ampere if used as a line wire stretched in the air, and if coiled up in a coil will carry 1 ampere without overheating. Since the currents used in telegraphing are much smaller—from 4 to 10 thousandths of an ampere—thinner wires than this can be used for the coils of telegraph instruments. On the other hand, the currents used in electric lighting are much larger; ordinary arc-lamps take from 5 to 10 amperes, and thicker wires are required. In the coils of electromagnets, where there is no ventilation to disperse the heat, a suitable cross-section to allow for the wire is about $\frac{1}{600}$ or $\frac{1}{700}$ of a square inch for every ampere. If the magnets are needed for intermittent service only, so that they have time to cool, the permissible current-density may be at least five times as great as this.

A STUDY OF INVERSIONS

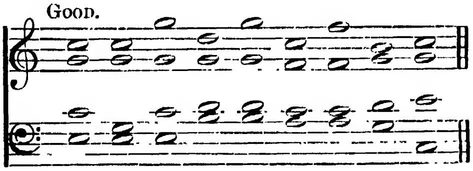
Inversions of Common Chords. Discords. Suspensions. Passing Notes. Modulation. Figured Bass. Harmonising Melodies

By J. CUTHBERT HADDEN

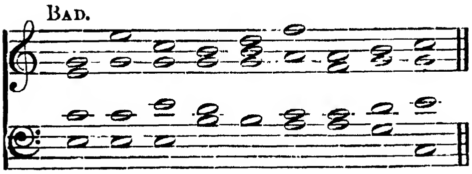
PROCEEDING now to a detailed study of inversions, we observe at the outset that first inversions of every triad in the major scale are allowed, while second inversions are allowed (by the theorists) only in the case of the tonic, dominant, and subdominant chords. First inversions, as such, are not subject to any restriction, and should be used whenever they promote the melodic flow of the bass. What we have to notice particularly about them affects the question of doubling. As in the root positions, the best note to double is the root itself, now the sixth from the bass note; when the context does not allow of that being done, then the other notes may (sometimes indeed *must*) be doubled. Certain chords, however, are subject to exceptional usages in the matter of doubling. Thus, in the first inversion of the dominant triad, the leading note of the key is the bass note, and this, being a peculiarly delicate constituent, should in no case be doubled. The same rule holds with regard to the first inversion of the imperfect triad on the leading note, where the sixth is the leading note and must not be doubled. In this chord the bass note should be doubled.

In the first inversion of all *major* triads it is inadvisable to double the bass note because it is the major third to the root. Reducing all this to a simple rule which the student can commit to memory, we say: In first inversions of common chords double either the third or the sixth (the original fifth and the root), whichever is most convenient, but avoid doubling the bass note. To emphasise this to the eye, we quote an illustration from Sir John Stainer's Harmony Primer:

Good.



Bad.



The last two chords in each case are, of course, in their root positions.

Second inversions of common chords are hedged about with several restrictive conditions which will at first appear somewhat perplexing. Recall the fact that such inversions are allowed only on the tonic, dominant, and subdominant chords. As regards the second inversion of the tonic, its use is very largely, if not mainly, cadential. That is to say, it is a determining factor of the perfect or the imperfect cadence. Thus at *a* we see it in the perfect, at *b* in the imperfect cadence.

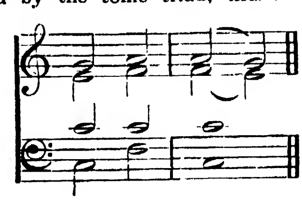
(a) (b)

In both cases the same bass note (G) bears two different chords—first, the second inversion of the tonic, and second, the dominant in its root position. This is quite "the most usual way of following the second inversion of the tonic," in which, by the way, the bass note is nearly always doubled.

The second inversion of the dominant, with the supertonic in the bass, is less restricted in its use, though it is generally both preceded and followed by the tonic chord or its first inversion.

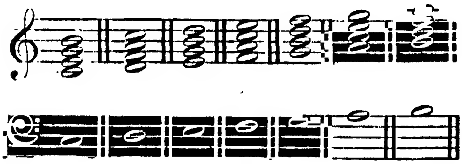
It should be approached and quitted by step, and the bass note may or may not be doubled, according to convenience. The sixth from the bass, being the leading note, must never be doubled.

Of the second inversion of the subdominant there is little to say, except that it is preceded by its own chord in the root position and followed by the tonic triad, thus:



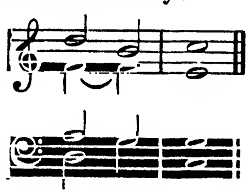
In this way it may be regarded as a sort of ornamentation of the plagal cadence, already described.

The subject of discords and how to treat them is so vast that only its fringes can be touched here. The student already knows what a dissonant interval is. When such an interval is introduced into the common chord, the result is a *discord*. The common chord, we have seen, is a combination of two thirds, one placed above the other. If we add still another third, we immediately produce a discord, for the added note is a seventh from the root, and the seventh is a dissonant interval. Chords of the seventh may be formed on every degree of the scale, as here:



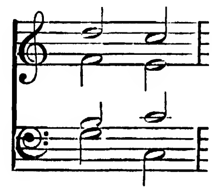
Of all these, the chord of the seventh on the dominant is the most important, inasmuch as from its combining those sounds which do not belong to any other scale it decides the tonic harmony Thus in the above example, the fifth chord could not possibly be in any other key than C. Take it into the first sharp key (G) and you have to sharpen the F, into the first flat key (F) and you must flatten the B. The student should therefore master this chord before attempting to deal with other chords of the seventh.

Prior to a study of the chord itself, we must, however, learn of two essential conditions attendant upon the use of discords. These conditions are (1) that the dissonant interval must be *prepared*, and (2) that it must be *resolved*. By preparation is meant the use of the coming dissonant note as a *consonance* in the previous chord, generally, too, in the same part. By resolution, again, is understood the passing of the dissonant note to a concord in a regular defined way. Thus, in the following illustration, the dissonant F in the dominant seventh is "prepared" by being struck as a consonance in the previous supertonic chord, while its "resolution" follows naturally upon the E of the tonic harmony:



The resolution of all discords whatsoever is imperative. Such resolution may indeed be delayed, and it may be irregular, but "the feeling of *rest* in a concord must follow sooner or later." The law as to preparation is not so strict. Dominant discords, for example, are allowed without preparation, and there are other exceptions. For the present the student, if he makes exceptions at all, should except only the dominant discords.

Now we will look at the dominant seventh. We have said that here the seventh need not be prepared. How, then, is the chord resolved? In the natural resolution the seventh descends one degree; the third, as leading note, ascends one degree; the fifth either ascends or descends; and the bass proceeds to the tonic by ascending a fourth or descending a fifth, thus:



There are other "resolutions"—for example, on the triad of the submediant; on a second inversion on the same bass note; and on one of the dominant seventh's own inversions. In all these cases, however, the seventh must descend one degree, and the leading note (except in the last case) rise to the tonic. When it is necessary to omit some of the constituents of the dominant seventh, the fifth and eighth of the bass may, with least consequence, be omitted. Neither third nor seventh ought ever to be omitted; nor should these intervals be doubled, for, having a fixed progression assigned to them, they would, if doubled, make consecutive octaves. The dominant seventh has, of course, three inversions, all of which are in frequent use.

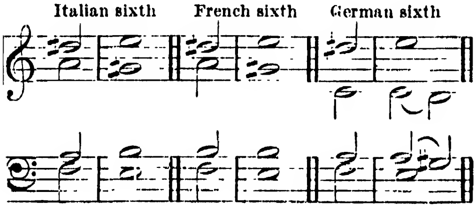
With regard to chords of the seventh on the other degrees of the scale, the essential thing to remember is that they demand the regular preparation of the dissonant note; which, again, must always be resolved by descending one degree. The bass, in all ordinary cases, ascends a fourth, or descends a fifth. These "secondary sevenths," as they are sometimes called, are not extensively used. That on the supertonic is the one most frequently met with, and, among the inversions, the first is in most general use. Some theorists disallow the second inversion entirely.

The dominant chord bears out its name in many ways. Thus, it forms the foundation of the elaborate dissonances of the ninth, eleventh, and thirteenth, in addition to the seventh already considered. These chords are formed by a continued superimposing of thirds, as thus:

Their introduction should be left to advanced students of harmony. Two very important

chords derived from the dominant seventh must, however, be noticed here—the chords of the diminished seventh and the augmented sixth. The first may be produced by taking any chord of the dominant seventh, and raising the bass a chromatic semitone, as here:

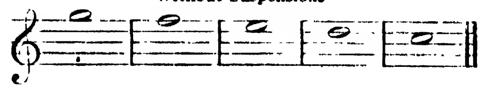
All three inversions of this chord are freely employed. The chord of the augmented sixth is found on the submediant of the minor key. It has three forms, known respectively as the Italian, the French, and the German sixth. We give an example of each:



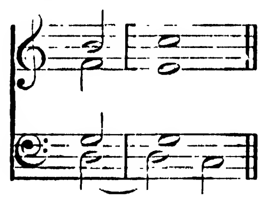
In the case of the German sixth, it will be observed that it is necessary to introduce a second inversion previous to the resolution, in order to avoid consecutive fifths. A very great deal might be said of these beautiful chords and about others derived from them, but it will be enough for the student to become familiar with them on paper and by ear.

A word or two about *suspensions*, so called. A suspension occurs when a note (there may be two notes) of one chord is carried into the following chord. Thus, if we write

we have what is technically termed a suspension of 9 to 8—that is, a ninth (D) above the bass passing to the octave or eighth. The most common dissonances of this class are the ninth suspending the eighth, the seventh suspending the eighth, the fourth suspending the third, and the sixth suspending the fifth. This will be made clear by comparing the following descending melodic phrase, accompanied with its fundamental bass, first without and then with suspensions.



The ninth and fourth should generally be prepared, the first by third, fifth, or sixth, the second by any concord. The ninth ought never to be prepared by the eighth, otherwise consecutive eighths would occur. When the bass is suspended, the suspension is often termed *anticipation*, but the distinction seems pedantic and unnecessary.



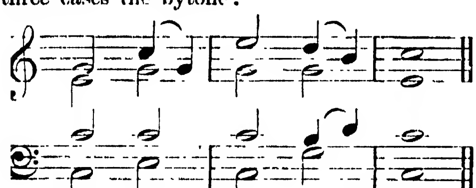
So far, the harmonies considered have introduced no notes but those essential to the respective chords. We have now to notice the case of unessential notes, incidentally thrown in between one chord and another. These are known as *passing notes*. They may be defined very shortly as scale sounds lying between notes essential to the harmony but not themselves essential. Their nature will be readily understood from this illustration, where the passing notes are marked x:

The purpose of such harmonically unessential notes is to impart variety, brightness, and continuity of movement to a part or parts. Generally they are taken at the unaccented portion of the beat, though there is no rule prohibiting their use at the accented part. Sometimes they are approached by a skip; but in any case it is advisable that they should move upward or downward, according as they are approached from below or from above.

They can be taken in two or more parts at a time, but in that case they must either be consonant with one another, or, if dissonant, must move in contrary motion. See, in illustration of these points, the following bars from a chorus of Handel, the passing notes being printed small size:

A passing note, it should be observed, is not allowed to excuse a progression of parts which would be faulty without it.

What are termed by some writers *harmonic bytones* are often classed with passing notes. They serve, indeed, practically the same purpose, but they *belong to the chord* in which they occur, and have therefore no theoretical connection with the passing note strictly so called. Here are examples, the second crotchet being in all three cases the bytone:



These bytones being actual constituents of the chord, the student must take care that, in introducing them, he does not leave the chord without one of its essential notes. Thus, if the B in the treble of the above illustration had not been introduced as a companion to the D of the tenor, the chord would have been bereft of its third, and that third the leading note too.

We must now say something about *modulation*. By this term is understood the passing from one key to another. Few compositions, however short, remain in the original key throughout. They would be very monotonous if they did; the ear demands a change of tonality. Modulation is entirely a matter of harmony. A melody may *imply* a change of key, but no actual change can be effected without attendant chords. The modulations most frequently introduced are those by which the music is taken into the keys of the dominant or subdominant, as from C to G or C to F. Such modulations can all be brought about by very slight changes in, or additions to, one or other of the chords of the original key. Thus, take a modulation to the subdominant as at *a*. Here we have simply to add a minor seventh to the tonic, which latter thus becomes the dominant of a new scale, the scale of F. Again, at *b* a modulation to the dominant is easily and naturally effected by making the third of the chord of the supertonic of the original scale major and adding a seventh to it. Once more,

(*a*)

we may modulate into the relative minor, as at *c*, by making the third of the chord of the mediant major and adding to it a seventh.

It is now that the student will come to realise the great value of the dominant seventh, for it is by this chord and its inversions that the very large majority of modulations are managed. The old tonic becomes the root of the new dominant seventh, and by the fixed resolution of the latter we are brought into the tonic harmony of the new key, which is thus at once established in the ear. There is no more obvious, more rapid way of effecting the commonest modulations than by this all-important chord. Of course there are many uncommon and abrupt modulations, and every modulation, common or uncommon, admits of great varieties of treatment.

To be continued

DRAINAGE APPLIED TO BUILDING

Pipes. Channels. Traps. Yard and Special Drainage Systems and Materials. Water Gullies. Road Gullies. The Work of the Drainlayer

By Professor R. ELSEY SMITH

Objects of Drainage. The objects to be arrived at in a modern system of drainage as applied to individual buildings are (1) to convey away the sewage without any risk of contaminating the land through which the drain is carried; (2) to ensure that the whole system is one that shall be self-cleansing and shall be effective even under the conditions of complete want of attention which usually prevail; (3) to provide means of ascertaining readily the causes of any interference with the regular working of the system and for promptly dealing with such interference; (4) to provide against the possibility of introducing into the building by means of the system of drainage the poisonous gas generated in the sewers and cesspools, and even to some extent within the system itself.

These are the most important requirements which must be borne in mind in dealing with a system of drainage, and to provide for meeting them, not only good design, but the best materials and workmanship are essential. The tests applied to a drainage system are properly severe. The work is almost entirely buried out of sight, and in most cases, unless a defect shows itself, it receives no attention from year's end to year's end, and it is therefore of the highest importance to secure conditions that shall be as good as possible.

The drains of an ordinary building consist of a series of tubes through which the matter to be conveyed flows until it is discharged into a public sewer or cesspool, or is distributed over land or otherwise dealt with. [For treatment of sewage, see CIVIL ENGINEERING.]

System and Materials. There is often a double system of such tubes, one of which is reserved for water which is clean and practically free from solid matter or contamination, and usually consists principally of the rain-water collected from the roofs of any building; these are described as *rain-water drains*. The other receives all foul water, including the discharges from water-closets, urinals, sinks of all kinds, and bath and lavatory wastes, all of which contain putrescible matter and are liable to rapid decomposition and to generate a gas known as *sewer gas*, highly injurious to health. These are generally classed as *soil drains*, a term more particularly applied to those conveying discharges from water-closets. The circumstances of various buildings differ widely, but whether an isolated country house or a town building is to be dealt with, certain principles must be observed, and the actual methods of construction are to a large extent identical.

The materials used in the laying of a drainage system are to a considerable extent ordinary building materials. The preparation and laying of concrete has been already dealt with. Certain work in bricklaying must be referred to, but for fuller explanations of the bricklayer's work see BRICKLAYING. The materials now to be considered are those employed in the actual formation of the drains—*pipes, channels, bends, traps* of various forms. [For the construction of large sewers and conduits, see CIVIL ENGINEERING.]

Pipes. These must be straight, true in section, absolutely impervious to water, not easily liable to fracture, and of material that will not be affected by the acids contained in the sewage, and the inner surface must be perfectly smooth and offer no obstruction to the flow of its contents. It is desirable that the diameter of the pipe should be as small as possible, provided it is adequate to the maximum flow, so that at periods of minimum flow the depth of water in the pipe compared with the area of that part of the invert covered by it, described as the wetted perimeter, should be as large as possible. The materials used for such pipes are *glazed stoneware, glazed earthenware*, and *glazed terra cotta* and *cast iron*. The various forms of earthenware pipes referred to are all similar in form [for manufacture, see POTTERY], and are almost always salt glazed. They are usually about 2 ft. long [**12**]. One end is formed with a socket to receive the other, or *spigot* end, of the next pipe. The outer surface of the spigot and the inner surface of the socket have, as a rule, fine annular channels formed on them, their purpose being to assist the adhesion of the cement.

The internal surface must be thoroughly glazed, and free from all excrescences and roughness which would check the flow of sewage, and pipes should be inspected to ensure this. A slight roughness or projection in one spot need not necessarily lead to condemning a pipe, but care must be taken to see in laying that such defect is placed not in the invert, but at the top of the drain. Such pipes are made of various diameters, from 3 in. upwards. The thickness of the material in stoneware pipes is usually $\frac{9}{16}$ in. for 4 in. pipes, $\frac{11}{16}$ in. for 6 in. pipes, and beyond this size $\frac{1}{12}$ of the diameter. There are some variations from the general type. *Taper pipes* are formed which are regularly reduced in diameter from one end to the other [**16**], and may have the socket formed on either the large or the small end. *Cleansing pipes* [**17**] are employed for building into manholes that are not fitted with traps, but have a kind of hood-shaped enlargement formed at one end, increasing the vertical but not the horizontal diameter to facilitate the introduction of cleaning rods.

A rougher class of pipe is used for land drainage, where the important consideration is the collection and removal of water which percolates through the ground, and which is not contaminated with sewage.

These are known as *agricultural drain-pipes*, and are short tubes from 2 in. to 6 in. in diameter, formed of burnt earthenware, without sockets, and unglazed. They are laid end to end, and are not jointed. Their purpose is to give free passage to the water collecting in the trench in which they are placed, and which can enter the pipe at any joint. They are sometimes used for passing water collected by embankments through the base of the wall to the front, and for this purpose are embedded in the concrete or masonry, and are known as *weeping pipes*.

Bends. These are pipes so formed as to change the direction of the axis of the pipe. They are made to a great variety of curves, from a quadrant [18] to a very flat bend. They should not be used in soil drains, but may, if necessary, be used in rain-water drains.

Junctions. Various forms of these are manufactured. They may be Y-*junction*, single, or double [19], and they may be arranged so that the inlet joins the main pipe at various angles; but it is undesirable that the angle between the axis of the two drains should exceed about 45°, and right-angled junctions are not tolerated, as nothing is more apt to produce an obstruction in the drain. Junctions are often made between pipes of different size—*e.g.*, one of 4 in. diameter may join one of 6 in. Junctions, like bends, should only be employed for rain-water drains, and not for soil drains.

Channels. These are open pipes [20]; usually semi-circular, and with half-sockets. They are used sometimes for the conveyance of surface water at the ground level; in a drainage system their special use is to enable junctions to be made between various soil drains. The manner of using them will be more fully described in connection with the construction of *manholes*.

Taper channels are formed in a manner similar to taper pipes. *Bends* are also formed in channels [18], and for some forms of bend the section, instead of being semi-circular, is a full three-quarter circle [20]. There is a much greater variety in the form of *channel bends* than of pipe bends, as in some cases it is necessary in forming manholes to bring in a branch drain from a direction that will require the flow of the contents to be almost reversed in the manhole [20], and it is mainly in the case of such bends that three-quarter channels are required, the outer side of the bend being covered in to retain the flow of water in the channel, which without such protection would tend from its own velocity to overflow it, and deposit any solids on the sides of the manhole. For this extreme case, bends of a great variety of radius and of different lengths may be procured to fit almost any angle at which a drain can be received, a slight adjustment being always possible. The upper end of any channel is provided with a socket, and is at right angles to the axis at this point, but the lower end is splayed so as to be parallel to the axis of the central channel where it is employed to form a junction.

Traps. These are devices to prevent the return of the sewer gas from the sewer to the building. The earliest [21] form consisted of a small chamber in the line of the drain sunk below its general level, with a *diaphragm* fixed across it extending from the top of the chamber to below the level at which the water would stand in it. A barrier is thus interposed, closing the upper part of the chamber and the drain above it against any return of an air current, while not preventing the flow of the sewage underneath the diaphragm. This was known as a *dip trap*. If well constructed, it was efficient so far as its special purpose was concerned, but had various drawbacks—it checked the flow of the sewage, and solids were apt to be deposited in the chamber and block it, and it was not easy to make, and keep it, air-tight. Such traps are no longer used, but the principle of the dip trap is employed in all forms of traps, the essential feature being the interposition of a barrier in the course of the pipe that will, under ordinary conditions, prevent the return of air up the pipe. Such traps, however, are now formed of the same material as the pipes, and though some of them are made in more than one piece, the portions containing the barrier between the outlet and the basin, in which water always stands, are of a single piece.

The barrier is formed in various ways in different traps, but always extends below the level at which water stands in the trap; the bottom of the outlet is arranged at a higher level than the bottom of the barrier. The pipe is thus actually closed or sealed by the body of water always standing in it against the upward passage of air or gases, while allowing water or sewage to flow through it. The depth to which this barrier penetrates below the surface of the standing water is referred to as the *depth of the water seal*.

Modern Forms of Trap. The modern forms of intercepting trap [24] are made by introducing into the length of the pipe a bend of such a character that the upper part of the pipe dips below the water-level forming the seal, while the lower part of the pipe forms a basin to retain the liquid. The lower end is formed with an ordinary spigot to join the drain below; the upper end has a half-socket to receive the channel. The upper half above the seal usually dips sharply; the lower, or outlet half has a more gradual rise, the object being to interpose as little check to the flow of the sewage as possible; and where the conditions of the drainage system permit, the upper side may have a cascade formed by keeping the inlet at a higher level than the outlet, so that the flow is discharged into it with a slight impetus.

The form of the trap makes it impossible to introduce a cleaning rod through the trap itself, and an upper arm is provided for this purpose. This is carefully closed when not in use, or the utility of the trap would be destroyed; but the stopper closing it may be attached by a chain

SECTIONS OF DRAIN-PIPES AND FITTINGS

As these goods are made in various sizes, no scale is shown

to the upper part of the manhole, so that, should the trap become stopped and the manhole filled with sewerage or water, the plug may be withdrawn and the chamber emptied.

Such an intercepting trap is used in a drainage system at or near its termination, before it enters the sewer or cesspool, to intercept the return of sewer gas. Various makers manufacture them in a variety of forms, but the essential as described above should be found in all of them.

The Problem of Back Flow. It happens occasionally that a drain is subject to a back flow of water or sewage from the sewer. This may arise when the outlet discharges into a tidal river at times of exceptional tides, or, in the case of a sewer being of inadequate size, on the occasion of exceptionally heavy rain. This is not easily dealt with ; no form of check that does not act automatically is of any great value in most cases.

Flaps are sometimes placed at the outfall of a drain [22], which, on any back pressure arising, should close the outlet till such pressure is removed ; but this must be applied in the sewer, and in small sewers it cannot always be adopted. A form of trap designed to meet such cases is the *ball trap* [23]. This is provided with a hollow metal ball that, under ordinary circumstances, leaves the orifice free, but if any back pressure arises is lifted by the returning water and is pressed against and closes the orifice. This device is open to the objection that the orifice, or the ball, may become somewhat foul from the sewage, and may not close properly, but it has been found efficient in many cases. The ball is sometimes hung with a hinged joint from the top, and in some cases is loose, the trap being designed so as to guide it into position when floated.

Gullies. Traps are required in many other situations, and take various forms. Those termed *gullies* are intended to receive the discharge from sinks and rain-water pipes, yards, paths, &c., and are open to the air at the top. Their object is to prevent any pipe which is connected with the inside of the building, or the top of which terminates near a window, from having a direct connection with the drains. The discharge may take place above a grating placed at the top of the gully [25], but this grating may get stopped through the deposits of solids in the discharge itself, or through an accumulation of leaves, or to some accidental circumstance, and the discharge will then not enter the drain, but overflow around it and soak into the ground. Pipes should therefore discharge into a gully below the level of the grating, a small pit being formed, if necessary, for this purpose and covered with a grating. For many pipes a good method is to connect the ends directly to inlets provided at the back or sides of the body of the gully.

Some makers provide gullies with extending pieces [27], so that the gully may be sunk to any required level below the ground. Such pieces may each have one or more inlets provided, so that the gully may receive the discharge from several pipes. Gullies which are formed of two or more pieces must be jointed. The upper part is adjustable to the pipe, the lower part to the drain.

Yard Gullies [26] and Surface Water Gullies. These differ from the ordinary gully in the manner of forming the seal and in the form of the bottom ; this is made deep, and the outlet is kept near the top so that the body forms a catch pit which will retain any sand, gravel, or other solid material washed into it during heavy rain, and prevent it from passing into the drainage system. Such gullies are often provided with metal receivers fitted with a handle ; these are placed in the bottom and receive any solids, and can be lifted bodily out, emptied, and replaced. The lower part of the gully may be made deep and of considerable capacity, and the water seal should also be deep, as in dry weather such gullies are very liable to lose the water which forms the seal by evaporation.

The Road Gully [29]. This is a variation of the form of gully last described, and has a very large body or container sunk deeply below the trapped outlet, and capable of holding a considerable bulk of material washed from the road surface. These are usually emptied periodically by means of long-handled scoops.

The use to which scullery sinks are put results in the discharge of a great deal of greasy matter into the drains. When this leaves the sink it is often quite hot, but on being discharged into the water standing in a trap it becomes chilled, the grease congeals, and is very liable to foul the drain which carries it off, adhering to the sides and decomposing. To meet this difficulty *grease traps* are provided.

Grease Traps. The object of these is to retain the greasy matter in the trap till it has congealed. To achieve this the body of the trap is made large, so that a considerable bulk of water is retained in the trap and is always cool or cold. The outlet is considerably below the surface. The grease, on entering the trap, rises and collects on the surface, and there congeals.

There are two methods of disposing of this congealed grease. The first is to provide a form of tray that can be lifted out, bringing out the grease, which must be burnt or otherwise disposed of [28]. There is, however, a great probability that the duty of regularly cleansing out such a trap will be neglected. The more satisfactory method is to supply a trap provided with a flushing rim [27], such as is found in the pan of a water-closet, and to connect this with a tank which discharges automatically at fixed periods a considerable body of water into the trap through the rim, and which completely flushes out the trap, breaks up the congealed grease, and carries the whole through the drain with the flush of water. The amount of water used each time is determined by the size of the cistern, and depends upon the use which is made of the trap. The frequency of the discharge is capable of regulation.

To be continued

ELECTRICAL, WATER & GAS ENGINEERS

The Most Promising Branch of Municipal Work. Tramways Department. Theoretical Qualifications. Well-paid Municipal Offices

By ERNEST A. CARR

[illegible] study of the various branches of municipal engineering has as yet been restricted to the borough or county engineer's department, and to that of the surveyor. To complete the task, we have to consider the three special classes of engineering associated with the municipal supply of electricity, water, and gas. In the larger boroughs each of these forms a separate department of the staff; in others they are under the general control of the surveyor or engineer.

Electrical Engineers. "Which do you consider the most promising department of local government work for a youth to enter?" was lately asked of a borough official of high standing and of many years' experience. His answer was a model of terseness: "The electricity branch." Another expert, to whom the same query was addressed, replied: "Undoubtedly the engineering, especially electrical and traction."

The reasons for these replies are not far to seek. The application of electricity to the public service has proved of immense value, and is developing with startling rapidity. During the last 10 years the income of local authorities from electricity works has increased 800 per cent., and from tramways (chiefly electric) no less than 2,500 per cent.! A network of municipal tramways, telephones, and electric lighting systems is fast overrunning the busier districts; new departments are formed, often with a large staff to work them, and with each fresh development the scope afforded to capable engineers is enlarged.

As yet, indeed, the demand for highly trained electrical engineers has been equal to the supply—a surprising state of things when we consider the congested state of the labour market generally. In a few years' time matters will doubtless have adjusted themselves, and only the possessors of recognised diplomas will be selected for chief appointments. Meantime such posts are often awarded—notably in the tramway works—to men who have proved themselves practical experts, but whose paper qualifications are of the scantiest.

Liberal Remuneration. A further attraction is the marked tendency of local authorities to deal liberally with their electrical engineering staff. Nor is the tendency surprising, for electric works are often not only very successful in themselves, but highly profitable to the ratepayers. Thus, in a single year's working the electric trams in Manchester earned a net profit of £120,950; in Glasgow, £93,257; and in Liverpool, £32,081. On electrical works generally, excluding tramways and their huge gains, no fewer than 115 towns that year made a profit, great or small, amounting in all to £436,000.

For such satisfactory results—the more satisfactory because obtained in spite of high wages and low charges—credit is chiefly due to the various electrical staffs. It is only just, therefore, that their services should be liberally recompensed. This striking passage from an utterance of the Lord Provost of Glasgow applies with particular force to such work as theirs: "It will be an evil day for the municipalities when those who are the captains of their great departmental industries are not rewarded with material recognition on a scale adequate to the services rendered."

Principal Appointments. The larger boroughs owning important electrical works place these in charge of a chief electrical engineer. Where a tramway service is included, his post is both lucrative and very responsible. In any event he ranks among the best-paid members of the staff.

A successful officer of the front rank must have had a sound scientific and practical training in electric and mechanical work, and especially in traction, lighting, and permanent-way engineering. He should, further, be a man of energy and ideas, with good organising powers, who is in touch with every new scientific or commercial development that may affect his work, and competent to give advice on questions of principle, and on the many types of electrical apparatus in the market. The engine-house, power-station, and sub-stations are under his control, with their boilers and superheaters, generators, dynamos, batteries, switch gear, and every other item of the service system—and perhaps the dust destructor also, as a source of useful heat. In brief, he must be a shrewd, practical expert in every method of generating, transmitting, and distributing electrical energy.

Tramways Engineering. In many boroughs the electrical engineer's duties are combined with those of tramway manager. Other authorities keep the two posts distinct. The latter office, however, is in itself an engineering appointment, though the standard of training exacted is not always high, and many duties of supervision and business detail are added. For either post the salaries paid range high wherever the electric traction is considerable; and we may conveniently discuss both positions together.

London's tramways manager receives £1,500 a year, and its chief electrical engineer £1,000. The Manchester Corporation pays each of these officials £900, and the tramways electrical

engineer £300; while the manager of the city traction at Belfast receives £1,250, to be ultimately increased to £1,500. A chief electrical appointment of average value is probably that of Newcastle-on-Tyne, which begins at £700 a year, and increases by £50 yearly to £800.

Smaller electric services naturally involve lesser stipends. Thus, in two London boroughs (neither, of course, owning tramways) the commencing salaries of the electrical engineers are £600 and £400 respectively, and at Bournemouth also the latter figure is paid. Similarly, the stipends of the tramway managers at Brighton, Huddersfield, and Leyton are respectively fixed at £300 (rising to £400), at £350, and £300.

Chief engineering posts under the minor authorities—the tramless small towns and busier urban districts—are scarcely of professional rank. They often involve merely the charge of a small lighting station and a working staff. The salaries paid vary from £150 to £400, according to the plant and electrical output.

Consultant posts in municipal electric engineering may be dismissed in a few words. Consulting engineers are recognised experts in private practice, who are retained by local authorities to advise their engineering staff in the execution of electric works. They are remunerated either by fee or at a "retainer," which may be £150, £300, or £500 a year, according to the nature of their services.

Qualifications. A good many of the foremost electrical positions in the municipal service are held by graduates in civil engineering, and by Associate Members of the Institution of Civil Engineers. The diplomas of the Institution of Electrical Engineers—M.I.E.E. and A.M.I.E.E.—are at least as frequent, and are sometimes coupled with those of the Institution of Mechanical Engineering. [See ENGINEERING.] Other officers—and those by no means the least capable—can boast no higher certificate than those of the Board of Trade, or the City and Guilds of London Institute—for the councils making appointments naturally pay more regard to a candidate's proven record in practical engineering than to the regularity of his training; and some of the engineers in charge of small undertakings may be said to have graduated in the municipal workshop.

Especially is this true of certain of the semi-professional posts already discussed—such as tramways manager, or manager and engineer jointly, to the lesser authorities. In some instances the manager has been selected from the working engineering staff, and in others by promoting a traffic superintendent who had qualified by supplementing his working knowledge of tramways with such evening studies as he could pursue.

The Need of Scientific Training. To have been successful under such arduous conditions reflects the greater honour on the men who accomplished the feat. We are considering the service, however, from the standpoint of the prospective candidate. It is, therefore, essential to bear in mind that, despite occasional successes of this character, the need of some scientific training in competing for electrical and tramway appointments is already great, and rapidly grows greater, and that to omit any available chance of thus qualifying is simply to handicap oneself severely in the contest.

Experience in municipal or private electric traction and lighting remains, of course, the supreme recommendation. It is noteworthy, therefore, that a number of borough electrical engineers receive articled pupils who have passed through a technical school, the premium charged varying between 30 and 150 guineas. On expiry of the articles, a post as assistant on the electrical staff of a local authority should be readily obtainable; and from that position the way to a diploma and a chief appointment is hard, but fairly direct.

Assistantships. There are a great many subordinate posts other than assistantships proper in the electrical department of a busy corporation. Many of these are worthy of the attention of fully trained men who wish to obtain a footing in the service with a view to a principal engineership. Others are within the scope of a clever, hard-working mechanic. Mains engineers and surveyors receive from £275 to £350, permanent-way engineers about £300, and the resident engineer attached to each station earns the same salary, or a little less. Assistant engineers of professional (as distinct from working) grade receive from £100 or £120 up to £350, according to their degree of experience and training. The London County Council lately offered a number of vacancies at £365 a year for "fully competent engineers, with good experience in the design and construction of the permanent way and general arrangement of electric tramways on the conduit and on the overhead systems."

Shift engineers, mains superintendents, and working engineers-in-charge, are paid between £150 and £220. For the rank and file the following rates of pay may be taken as typical: Foremen, £2 15s. to £3 15s. a week; working engineers and electricians, £2 2s. to £2 15s.

A Diploma a Strong Recommendation. The scientific training expected of candidates varies almost indefinitely, according to the needs of particular posts and the views of the appointing authorities. Usually no special qualification is insisted upon; but in seeking a professional assistantship, the rank of student, either in the parent engineering institute or its electrical offshoot, would form a strong recommendation. Apart from such training, the most useful equipment is a sound practical knowledge of engines and dynamos, generators and motors, and the special fittings for C.C. and A.C. (single and polyphase) systems.

It has always been a moot point whether large or small electrical undertakings furnish the best training-ground for the future engineer. In the former case the staff is generally better paid and the apparatus more complete; and the smallest works provide no experience in that

supremely important subject—electric traction. On the other hand, an assistant's work in a borough of moderate area is generally less specialised than in one of the great industrial centres, and affords a better "all-round" training.

Waterworks Engineers. Waterworks construction and control, as an important branch of civil engineering, will be found fully treated in our engineering course; and its municipal differs so slightly from its general aspect that little can usefully be added here. The following admirable summary of municipal work, however, is from the pen of a leading practitioner, and may be scanned with advantage. It was read before the British Association of Waterworks Engineers by the president, Mr. Philip H. Palmer, M.Inst. C.E., water engineer to the Hastings Corporation: "The practice of water engineering is becoming daily more technical and complicated, and deals with the important subjects of rainfall—the obtaining of accurate data being the prime factor in ascertaining the supply available from a given drainage area—geological considerations, losses by evaporation, discharge by floods, the regulation of fittings, quality of different kinds of water and their suitability for domestic or industrial purposes, filtration of water, designing of works generally, pumping plant, working of meters, and a general knowledge of mechanical work."

It need only be added that local authorities are paying increasing attention to the need of an adequate and pure water supply, and in many districts are devoting enormous sums to the construction of reservoirs, conduit systems, and filter-beds. All these activities improve the prospects of the capable engineer. A recent instance of such municipal enterprise is the supply of Birmingham with excellent water from huge reservoirs constructed in the Elan Valley, fully 70 miles from the city. The water supply of the whole area of Greater London has lately been municipalised by purchase from the various water companies owning it, and their large staff of engineers taken over.

Waterworks. The designing and execution of waterworks (as mentioned in the Municipal Engineering section) is usually entrusted to the borough engineer, with or without the aid of consultants. Sometimes, however, a waterworks engineer is specially appointed for the task. None but a very able civil engineer is competent for so grave an undertaking, and the salary paid is proportionately high. £1,200 to £1,500 a year are average figures for such duties.

For the control of existing waterworks the responsible engineer receives from £500 to £800 or £1,000 a year, and the resident works engineer between £250 and £400. The positions and salaries of a typical waterworks engineering staff (both professional and working) are indicated by the following list, compiled from the paysheets of an important corporation:

Waterworks Engineer, £1,000.
Engineer and Manager of Hydraulic Supply, £600.
Chief Assistant Engineer, £310.
General Surveyor of Water Mains, £600.
Assistant Surveyor of Water Mains, £280.
Local Surveyors, £200 to £280.
Works Inspector, £280.
Inspector of Fittings, £290.
Assistant Inspector of Fittings, £210.
Foreman Inspector of Pipe Laying, £180.

Gas Engineers. While gas continues to hold its own as an illuminant against the claims of electric light there will be no lack of scope for the municipal gas engineer. That it is doing so in fact seems evident from the latest Board of Trade returns. These show that 256 local authorities possess gasworks, and that the number is steadily growing. The latter fact is hardly surprising, in view of the following instances of yearly profits from municipal gas. Manchester, £60,000; Leeds, £30,000; Nottingham, Salford, and Belfast, £20,000 each; Blackpool and Bolton, £15,000. The field of municipal employment is thus both wide and full of promise.

The gas engineer's qualifications and prospects need not be discussed in any detail, for what was said on this score concerning his brother officials of the electrical and water works applies no less to himself. The sole material distinction is in the nature of his duties, which are a highly specialised department of mechanical and thermochemical engineering, rather than of electrical or civil engineering.

The Nature of the Work. The work of the gas engineer includes the construction and maintenance of retort-houses, gas-holders, and tanks, purifiers, sulphate works, waste liquor and tar tanks, and other gas plant, and their control in working. A special feature in modern gasworks is the manufacture from residual products of naphtha, pitch, benzole, sulphate of ammonia, and carbolic acid. The apparatus for these industries, and the carburetted water-gas plant, fall also within the province of the gas engineer, who must thus be something of a chemist as well as a mechanician.

As an instance of the important construction works entrusted to these officers, it may be mentioned that the enormous gasworks now in course of erection at Provan, Glasgow, and capable when completed of producing 48,000,000 cubic feet of gas daily, were designed by the late Mr. William Foulis, M.Inst. C.E., whilst engineer and general manager of the Glasgow Corporation's gas department.

Practically the same level of salaries prevails among public authorities for the gas as the water engineering staff. This is illustrated by the following table, compiled from the same source as that given above:

Gas Engineer, £1,000.
Superintendent, £700.
Deputy Superintendent, £450.
Superintendent (street mains), £450.
Deputy Superintendent (street mains), £325.
Stations Managers, £300 to £400.
Deputy Stations Managers, £225 to £250 (with house).
Foremen Mechanics, £175 to £180.

To be continued

THE MACHINERY OF DIGESTION

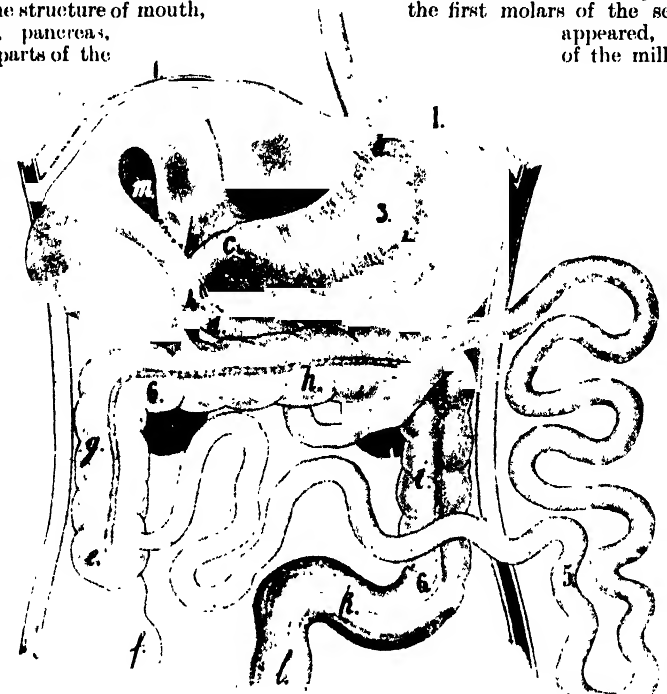
The Digestive System and the Organs of Digestion. The Teeth and Mastication. How the Food Descends. Throat and Stomach

By Dr. A. T. SCHOFIELD

WE have now done with the necessary preliminaries of the first two divisions of this section, and are free to study the systems in order, and travel through the body, viewing its structure, adaptation, and marvellous processes with interest and wonder.

We begin with digestion. Let us first observe the machinery engaged in the process, and then in a subsequent chapter we can follow the actual digestion, say, of a beef sandwich, until it is changed into flesh and blood. In this chapter, therefore, we will consider the structure of mouth, stomach, liver, pancreas, and bowels as parts of the great digestive system.

The food is introduced into the body and digested in a special tube [25] called the alimentary canal, that passes completely through the body *without having at any part any direct communication with the interior*. When any communication does occur, as in disease (typhoid fever, etc.), death probably ensues. This tube commences at the mouth and terminates at the lower part of the bowel (the anus), and, in man, is nearly 30 ft. long. The digestive tube is sub-divided into four parts—the mouth, œsophagus, stomach, and intestines. Connected with it are two large digestive glands—the liver and the pancreas.



25. ABDOMINAL VISCERA

1, Diaphragm; 2, œsophagus; 3, stomach (*a*, cardiac end; *b*, fundus; *c*, pyloric end); 4, duodenum (*d*, opening of the pancreatic and the common bile duct); 5, jejunum and ileum; 6, large intestine (*e*, cæcum; *f*, cæcal appendix; *g*, ascending colon; *h*, transverse colon; *i*, descending colon; *k*, sigmoid flexure; *l*, rectum); 7, spleen; 8, liver, showing the under surface (*m*, gall-bladder; *n*, hepatic duct); 9, pancreas; 10, right kidney; 11, left kidney

The Teeth. The first part of the digestive apparatus that we encounter in the mouth is the teeth. The teeth should be 32 in number in the adult, and 20 in the child; but, as a rule, there are some missing. The approximate date when each tooth appears is marked in the diagram [26]—in *years* on the upper or permanent teeth, and in *months* on the lower or milk teeth. As a rule, the teeth in the lower jaw are cut before the corresponding teeth in the upper jaw. It will be seen from the diagram that the 12 extra teeth in the adult are all molars, room for which is found by the greater size of the jaw. The two *bicuspids* in the adult take the place of the two molars in the child. At birth the germs of the milk teeth and the permanent set are in the head, and at six years of age, when the first molars of the second set have appeared, and before any of the milk teeth are lost, all the teeth, except the wisdom teeth, are in the head—48 in number.

A tooth [27] consists of the *crown*, or the visible part; the *fang*, or fangs, or the part buried in the socket (*alveolus*) of the jaw; and the *neck* that unites the two. The main part of the tooth, both crown and fang, is made of dentine, or *ivory*, hollowed in the centre somewhat in the shape of the tooth, and forming the *pulp cavity* in which are situated the blood-vessels and nerves of the tooth. These enter through a small opening at the end of the root, or fang. The dentine is one-fourth animal matter and three-fourths mineral—the one being *gelatine*, the other mainly *phosphate of lime*. It contains a number of minute tubules, many of which communicate with the pulp cavity. On the crown the dentine is covered by a cap of a porcelain-like material called *enamel*. It is the hardest substance in the body, and only contains

about 2 per cent. of animal matter. It is composed of hexagonal rods, and presents in transverse section somewhat the appearance of a honeycomb. The enamel is thickest at the top of the tooth, and gets thinner towards the neck. It is itself covered by a thin horny layer called *Nasmyth's membrane,* familiarly known as the "skin of the teeth," which protects the enamel against the action of acids. In the root, or fang, the dentine is covered with *crusta petrosa*, or common bone, thickest at the end, and, like the enamel, thinning towards the neck.

Varieties in Shape. Teeth are of three principal shapes [**28**]: the *incisors*, or chisel-shaped, for cutting the food; the *canine*, or pointed, for tearing; and the *molars*, for grinding. Such a variety is evidently intended to deal with a mixed diet. The *condyles*, or the pivots of the lower jaw, are also arranged for the same end. In the carnivora, where the teeth are mainly for tearing and the jaw only moves up and down, the condyles are shown as [**29**] *transverse*. In the rodentia, where the teeth are for cutting, the condyle is *antero-posterior*, allowing of a backward and forward movement of the jaw. In the ruminants, where the teeth are mainly for grinding, the condyle is *circular*, allowing of a rotatory motion; while in man it is *oblique* and *partly circular*, allowing of a combination of all these different motions. The lower jaw has a *double joint*, a pad of fibro-cartilage being interposed for the double object of deadening the sound when chewing (the jaw being close to the ear), and of diminishing the risk of dislocation, while allowing of the freest movements. When the jaw is open, the lower teeth are in advance of the upper; when shut, the upper are in advance of the lower.

What Mastication Is. The action of mastication, like so many others in the body, is partly unconscious and partly under the control of our own will. The process of mastication consists of a combination of tearing, cutting, and grinding the food into a pulp by means of the teeth, assisted by the tongue and the rotatory movement of the jaw.

The second part of the process of mouth digestion is that of *insalivation* of the food, by which means it is all uniformly moistened, alone enabling dry food—such as biscuits—to be eaten at all, and by which the *starchy food is changed into sugar*. *Saliva* is a transparent, watery, slightly viscid alkaline fluid, with a specific gravity of 1005, and of the following composition:

Proteid	2 per cent.
Salts..	2 per cent.
Water	95 per cent.
Ptyalin	1 per cent.

It is manufactured at the rate of about a quart a day, and has several purposes. It moistens the mouth and tongue and food so as to be conveniently swallowed. Mastication mixes the food with it. Its chief value lies, of course, in the ferment—*ptyalin*—which it contains, the full virtues of which will be explained subsequently.

The saliva is formed in three pairs of glands. One pair, the *parotid glands*, are situated in the cheeks, and open into the mouth by a small duct (Steno's) at the back of the second molar tooth on each side. These glands secrete a clear limpid saliva free from mucin [**30**]. The other two pairs are the *sublingual* and the *submaxillary*. The former are beneath the tongue, and open with the former by common ducts (*Wharton's*). The saliva from these is more viscid, and contains much mucin. The flow is checked by nervous influences, such as terror. The ordeal of rice, practised in India, is based on this fact. If the man can swallow the dry rice—which is very possible by the aid of saliva—he is pronounced innocent; if he cannot—the flow of saliva being checked by fear—he is pronounced guilty. It is also inhibited by certain drugs such as tannic acid, and is excited by other drugs, such as pellitory root. Hence, sipping tea at meals checks the digestive process here, and also in the stomach. The flow of the parotid gland (from its position) is specially stimulated by the act of mastication.

The Throat. The throat, or *pharynx*, is divided from the mouth proper by the two *tonsils* at the sides, and the *soft palate* above, which hangs down like a curtain with a prolongation called the uvula in the middle [**31**] The pharynx contains *seven openings*: two in the floor—the anterior, the *larynx*, leading to the lungs; the posterior, the *œsophagus* or *gullet*, leading to the stomach. Above are the two posterior *nares*, or nostrils, the usual seat of growths in children, called adenoids; while on each side are the openings of the two *eustachian* tubes that carry air to the middle ear. The seventh is the *mouth*, in front.

The tonsils are masses of lymphatic tissue of those white corpuscles that war on bacteria. They contain numerous crypts or holes (some 10 or 12 in each), at the bottom of which glands open that secrete a tenacious mucus which coats the "bolus" of food as it passes between them. The researches of Metschnikoff and others lead us to think that they, in common with similar groups of cells in the intestines, may be the seat of active combats between invading bacteria and the defending leucocytes with which they are filled.

Nature's Device. The whole of the upper part of the pharynx and neighbouring passages are lined with columnar ciliated epithelia, which present an amazing appearance. This form of cell has on its surface several hairs. These, closely set together and covering the whole of the pharynx behind the tonsils, give the appearance of a rich velvet pile. But as these hairs are never still, but are incessantly lashing towards the mouth several times a minute, they present rather more the appearance of a field of corn swayed by the wind. They do not wave to and fro, but *lash* in a special direction all through life, day and night without ceasing. Those in the lower tubes lash upward, the upper ones downward, the side ones forward, and pass all particles or accumulations of all sorts into the mouth, and so get rid of them. This is one of the most beautiful and useful devices of Nature. The œsophagus, or gullet, is the narrowest and

strongest part of the alimentary canal. It is a tube nine inches long, reaching from the throat to the stomach.

How Food Descends. The passage of the food, liquid or solid, down the gullet is *never by gravity*, but is always a muscular act, excited by the food stretching the tube. The peculiar motion of smooth muscular fibre is called *peristaltic*, and is in a succession of waves, spreading from above downwards, thus gradually pushing the food either downhill, or as in horses drinking from a stream, uphill into the stomach.

The *stomach* [32] is a bag about 10 in. long, 4 in. broad, and 4 in. deep—but varying greatly in size according to the food it contains—lying transversely across the body from left to right, behind and below the end of the *sternum*, or breastbone. It is separated from the lungs and heart in the *thorax* above by the *diaphragm;* but the heart especially may, when it is distended, be said almost to rest upon it.

The Stomach. The shape of the human stomach is similar to the "bag" in the bagpipes, which is formed from that of a cow. The proximity of the heart to the stomach explains the phenomena of palpitation in case of stomach distension, and is well illustrated by the case of a man who died from a thorn he had swallowed into his stomach penetrating into the heart. The stomach is simply a distension of the general intestinal canal for a special purpose. Ruminants have altogether four stomachs, for the long processes of digesting raw vegetable food. Birds, being destitute of teeth, have stomachs with surfaces so hard that they grind the food there, instead of in the mouth. These are called gizzards.

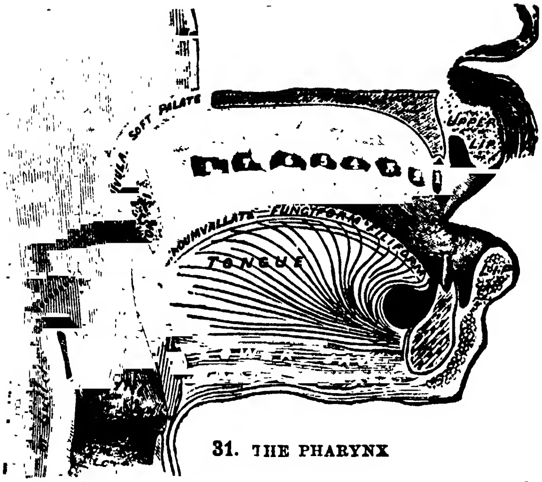
The gullet, or œsophagus, enters at the upper surface of the stomach, about 3 in. from the left or cardiac end. The opening into the bowel, called the *pylorus*, is at the extreme right end. The lower sweep from the gullet round to the pylorus is called the *greater curvature*, while the upper sweep above is called the *lesser curvature* of the stomach. The stomach secretes a ferment called pepsin. The whole of the stomach is lined with fine tubular glands [33], which secrete from the blood a fluid called the gastric juice, at the rate of about a gallon a day. This contains the ferment and also free hydrochloric acid. Its rough analysis is as follows:

Water	99·3
Pepsin	·3
Hydrochloric acid ..	·2

The smell or sight or thought of food causes this straw-coloured fluid to ooze out into the stomach, so that by the time the food arrives below there is sufficient always ready to begin operations at once. These consist in more fluid being poured forth, and the stomach commencing to move violently like a churn, the motion being kept up for hours. Now, here, again, is a wonderful thing — that such a violent motion can take place inside us of which, as a rule, we are wholly unconscious.

The Intestines. The *intestinal* part [25] of the alimentary tube in man is 27 ft. long, the *small intestine* being 21 ft. and the *large* one 6 ft. Its length in different animals is dependent on the food they take. It is shortest in carnivora, where digestion is quickest, and longest in the herbivora, where digestion is slowest, as in the sheep, where it is about thirty times the length of the body, as against ten times the length in man (measured from the vertex to the buttock). In carnivora, such as the dog where digestion is quick, it is about three.

The *small intestine* in human beings is a tube about 1 in. in diameter, beginning at the pyloric valve, and forming a convoluted mass in the centre of the abdomen, and terminating at the *ileo-cæcal* valve, where it



31. THE PHARYNX

enters the large intestine, or colon, a little above the right groin, just by the appendix. It is divided into three parts. First, next the stomach, the *duodenum,* which is the shortest and widest, and is so called because it measures the breadth of 12 fingers (about 1 ft. long). This curves like a horseshoe round the head of the digestive gland called the *pancreas.* A double tube opens into it here, conveying the bile from the liver and the pancreatic juice. Next, the *jejunum,* about 8 ft. long, so called because after death it is generally *empty*; and, lastly, the *ileum,* about 12 ft. long. The upper part of this intestine, and particularly the duodenum, is full of glands, and of elevations called *villi;* also of collections of white cells called *Peyer's patches.*

32. STOMACH AND DUODENUM

a, Œsophagus, lower part; *b*, lesser curvature; *c*, greater curvature (an artery running along it); *d*, fundus; *e*, anterior wall; *f*, pylorus (transition between stomach and intestine); *g*, duodenum; *g'*, first portion; *g''*, descending portion; *g'''*, transverse portion; *h*, beginning of jejunum; *i*, common bile duct; *k*, pancreatic duct. The two latter unite before their entrance into the duodenum

The *colon,* or large intestine, is about 2 in. in diameter, and may also be divided into three parts—the *ascending, transverse, and descending.* The first part begins at "Appendicitis Corner," with a blind extremity where the appendix is attached, and runs straight up the right side to the lower border of the ribs. The *second* passes across from right to left just below the ribs; and the *third* part descends from the left ribs to the termination of the canal. As it descends it bends into a large double curve like an S, called the *sigmoid flexure,* and thence becomes straight (called the *rectum*), ending at the *anus.*

Intestinal Valves. These are five in number. The *pylorus* is a muscular ring capable of closing the exit from the stomach. The *ileo-cœcal* valve is the second, where the ileum joins the colon, and has two flaps that allow passage into the large intestine, but none backwards. The third is a circular muscular construction at the commencement of the rectum that prevents the entrance of the intestinal contents into it, except at times. The fourth is the *internal sphincter,* and the fifth the *external sphincter* of the anus, at the termination of the canal, both being firm muscular rings. The latter has striped muscle fibre, and is thus under voluntary contro

The whole of this digestive tract—at any rate, from the throat to just above its termination at the anus—consists, as we have seen, of a tube of various sizes and shapes, lined with a special mucous membrane full of glands secreting digestive fluids of various sorts and elevations like the fingers of gloves, called villi [34], and made of muscular walls that are completely under the control of the unconscious mind. The muscle is what is called unstriped (save just at the anus, which is under conscious control), and moves in a peristaltic or vermicular or worm-like manner. It does not contract as a whole, but the contractions spread in waves from fibre to fibre, gradually forcing the contents onwards.

Digestive Fluids. The *pancreatic juice* is a product of a gland called the pancreas, or in animals the

sweetbread [35], lying across the body, from right to left, behind the stomach, its head surrounded by the duodenum, and lying against the liver on the one side, and the tail touching the spleen on the other. It is somewhat the shape of a hammer, with the handle coming to a point. It is from 6 to 8 in. long, and about $1\frac{1}{2}$ in. broad and thick, and weighs nearly a quarter of a pound.

The pancreatic juice itself is a clear, viscid, strongly alkaline fluid, very like saliva, sp. gr. 1015, secreted at the rate of *three-quarters of a pint in the day*. It is the most powerful digestive fluid in the body.

34. TRANSVERSE SECTION THROUGH THE SMALL INTESTINE
1, Serous or peritoneal coat; 2, inner longitudinal coat; 3, inner circular coat; 4, 5, muscularis mucosæ; 6, submucous coat; 7, intestinal villi, with the epithelial lining; 8, arrangements of the blood-vessels of the villi; 9, network of lymphatics in the submucosa; 10, villi with central chyle-vessels; 11, nerves of the submucous and muscular coats; 12, crypts of Lieberkuhn; 13, lymph follicle; 14, lymphatic vessel

The *bile* is the second digestive fluid in the intestines, and is a secretion formed by the liver. It enters the *duodenum* by the same opening as the pancreatic juice, down the common bile duct, at the rate of a *quart a day*. It is a somewhat viscid fluid, of a golden-yellow colour, bitter taste, slight alkaline reaction, and with a sp. gr. of 1020.

The liver [25] is a large organ behind the lower ribs on the right hand side of the body, has five letters, five lobes, five ligaments, five fissures, five vessels, five functions, and weighs 50 oz. It is situated partly under cover of the ribs on the right side of the body, just beneath the diaphragm, and consists essentially of a mass of *hepatic* or modified epithelial cells, divided into clumps called *lobules* (one-twentieth of an inch in diameter), not visible to the naked eye, separated from each other by fine fibrous tissue, with which the whole organ is invested, and by blood-vessels.

35. THE PANCREAS
1, 2, Tail and head of the pancreas; 3, pancreatic duct (canal of Wirsung); 4, supplementary pancreatic duct; 5, opening of pancreatic duct; 6, opening of common bile duct

Circulation. The circulation of the blood is maintained by special means. The heart is not sufficiently powerful to drive the blood through two sets of capillaries—those in the alimentary canal and those in the liver; hence the veins in the liver are not collapsible, but always open, and every movement of the intestine drives the blood forward by the collapsing of the abdominal and portal veins, into the open veins of the liver. It is then sucked up into the thorax at every inspiration, through the greatly diminished pressure there and thus reaches the heart through the ever-open hollow vein called the *inferior vena cava*.

The *formation of bile* is *one* of the chief functions of the liver cells. As produced, it is passed into the tiny ducts that lie between the opposing surfaces of the cells, and then passes out of the liver to be stored in a special receptacle called the *gall-bladder*, which is a strong bag about 4 in. long, able to hold about 1 oz. of bile. If digestion is going on at the time, the secretion becomes more active, and the bile, instead of entering the gall-bladder, passes straight down into the duodenum. The properties and uses of bile have been already described.

The *formation of glycogen*, or *animal starch*, is the *second* chief function of the liver. It is a substance *isomeric* with, or having the same formula, as starch, and colours red with iodine. The molecule of water added by the ptyalin, which changes starch into malt sugar, is here removed, thus converting it into glycogen. It is readily changed back as required into sugar by a ferment present in the liver.

The *third* chief function of the liver is the purification of the products of digestion from self-made poisons. If for any reason this fails to be perfectly done, a bilious attack is the probable result.

To be continued

SILK AND THE SILKWORM

The Cultivation of the Worm. Raw Silk. Silk Reeling. The Utilisation of Silk Waste. The British Silk Trade

By W. S. MURPHY

SILK is the finest of textile yarns, the most beautiful of woven fabrics. The choice garment of beauty, the flowing robe of regal dignity, the vestment of priestly office—silk is the poetry of the textile world. It enriches and adorns every other fabric. The noblest of fibres, it is worthy of noble use.

The manufacture of silk did not become an industry in our own country until late in the sixteenth century, and here, as elsewhere, it was religious persecution in Continental Europe that planted the seeds of what became an important trade. At first British silk weavers depended on Continental "throwers" for yarn, but in 1718 a silk-throwing establishment was started in Derby. The process of utilising silk waste introduced by Samuel Cunliffe Lister, of Manningham, marked an epoch in the English silk trade. But the silk industry has declined from the middle of last century, and from being responsible for the employment of nearly 150,000 employés it has shrunk until now only about one-fourth of that number find in it the means of subsistence.

Centres of the British Silk Industry. The principal centres of silk manufacture in Great Britain at the opening of the twentieth century were as follow:

CONGLETON. The abandonment of Protection probably hit Congleton harder than any town in England. Up till 1858 silk-throwing was the principal industry, employing over 5,000 people. In 1859 there were forty mills in the district, and the number had dwindled down to six in 1890. The trade, however, has not quite lost its vitality, and shares in the present moderate prosperity of the silk industry, producing yarns, ribbons, trimmings, crapes, bindings, and gauzes.

COVENTRY. For over 200 years silk ribbons have been made in Coventry, and ribbon manufacture is still a staple industry of the town. Latterly, however, the silk weavers of Coventry have taken up other branches of the trade, and now produce a wide variety of stuff such as plaids, ottomans, failles, plush shades, brocade neckties, chenille, and other trimmings.

DERBY. Though the first silk-throwing mill in this country was built there, the silk trade of Derby has never been of very great importance. Trimmings, surgical bandages, silk stockings, and silk yarns are the chief products.

LEEK. This town very probably owes its silk industry to the charity which the Vicar of Leek extended to French Protestant refugees fleeing from persecution. The history of Leek silk trade is a record of almost continuous progress. Beginning with button-making, Leek manufacturers proceeded to take up ribbons, brocades, serges, handkerchiefs, damasks, and sewing silks, the last mentioned being at present the chief output. Over fifty firms are engaged in silk manufacture in the district. Silk-dyeing is also very important in Leek.

LONDON. Spitalfields silk industry began in 1563. Small at first, the trade received large and powerful impulse from the Dutch refugees in 1585. The product of this industry has changed several times during the 300 years of its existence. Originally, silk stockings, vestings, and garment goods, plain and figured, were woven in Spitalfields, but at the present day the looms are employed upon plain and figured silk, and velvet for furniture, scarfs and ties, umbrella and sunshade coverings, chenille and trimmings. Lately, the dress goods trade has been revived.

MACCLESFIELD. A silk-throwing mill was established here in 1756 by Mr. Charles Roe, and the industry prospered so long as it was exempt from foreign competition, but in recent years it has greatly declined. Macclesfield weavers, however, are still famous for ladies' neckties, sarcenets, bandanas, and handkerchiefs, and have lately entered into a close competition with the silk cloth manufacturers of the Continent, in which they are holding their own.

MANCHESTER DISTRICT. Early in the nineteenth century silk manufacture was set up as a rival to cotton in the Manchester district, but the competition was almost fatal to the finer industry. Cotton swept all before it, silk only surviving in the outlying parts, as Patricroft, Leigh, Middleton, and West Houghton were then. In these places a fair amount of weaving is still done, the products being piece goods, galloons, and small wares.

NORWICH. In 1564 Queen Elizabeth granted, at the instance of the Duke of Norfolk, licence to 300 Dutch and Walloon refugees to carry on the industry. Since that date silk manufacture has continued in Norwich, the trade now consisting of crapes and spun silks, chiefly decorative furniture cloths.

YORKSHIRE. The silk trade of Yorkshire is confined almost wholly to spun silk. The waste from silk-throwing, spinning, and weaving, and the broken cocoons, is put through machinery similar to that employed in making worsted yarns, and woven into plushes, velvets, and plush goods. Bradford and Halifax are the principal centres of this industry.

Signs are not wanting that, after many ups and downs, the silk trade of this country has entered on an era of progressive prosperity. By the adoption of the best French and Italian practice, and by technical education, the silk

industry of Great Britain is steadily developing, and the future is full of promise.

Silkworm Cultivation. Silk manufacture originated in China. According to Chinese tradition, the Emperor Foh-hi, about 5000 B.C., taught his people how to cultivate the silkworm. During the reign of Hoang-Ti, 2600 B.C., his empress See-Ling-Chi invented the cocoon-reeling mill [13] and the weaving loom.

For thousands of years the Chinese jealously guarded the silkworm from the knowledge of the outer world, but the culture of the silkworm spread west, through Bokhara, Khiva, and Samarcand, to Teheran, and became an established industry of Persia.

Spreading by land, the knowledge of silk also diffused itself by sea. The Phœnician traders brought silks from China, both yarns and cloths, and distributed them over the Western world at least 1,000 years before the Christian era.

Silkworm rearing was the monopoly of the Emperor at Constantinople for a considerable time; but gradually the culture extended south to the Levant, and silkworm gardens became common in the south of Greece.

Silk in Western Europe. Spain was the first country of Western Europe to receive the silkworm, the Arab conquerors introducing it there about the tenth century, probably from their homes on the borders of Persia. When the Moors took over their Spanish dominions from the Arab caliphs they greatly extended the industry, and silk factories were established at Seville and Grenada in the thirteenth century.

Roger, the Norman King of Sicily, invaded Greece, took captive a number of Corinthian weavers, and settled them in Palermo, at the same time importing the mulberry and the silkworm. This was in 1147; and in a few years silk culture spread to Calabria, and thence into Italy, where an important silk industry grew up within a century. Lucca was an important centre of the industry in 1248, but civil wars being of frequent occurrence in that town, the authorities of Milan, Florence, Bologna, Venice, and Genoa offered asylum to the silkworkers. It would seem that the invitations were accepted, for the silk industry was established in all these places before the middle of the fourteenth century.

In 1516, when Francis I. of France had obtained possession of Milan, he settled some of the Milanese silk producers at Tours, and laid the foundations of the French silk industry. We must remember, however, that the mulberry trees planted by Pope Clement two centuries before had their effect in fostering silkworm culture in the valley of the Rhone, affording the weavers of Lyons the plentiful supply of raw material of which they have made such splendid use.

LIFE HISTORY OF THE SILKWORM

Silkworm cultivation has been tried in England at intervals during the past three centuries. The most notable experiment was that of the British, Irish, and Colonial Silk Company, started with a capital of one million sterling in 1825. No result came from the experiment. So far as our knowledge goes, the many later attempts have also resulted in failure as commercial ventures. Climatic and other conditions in this country seem to operate against the success of silkworm cultivation.

Cultivation of Silk in United States. The vast territory of the United States seems to offer a wide and suitable field for silkworm cultivation, but hitherto all the efforts of the Americans have failed. In 1660 a man named Aspinwall planted mulberry trees on Long Island with a view to silk culture. The industry seems to have taken some slight root, and a century later the British Government offered bounties amounting to 25 per cent. on the value of all raw silk exported from the colonies to Great Britain. The War of Independence put an end to the arrangement. In 1831 a determined effort was made to establish silk culture in the United States, and some success was attained in both Connecticut and Massachusetts; but speculators created a mania, known as the "Horus multicaulis craze," and the financial disasters ensuing overwhelmed the industry.

The same story was repeated in 1861, when M. Prevost, a French enthusiast, instituted silkworm culture in California. In 1878 Professor Riley, entomologist of the United States Department of Agriculture, aroused renewed interest in the subject. In the following year the department began a series of experiments which continued over 10 years, seeming, to observers

at the time, to exhaust every expedient in the effort to make the industry commercially successful. After an interval of 10 years the Department of Agriculture determined to renew its efforts, and in 1902 experiments were begun.

It would seem that the chief obstacles to the success of silkworm cultivation in the United States are the high cost of labour and the comparative profitableness of agriculture and other manufacturing industries. In some of our Imperial dominions those two obstacles are almost wholly absent, and the prevailing climatic conditions more nearly resemble those of the countries in which the silkworm is native.

At the International Exhibition 1873, cocoons produced in the colonies of New Zealand, New South Wales, Queensland, and Cape Colony were shown; but up to the present raw silk does not appear among the exports of these colonies.

Rearing the Silkworm. All silkworms are moth caterpillars [8], and the varieties are very numerous. Caterpillars, it is well known, feed on vegetable leaves. The favourite food of the common silkworm, *Bombyx mori*, is the white mulberry leaf. Cultivated mulberry trees are propagated by grafting cultured shoots on wild stems. The wood should be carefully pruned to promote leafage. In China the bushes are never allowed to grow taller than 6ft. Left free to grow, the mulberry attains a height of 50 ft.

Other caterpillars are not so particular in their choice of food as the *Bombyx mori*, and silk cultivators have found it profitable to breed some of the other varieties. Small as the silkworm appears, this question of food is a very serious one, a single ounce of eggs producing worms which consume during the period of development no less than 1,500lb. of mulberry leaves. In the table following we give the leading varieties of silkworms, with the foods on which they can be reared.

Species.	Foods.	Where cultivated.
Bombyx Mori	White Mulberry	China, India, Japan, Persia, Turkey, Greece, France, Italy, Spain.
Cynthia	Ailanthus.	China, India, Japan, France, Italy.
„ Pernyi	Oak	Newchang (China), India.
„ Mylitta	Oak	North China.
Attacus Atlas ..	Omniverous	China, Burmah, India, Ceylon, Java.
Cynthus	Ailanthus..	India, France, Italy, America, Java, Nepaul.
„ Ricini ..	Castor-oil Plants	Assam, India, Cachar.
Antheraa Paphia (Mylatta) (Tussih moth)	Ber, and various Indian shrubs	Over all India, and lately introduced in Europe.
Antherea, Mazankoong	Oaks	Assam.
„ Assama	Laurus obtusifolia	Assam.
Actias Selene ..	Various wild fruit trees ..	Mussooree, Sikkim, Madras.
Yama-mai.. ..	Wild Oak.. ..	Japan, Italy, France, America.

Food and Treatment. The moth of the common silkworm is about 1in. long, the female [12] slightly larger than the male [11]. The insect has a thick, hairy body, short head, and broad wings of whitish grey, barred with pale brown, resting convexly over the body. After the pair have lived four or five days, the female lays her progeny of 500 eggs, and the parents die. The microscopic globules have been deposited with a soft, gummy substance, which, if allowed to dry, forms a silky coating; but that must be prevented. As soon as the eggs have been laid, the silk cultivator washes them, and provides for them a clean tray on which to begin life. Here the eggs are kept in a warm temperature till hatched, when the worms emerge a little over one-twelfth of an inch long. For a period of four days the little things wriggle about, and then become torpid and sick. The first skin has hardened, and will not admit of further growth. On the fifth day the skin breaks at the neck, and the caterpillar, by wriggling and writhing, frees itself from the old skin and reappears in a new dress, very lively and ravenously hungry. Food must be given sparingly at this state, but at regular intervals. In three days the moulting process begins again, and on the fourth day the caterpillar assumes its second dress. This skin lasts about five days, and is cast off as before. A fourth, and in some cases a fifth, skin is assumed, and then the worm, having attained a length of 3½ in., ceases to feed, and seeks a suitable place in which to begin its spinning. In China, India, Japan, and other countries, sub-tropical and tropical, the silkworm is allowed to mount on bushes in the open air, but the European cultivator requires to provide nests for the operation of cocoon-spinning. Some simply supply little bunches of twigs, others make small paper cones, and allow the silkworms to use them as they please; but the Italians have devised little box trays formed by slips of wood, which seem to answer the purpose very well.

Some Rules. Before leaving this subject, we would repeat the advice which experienced silkworm-rearers have given to those who would be successful in the industry.

Feeding. Clean, dry, wholesome food is essential. Spotted, worm-eaten, or mildewed leaves are injurious to the caterpillars. Feed sparingly during the time they are casting their skins. Supply the full-grown worms with as much food as possible.

Warmth and Light. Keep the eggs in an even temperature of not more than 64° F. Avoid hot sun, and give plenty of light. After hatching raise the temperature gradually to about 82° F. till the worms have cast their skins, when the temperature should be lowered and gradually raised again. Avoid draughts and sudden variations in temperature.

General Influences. Loud noises of any kind are apt to induce disease in the silkworms. Smells, agreeable or otherwise, exercise a disturbing effect, and should be avoided. Smoke is another nuisance much dreaded by the experienced silk cultivator.

Gathering the Silk. Let us examine the full-grown silkworm. On the underside of the yellowish-grey body two intestine-like tubes are visible, extending from the tail to the mouth, on the upper lip of which is a curious little point called a spinneret. The tubes are full, and stand out in the body. The head moves about, and gradually a coarse, silky substance appears and winds round the body. This is the floss which forms the outer coating of the cocoon [9 and 14]. Drawing itself in, the silkworm goes on spinning, filling out the floss as round after round of silk winds on its body. Within five or six days the spinning is done, and a cocoon the size of a pigeon's egg formed. Our silkworm has spun a length of from 600 to 1,000 yards of silk, though of that amount we may not be able to reel more than 300 to 500 yards.

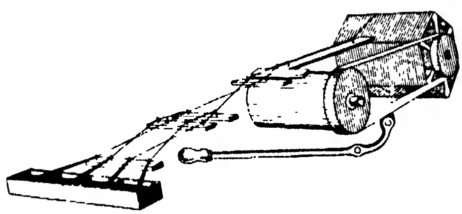
Stifling. Nature does not intend that the cocoons should be unwound. Left to itself, the worm grows into a moth, emerging through the broken cocoon [10], and the silk is "cast as rubbish to the void." If the silk is to be preserved, the worm must be killed. Various methods are adopted for choking or stifling the silkworms. The oldest practice was to subject the chrysalids to intense, dry heat in a closed oven. More scientific and certain in its effects is the application of dry steam, first devised by Professor Gastrogiovanni, of Turin. For this process the utensils are very simple. A basin with a furnace underneath, movable frames for the cocoons, trays, and a bell-receiver comprise the principal parts of the plant. Enough water is put into the basin, which is heated to 100° C., the bell cover is lifted, and the tray of cocoons inserted. In 15 minutes the intense heat has killed the caterpillars and preserved the thread.

Reeling the Cocoons. Empress See-Ling-Chi's invention [13] gave the principle of silk reeling to all subsequent machines. As shown in ancient Chinese prints, the reeler consisted of a small tray, five slips of lancewood, a small cylinder, and a hexagonal reel. Stripped of floss, the cocoons are put into the tray, which has been filled with warm water. With a whisk, or branching twig, we work on the cocoons to get hold of the proper thread. Having caught, say, two filaments, we twist them, and put them into one of the four nicks in the first lancewood slip. We find other two filaments, and place them in nick No. 2. Repeat twice, and fill up the four nicks with strands. Draw out the four strands and cross each pair, passing thread No. 1 into nick No. 2 of the second slip of lancewood, thread No. 3 into nick No. 4, and so on. In the third slip of wood there are only two nicks; into each of these twine two strands. The crossing has made them incline towards each other, and they twine prettily. We now have two strands. Cross the strands midway towards the fourth slip of lancewood, and put them through the nicks. On the fifth slip of wood there is only one nick, and the two strands are converged to it, combined in one smooth, round thread, and wound on to the hexagonal reel at the end of the machine.

In the modern filatures, as the silk-reeling establishments are named, the same process is followed. The cocoon basins are steam-heated, the guides are steel, the motor is the dynamo or the steam-engine, the end reel is large and heavy; but, except in small particulars affecting the speed of the operations, the main lines of the machines were laid down by Empress See-Ling-Chi 4,000 years ago.

Simple as the work appears, the reeler is called upon to exercise skill and care. The object is to produce a thread of uniform weight and thickness. The filaments of the cocoons, however, thin towards the inner rounds. To keep the thread uniform, another filament must be added, and another, sometimes three or four additional cocoons being employed in making up one thread.

Raw Silk. The skein of silk upon the reel is termed *raw* silk, and in that form appears upon the market. From China and Japan the raw silk comes in bales of skeins, weighing on the average 100lb., the skeins varying between 60 and 90 in. in length. French and Italian silks are sold in hanks of about 520 yd., the value being determined by weight.



13. A PRIMITIVE SILK-REELER

It is the ambition of every manufacturer to carry through the process of his trade from beginning to end. The reeling described is seldom combined by British workers with silk-throwing—that is, the making of silk yarns—and never with silk manufacture. About 1850 a process was patented in this country by which silk manufacture could be started with the cocoons. Mr. B. F. Cobb, the first authority of his day, stated in 1877 that this invention had been utilised by a Milan manufacturer; but none of the leading silk firms in Great Britain seem to have adopted it. The process is too elaborate to be given here, but it seems that development in the silk industry lies in its direction.

Spun Silk. No textile fibre produces so much waste in the processes of preparation and manufacture as silk. This is very tantalising, for it is the costliest of all fibres. The flossy covering of the cocoon, though genuine silk, is too coarse, tangled, and full of gum to be unwound, and it is cast out as useless waste. From a fourth to a third of the silk actually upon the cocoon cannot be unwound, and it is cast aside as waste, being called the "knub." To obtain the moths which carry on the race of silkworms we must allow them to burst the cocoons in which they have been imprisoned during the chrysalis state, and there we have more waste. When forming the threads—*filassing*, we name

the process—we make waste; and in all the subsequent operations there is waste, though in decreasing proportions. For many centuries the silk manufacturers of Europe especially found the proper disposal of the waste a very serious problem. With the increasing growth of towns, and the restrictions imposed by sanitary authorities, the problem became even more insistent. Incredible as it may seem, our beautiful and costly fibre, the most precious of textile materials, was, in its waste state, denied even the refuge of the manure heap. It was rejected as a field manure because it would not rot.

Utilisation of Silk Waste. Like most industrial changes, the utilisation of silk waste was a gradual growth. The waste from the throwing-mills and weaving factories was gathered and put through the same process as shoddy rags, quite unobtrusively, and merely in the ordinary course of trade, about 1830 to 1840. Thus reduced to a proper length of staple, the silk was put through the common process of textile manufacture, being treated in the same way as cotton or wool.

The waste utilised by the process indicated barely touched the great problem. There was a mass of silk waste outside its scope; but the modest beginning gave a hint to a man of genius who was able to take it. Mr. Samuel Cunliffe Lister, afterwards Lord Masham, had his attention called in the year 1857 by a silk broker in London named Spenseley to the immense stocks of Indian silk waste then being accumulated by the city without any prospect of use. Mr. Lister was a partner in a firm of worsted manufacturers, and had acquired some experience in the combing of wools. He examined the stock of silk waste held by Mr. Spenseley. Very unpromising material it seemed, looking, as Mr. Lister afterwards said, more like oakum than silk. He agreed to take a quantity at 1d. per lb., and undertook the experiment. First Mr. Lister boiled a quantity of the waste, and had the satisfaction of seeing the substance which resembled a coagulated mass of mixed gum and rags assume the appearance of a flossy tangle of fibres. From this point the rest seemed easy, and had he been content with inferior results, Mr. Lister would simply have fallen into the ordinary process. But his object was to produce a genuine silk thread resembling in essential character thrown silk. To accomplish this object the firm of Messrs. Lister & Co. expended a quarter of a million sterling in bringing to perfection a dressing machine which would produce a perfectly even sliver—that is, the soft rope from which the thread is drawn and spun. Upon the quality of the sliver depends in large measure the character of the yarn subsequently produced. This is specially true of silk, for the microscopic filaments obstinately retain little knots and irregularities which reveal themselves when the thread has been spun.

The spun-silk trade, as developed by Messrs. Lister & Co., made a link of connection between the silk and wool and cotton industries, with the result that silk manufacture was taken up in such cotton-spinning centres as Rochdale and Oldham, and in the wool manufacturing towns of Yorkshire

SHORTHAND

Fourth Instalment of the Special Course of Shorthand Taught by Messrs. Pitman and Sons on their Twentieth Century Plan

By Sir ISAAC PITMAN AND SONS

THE liquids *l* and *r* are often found following and closely united or blended with other consonants, forming a double consonant or consonantal diphthong; as in the words *pl*ough, *br*ow, *gl*are, *dr*ink, *fl*y, *fr*y, ma*ker*, dou*ble*, etc. In pronouncing these words, the combination of the *l* or *r* with the preceding consonant is uttered by a single effort of the organs of speech. These consonant combinations are represented by adding an initial hook to the simple characters to indicate their union with a following *l* or *r*.

Initial Hook adding L and R to Straight Letters. A small initial hook written *towards the* LEFT, adds *L* to straight consonants, thus

p, *pl*, *bl*, *tl*, *dl*, *kl*, *gl*.

A small initial hook written *towards the* RIGHT, adds *R* to straight consonants, thus

p, *pr*, *br*, *tr*, *dr*, *kr*, *gr*.

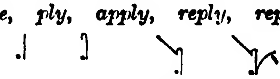
The following mnemonic aid will be useful for remembering the *pl* and *pr* series. If the *L*eft hand be held up, with the first finger bent, the outline of *tl* will be seen; and if the *R*ight hand be held up, in the same way, the outline of *tr* will be seen.

The consonant is not hooked initially, the characters and being employed for *w* and *y*.

The double consonants formed by the initial hooks should be considered as syllables, and named accordingly. Thus should be called *per*, as heard at the end of the word "pa*per*," and not *pee-ar*, which would be written or

Vowels are read before and after these double consonants as they are before or after single consonants, thus

pie, *ply*, *apply*, *reply*, *replica*,



eat, *eater*, *Peter*, *Peterloo*.

The double consonants in the following exercises should be called by their single names, and they will then be easily recognised; thus

per eh (pray).

EXERCISE.

1 

1 Plough, apple, odour, draw, pebble, feeder, rocker.
2 Pickle, globe, shudder, crumble, mocker, archer, track.

Initial Hook to Curves. An initial hook can only be added to curved consonants in one position, namely, inside the curve, thus The hook, however, may be made either large or small, as in the examples.

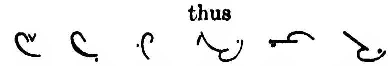
The consonants *l*, *r*, and *s* are not hooked to indicate the addition of *l* or *r*. The signs are, therefore, used as extra forms for *fl*, *fr*, and as extra signs for *thl*, *thr*, which with the corresponding heavy consonants, have duplicate forms, thus

fl, vl, *thl*, thl, fr, vr, *thr*, thr.

L HOOK.

A LARGE initial hook adds *l* to the curves

thus



fly, *evil*, *Ethel*, *official*, *camel*, *penal*.

The double consonant *shl* may be written either upward or downward; it is, however, generally written upward. The right curves must only be used AFTER another consonant; they are most conveniently written after *k*, *g*, *n*, or a straight up-stroke, as

cavalry, *gruffly*, *inflame*, *reflex*;

and after *b*, *l*, as *Bethel*, *lethal*

R HOOK.

A SMALL initial hook adds *r* to curves; thus

measure, *calmer*, *dinner*.

The double consonant *shr* is written downward only.

The alternative forms for *fr*, *vr*, *thr*, are employed as follows:

(a) When not joined to another stroke consonant, the LEFT curves are used when the word begins with a vowel, as

ever, *affray*, *ether*.

(b) The RIGHT curves are used when a vowel does not precede the consonant, as

fray, *three*,

(c) When joined to a stroke consonant which is written *towards the right*, the RIGHT curves should be used whenever possible, as in

throb, *proffer*.

(d) When joined to a stroke consonant written *towards the left*, the LEFT curves should be used whenever possible, as in

average, *Jeffery*.

(e) But in preference to an awkward joining, either form can be used, as in

Frank, *froth*.

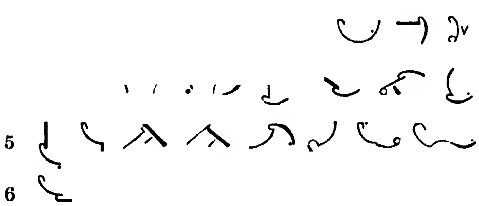
NG HOOKED.

In accordance with rule, the sign would represent the sound *ng-r* as in *singer*. There are, however, so few words in which *ng* is followed by *r*, that this hooked outline is used to represent the frequently occurring sounds of *ng-kr* and *ng-gr*, as heard in

banker, *tinker*, *finger*, *linger*.

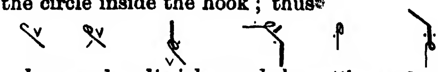
Words such as *singer* and *wringer* must, therefore, be written in full, thus

EXERCISE.



1 ARRival, rival, cavil, flap, muffle, fennel, kennel, shuffle.
2 Ethel, flog, flooR, flurry, ruffle, flinch, gravely, flask.
3 Fever, leather, ARthur, knuckle, freak, friaR, locker.
4 Canker, malinger, adverse, packer, loafer, docker.
5 Fisher, rider, owner, taper, bugleR, treacle, rumour.
6 Dover, river, giver, manner, tether, thrust, **freely**.

Circles and Loops Prefixed to Initial Hooks. The circle *s* is prefixed to straight consonants which are hooked for *l*, and to curves which are hooked for *l* or *r* by writing the circle inside the hook; thus



ply, *supply*, *disciple*, *explode*, *settle*, *pedestal*,

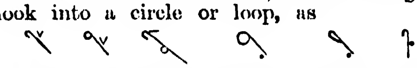
sickle, *physical*, *cipher*, *decipher*, *civil*, *peaceful*,

summer, *dulcimer*, *sinner*, *prisoner*.

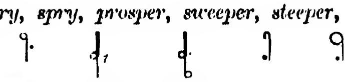
In cases where the hook cannot be clearly shown (which are comparatively few), the separate consonants should be written, as in

forcible, *unsaddle*.

The circles *s* and *sw* and the loop *st* are prefixed to the straight consonants which are hooked for *r*, by writing the circle or loop on the *same side* as the hook, thus turning the hook into a circle or loop, as



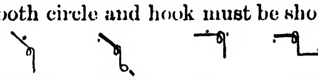
pry, *spry*, *prosper*, *sweeper*, *steeper*, *tray*,



stray, *destroy*, *distress*, *cuter*, *sweeter*,

slouter, *crew*, *screw*, *corkscrew*.

When the circle and hook occur medially *at an angle*, both circle and hook must be shown, thus

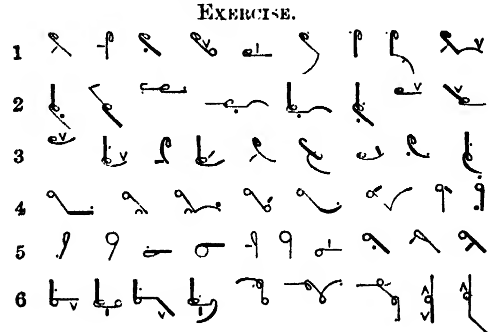


pastry, *abstruse*, *extra*, *gastric*,

The method of writing *skr* and *sgr* after the consonants *t* and *d* is shown in the following examples:

tucker, *tasker*, *degree*, *disagree*.

EXERCISE.



Exercise.

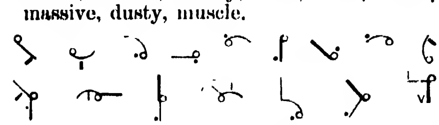
1 **Satchel, sidle, peaceable, exclusive, seclude, tricycle.**
2 **Feasible, noticeable, visible, traceable, plausible.**
3 **Simmer, chastener, listener, passover, lucifer, scrap.**
4 **Spread, jack-screw, stripe, sprung, suitor, stretcher.**
5 **Stater, cider, stalker, stager, stabber, scrub, scrupulous.**
6 **Exeter, lustrous, rostrum, rascal, crusader, decrease.**

Key to Exercises in Last Lesson.

Circle S and Z.

1 Set, siege, soar, cheese, lace, moss, rice, geese, soul, soothe.
2 Chosen, unsafe, musty, cask, desk, razor, massive, dusty, muscle.

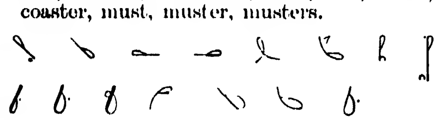
1
2



Loop ST and STR.

1 Stud, dust, duster, dusters, stowed, toast, toasts, toaster, steel, least.
2 State, statist, statistics, stiff, fist, coast, coaster, must, muster, musters.

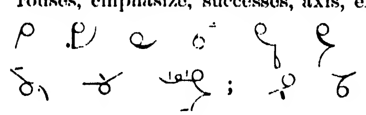
1
2



Large Circles SW and SS.

1 Sweat, swathe, swan, swell, swarm, swim, swing, swarthy, swallowing.
2 Successive, necessary, witticism, incisive, rouses, emphasize, successes, axis, excess.

1
2



Vowels and S and T.

1 Sue, saw, saucy, sauce, saucebox, Esau, asp, see-saw, icy, assessor.
2 Aside, asylum, daisy, disease, Zulu, zinc, mossy, incite, musty.

Group 1 **AGRICULTURE** **4** Continued from page 434	# FERTILISING THE SOIL **How to Treat Agricultural Soils. Various Kinds of Manure and their Special Uses. The Composition of Artificial Fertilisers**

By Professor JAMES LONG

MOST agricultural soils are well stored with materials which are essential to the growth of plants, but which are in an insoluble condition, and therefore unavailable. These materials dissolve slowly, the necessary change being effected by good cultivation and the introduction of air and warmth which follow it. Artificial, or chemical, manures are employed for the nourishment of plants because, in most cases, the food they contain is readily available. In many otherwise fertile soils one of the three essentials—nitrogen, phosphoric acid, or potash—is temporarily exhausted, the exhaustion of either rendering the soil infertile. If the farmer by simple experiment and careful observation of facts recognises which form of plant-food is needed, he is able to provide it, to restore fertility, and thus practically to command a crop. Although the three fertilising properties named are those which apply to every class of soil, there are occasions on which lime is needed.

Risks in Manuring. It is necessary for the young farmer not only to learn what manures to apply, but what quantities and when. He must, too, avoid the danger of careless mixing, that one form of manure may not destroy the properties of another. He must learn to distribute the manures evenly and in as fine a condition as possible, mixing, if necessary, some dry material, such as ashes or earth, with them for the purpose. Soluble manures, like nitrate of soda, are only used as top-dressings on growing crops, and then only upon the heavier soils. Sown in winter or on light soils, a soluble salt of this character is usually washed into the subsoil or drains, and lost. On the other hand, manures containing potash and phosphoric acid, like bones, dried blood, and other animal fertilisers, are slow-acting and unaffected by rain, in that they are not carried through the soil and wasted. Although there are manures, like the best Peruvian guano, which contain nitrogen, phosphoric acid, and potash, artificial fertilisers are usually classified as nitrogenous, phosphatic, and potassic.

Nitrogenous Manures. The nitrogenous manures include nitrate of soda, a deposit chiefly found in Chili, of which 95 per cent. should be pure nitrate. Nitrate, which contains 15½ per cent. of nitrogen, is highly soluble, and is used for growing crops chiefly on clays and loams. It should be employed only when the soil is in good heart and able to supply other necessary foods, or when those foods are provided in the form of dung or other artificials. Thus, for corn and grass in particular, nitrate is used after a dressing of dung or a phosphatic manure has been supplied, or with mangels which have received dung, or with potatoes which have received a small dressing of dung and supplies of potash and phosphoric acid. It should be remembered that an artificial manure is chiefly employed for the benefit of the growing crop, and this, above all, is the case with nitrate of soda and all highly soluble manures. The old practice of supplying slow-acting manures, such as crushed or ground bones, is uneconomical, good as the ultimate results may be, for money is expended for succeeding crops which may be better and more cheaply fed when the time for their assistance arrives.

Sulphate of Ammonia. This is a by-product in the manufacture of gas, contains about 20 per cent. of nitrogen, and is less soluble than nitrate of soda. It must be converted into a nitrate before it is available to plants. Sulphate can, therefore, be sown with the seed. It should be 95 per cent. pure.

Soot. Whether the produce of wood or coal, soot is valuable for the nitrogen which it contains, and is usually purchasable at 6d. a bushel. Coal soot, however, is much richer than wood soot, although it is now generally superseded by nitrate of soda, on account of the comparative slowness of its action. It is employed as a top-dressing.

Rape-cake. This is the pressed residue of rape-seed from which the oil has been extracted, and, when finely ground, is a useful nitrogenous fertiliser. It is also commonly employed on land which is subjected to wireworm, one of the most destructive of farm pests. The insect is believed to relish the rape, and to prefer it to plants.

Dried blood, horny materials, and woollen waste, all containing nitrogen, are occasionally used in some form for manurial purposes, but are slow acting, and generally uneconomical.

Phosphatic Manures. Bones are one of the chief sources of phosphoric acid, but inasmuch as their gelatine contains nitrogen, and as they are also rich in lime, they are largely employed where, by treatment with sulphuric acid, they have been brought into a quickly active condition. Thus we get dissolved bones or acid superphosphate, the insoluble materials being rendered soluble. It is necessary, however, to discriminate between bone superphosphate and mineral superphosphate, other materials than bone (such as phosphatic rock) being prepared for a similar purpose. Where a crop needs both phosphate of lime, for its phosphoric acid, and nitrogen, dissolved bones may be employed with advantage, unless the soil is of an acid character, or unless nitrogen and phosphoric acid can be purchased in other forms at less cost per lb. Bones, however, are subjected to the process of boiling and steaming for the removal of the gelatine, which is employed for purposes outside

agriculture. By this means the nitrogen is chiefly removed, although the percentage of phosphoric acid is increased.

Basic Slag. This is the ground cinder produced in the process of smelting iron. It contains from 15 to 18 per cent. of phosphoric acid in combination with lime. It is essential in purchasing this fertiliser to compare the prices and percentages of different samples as well as the fineness of the powder, which is all important, inferior samples costing as much for carriage and distribution as the best. The combination of lime with the phosphoric acid renders slag more suitable for soils deficient in lime, and for acid soils, than superphosphates, which are of a highly acid character. Soils which are sour, which are peaty, or which are rich in organic matter of any kind, are benefited by heavy dressings of basic slag, while many of the heavier clays have been so improved by its use that the herbage is not only enriched with clovers and trefoils, but the crops very largely increased in weight.

used, but owing to the higher price of the potash they contain, they usually give way to kainite.

Wood Ashes. Wood ashes, some of which contain as much as 10 per cent. of potash, 3 to 6 per cent. of phosphoric acid, and large quantities of lime, are always valuable as potassic manures, although they are slow acting; but it is a noticeable fact that wherever bushes are burnt, the ashes are wasted.

Seaweed. Seaweed is an organic manure which may be liberally used where the cost of collection is slight. It contains small proportions of nitrogen, phosphoric acid, potash, and lime. Its mechanical value is important on the heavier soils.

Salt (Chloride of Sodium). Salt is employed by many growers of the mangel and of the cabbage with advantage, experimental tests having shown that these crops are frequently larger where it is employed. Salt is believed to exert a mechanical as well as a fertilising action.

This manure is a deposit of sea-birds which feed chiefly upon fish. If of good quality, it is rich in both nitrogen and phosphoric acid. It also contains a small quantity of potash and a liberal percentage of lime. Of late years the quality of guano has diminished, the percentage of nitrogen being reduced. The more recent shipments are chiefly phosphatic in character, the phosphoric acid ranging from 5 to 35 per cent. A fish manure, really produced from fish offal, and described as *Fish Guano*, is found upon the market. This fertiliser is more or less rich in potash as well as nitrogen and phosphoric acid, but is generally inferior to good Peruvian, and before purchase should be compared both as regards price and composition.

Potassic Manures. *Potash* is a fertiliser seldom needed for heavy soils, but frequently employed on peats and lighter soils, especially in the growth of potatoes, clover, and allied plants. The chief supply is found in the mineral deposits near Strassfurt in Germany. The most commonly used of these salts is *kainite*, which contains 13 to 17 per cent. of potash. Muriate of potash and nitrate of potash are occasionally

in lime, and especially where plants like the clovers and the turnip, which need sulphur, are grown. It is quite unnecessary to employ gypsum where bone manures are used.

Gas-lime. This by-product of gasworks is, in its fresh condition, poisonous to plants, owing to the presence of sulphide of lime. Before use, it should be exposed to the air, when, absorbing oxygen, the sulphide is converted into the valuable sulphate. Land needing lime may often be dressed with gas-lime at a lower cost than with fresh or quicklime. It is believed that soil infected by parasitic plants and bacteria dangerous to stock is purified by gas-lime.

Night-soil. Night Soil is a manure of the first rank, containing in its fresh condition larger proportions of nitrogen and phosphoric acid than the manure produced by any class of farm stock. The liquid, however, is not so rich in nitrogen as that of the horse, the cow, or the sheep. Where employed, this fertiliser should be mixed with dry soil, ashes, peat moss, or any absorbent which will assist its conveyance and distribution.

COMPOSITION OF ARTIFICIAL FERTILISERS.—THE FIGURES GIVEN ARE PER CENT.

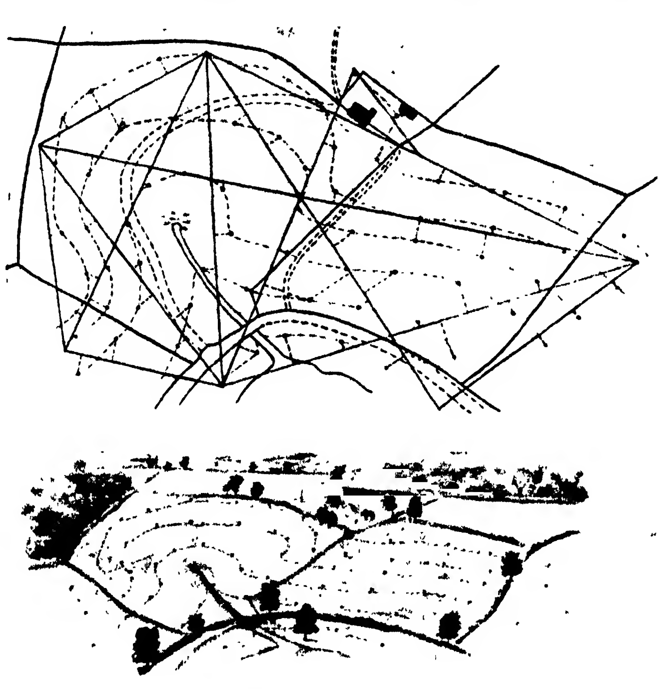
METHODS OF LEVELLING

Contouring. Explanation of the use of the Barometer and Hypsometer. The Aneroid. Triangulation. Measurement of Base Lines

By Professor HENRY ROBINSON

Contouring. Another form of levelling is that known as *Contouring*. A contour survey is one which has for its purpose the establishment of points on the ground of the same level. These points are afterwards picked up by offsets from survey lines, or by lines purposely run for that purpose. A survey of this description is shown in 35.

The method of carrying out a survey of this description is to place pegs, or small flags, in the places which exactly coincide with the required level. The staff is moved about until it reads a figure, which, when reduced, gives the correct level of the ground required. As an example, the value of a bench mark is 104·00, the level is set up and reads on the staff, held on the bench mark, 2·00. This shows the collimation line of the level to be equal to 106·00. If, therefore, it is necessary to obtain the 100·00 contour, the staff would have to be shifted about until it gave readings of 6·00, when those points would be the 100 contour points. Pegs or flags would then be ininserted and numbered, and afterwards picked up by survey lines, as shown in the illustration [35].



35. CONTOURING

Another purpose for which levelling is important is that of setting out gradients, whether for roads, railways, sewers, or other purposes. A gradient is stated in terms of the relation between the vertical fall or rise and the horizontal distance. For instance, when a road is said to have a gradient of 1 in 100 it implies that the vertical rise or fall is 1 unit in 100 units of horizontal measurement.

Degrees of Accuracy. The degree of accuracy that can be attained in levelling depends greatly on the instruments employed, and the care and time which can be devoted to the work. The accuracy which was necessary for the extended Government surveys of Great Britain and India is obviously unnecessary for surveys of comparatively small areas. A good practical standard for ordinary work would be to limit the error to $\frac{1}{10} \times \sqrt{\text{distance in miles}}$; this would give the following permissible errors:

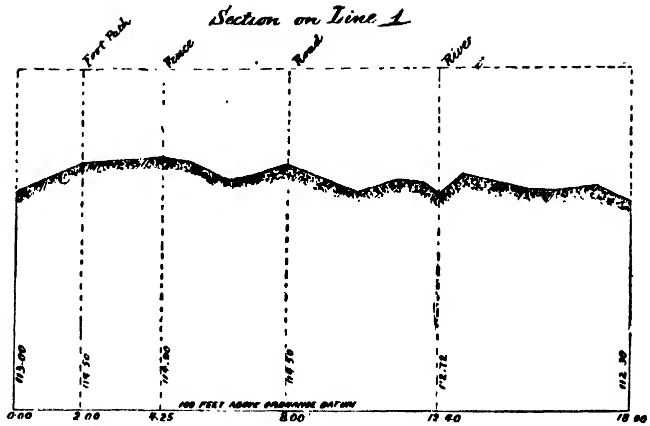
In 1 mile, 0·10 of a foot; 4 miles, 0·20; 9 miles, 0·30; 16 miles, 0·40; 25 miles, 0·50; 36 miles, 0·60; 49 miles, 0·70; 64 miles, 0·80; 81 miles, 0·90; 100 miles, 1·00.

It is necessary for the surveyor to know the value that can be assigned to the tilt of the telescope, corresponding to the displacement of the bubble when not exactly central in its run. With the ordinary levels used in this country $\frac{1}{10}$ inch run of the bubble corresponds to an angle of tilt of the telescope of about five seconds. A good practical rule to remember is that one second of arc is the angle subtended by about $\frac{3}{10}$ inch at a mile, or 0·0156 foot at 10 chains. So that if the bubble be $\frac{1}{10}$ inch out of the centre of its run, there will be an error equal to the above in a 10 chain read.

Plotting Sections. In plotting sections [36] it is usual to employ a scale for the vertical different from that for the horizontal, in order to exaggerate the appearance of the surface of the ground. A horizontal line is first ruled on the paper, and the various distances

at which levels have been taken are marked off on this line. It is generally necessary that this line be assumed to be some fixed number of feet above Ordnance datum, in order that the vertical heights may not be too great.

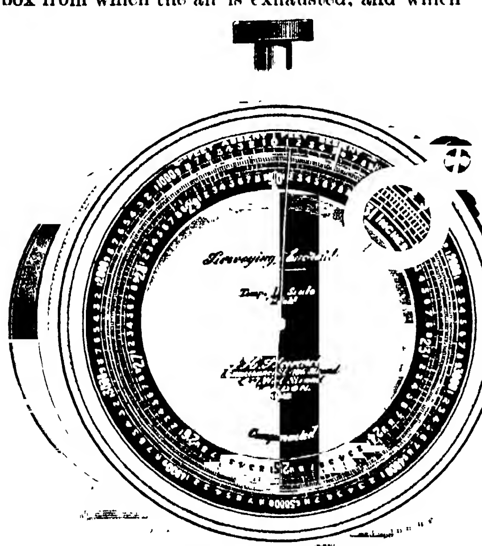
Whatever may be the distance above datum adopted it is written on this line, and must be added to whatever distance is scaled (if the reduced level is not given at the point required). The distances having been plotted, vertical lines are drawn, and the levels of each point scaled up the lines, marked, and the points joined, giving the result of the section taken in the field.



36. LEVEL SECTION

Barometer and Hypsometer. Before leaving the subject of levelling, it is necessary to refer briefly to the Barometer and Hypsometer for ascertaining the altitudes of places. In neither instrument is the accuracy attainable equal to that of staff reading, but both serve for approximate levelling in mountainous districts, and for flying levels in exploring a country. The difference of pressure of the atmosphere at various altitudes affords a direct indication of differences of level. The mercurial barometer (accompanied by a thermometer) is the most reliable instrument for permanent use in meteorological work, but the small range of its fluctuations, and the difficulty of reading the exact level of the mercury, render it less desirable as a levelling instrument than the Aneroid.

The Aneroid. The Aneroid [37] is a *pressure gauge*, consisting of a corrugated metal box from which the air is exhausted, and which is therefore sensitive to external pressure. The expansion of the box actuates suitable levers, springs, and wheel gear, communicating with an indicating pointer which moves round a circle graduated to feet. The scale is also made to correspond to inches of mercury, corresponding to equal arcs on the scale of feet. The instrument is compensated for variations in its own temperature.



37. THE ANEROID

An approximate rule for calculating heights up to several hundred feet is as follows:

Let H = reading in inches on the barometer at lower station.

Let h = reading in inches on the barometer at upper station.

Then $\frac{H - h}{\cdot 0011}$ = height in feet.

A More Accurate Method. For more accurate results the following formula, as given by Professor Rankine, is applicable to the mercurial barometer, with accompanying observations of temperature by two thermometers, one to give the temperature of the air, and the other attached to the barometer to give the temperature of the mercury.

	At Lower Station.	At Higher Station.
Height of mercurial column in the barometer	H	h
Temperature of the mercury in degrees Fahrenheit as shown by the attached thermometer	T	t
Temperature of the air in degrees Fahrenheit as shown by the detached thermometer	T′	t'

Then the height of the higher station in feet above the lower station is:

$$60360\ [\log H - \log h - \cdot 000044\ (T - t)] \times \left(1 + \frac{T' + t' - 64}{986}\right).$$

The last term of the formula is the correction for absolute temperature and becomes unity when T′ and t' are both 32° F.

For rapid calculation without logarithms, the general equation may be written:

Height in feet

$$= 52428 \frac{H - h'}{H + h'}\left(1 + \frac{T' + t' - 64}{986}\right)$$

where h' is the corrected barometric reading at the higher station and equals:

$$h\left(1 + \frac{T - t}{10{,}000}\right)$$

Since the force of gravity varies according to the latitude and altitude, a further correction is needed to represent this.

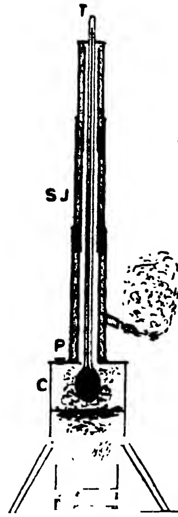
Let a = the mean latitude of the two stations.

Let h_m = their mean height above the sea.

The difference of level given by the previous formulæ must be multiplied by:

$$1 + {\cdot}00284 \cos 2a + \frac{h_m}{10{,}450{,}000}$$

In taking observations with the barometer it is well to have one instrument at the starting station, and observations taken with it at stated intervals all day, for comparison with the instrument used for taking the altitudes.



38. HYPSOMETER
T. Thermometer
SJ. Steam Jacket
P. Water Supply Plug
C. Copper Boiler

The Hypsometer. [38] The relation between the "Boiling Point of Water" and the pressure on its free surface affords a means of calculating elevations. The boiling point of water at sea-level when the barometer stands at 29·922 inches is 212° Fahrenheit. As the altitude increases the boiling point is lowered. A special instrument is made for the purpose of noting the boiling point with great accuracy.

The Hypsometer consists of a bulbed thermometer with a long stem, and graduated scale, reading only within the limited range of 180° to 214° Fahrenheit, so as to enable the scale to be read to tenths of a degree. The bulb is enclosed in a small boiler, and the stem is surrounded by two cases through which the steam circulates.

The following formula gives a close approximation for the heights of stations as found with the Hypsometer:

$$H = 519\,(212 - T) + (212 - T)^2$$

Where

H = height in feet of any station (A) above another where the boiling point of water is 212° F.

T = boiling point of water at the station (A) in degrees Fahrenheit.

Example. Let A and B be two stations whose difference of level is to be determined.

At A the boiling point is observed as		201° F.
,, B ,, ,, ,, ,,	,,	210° F.
,, A ,, air temperature ,,	,,	65° F.
,, B ,, ,, ,, ,,	,,	59° F.

Height of A above 212° boiling point station by formula .. .. = 5830 feet

Height of B above 212° boiling point station by formula .. .. = 1042 feet

Difference = 4788 ,,

This difference must be multiplied by

$$\left(1 + \frac{T' + t' - 64}{986}\right)$$

to find the correction for the actual temperatures, and also by the formula given previously for altitude.

Triangulation. Having explained the various methods that are employed in surveying where the lines are measured, it is now necessary to deal with the subject from the point in which direct measurement is done away with, except for the purpose of getting accurately a base line from which to begin operations. This is known as *triangulation*.

Triangulation is the surveying of a tract of land by dividing it up into a system of triangles, built up from a measured base, the triangles forming in themselves a series of polygons. It is known from mathematics that:

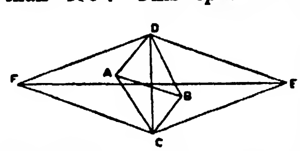
1. The three angles of any triangle are equal to 180°.
2. The sum of the central angles of a polygon are equal to 360°.
3. The sum of the internal angles in any polygon, plus four right angles, equals twice as many right angles as the figure has sides.

In this course, as before mentioned, the spherical shape of the earth is neglected, except for the purpose of reducing the measured base to mean sea-level. It is not intended to describe the methods of triangulation which were adopted for the great trigonometrical surveys of England or India, as for that purpose a considerable knowledge of mathematics and astronomy was necessary, and as it would carry this course beyond the limits prescribed for it.

It is necessary, however, for every civil engineer and surveyor to have some knowledge of triangulation, and the purposes for which it is employed. The triangulation of this country was divided into three systems:

1. The primary, or great instrumental work
2. The secondary triangulation.
3. The minor, or parish work.

Spherical Excess. In the primary triangulation of any country where the lengths of the sides are considerable, the spheroidal shape of the earth's surface will affect them. The angles read between the lines will be spherical angles, and their sum in any triangle is greater than 180°. This *spherical excess* has to be corrected in order to reduce the spherical angles to plane angles and to solve the triangles as plane triangles. For the purposes of this

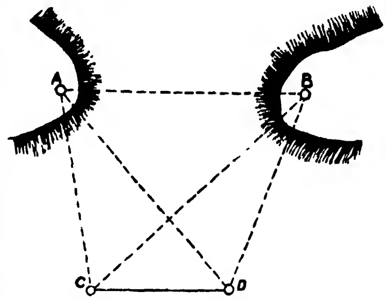


39. BASE LINE BY CALCULATION

course (other than the brief note above), the earth's surface will be assumed to be flat, and this will not lead to any appreciable errors in ordinary triangulation work.

As before stated, the survey is built on a base line measured with the greatest accuracy, as the whole of the after-work depends on it.

The Heliostat. When the stations are very far apart, use is sometimes made of the sun by an instrument called the *Heliostat*. This is simply a mounted mirror, with a small part of the silvered backing scraped away, making a blind spot. The rays of the sun are reflected to the required station, and readings taken to the blind spot in the centre of the mirror, by which means the position of the station where the Heliostat is mounted can be fixed,



40. SIMPLE TRIANGULATION

Steel tapes are often used for this purpose, but the method must depend on the accuracy that is required. The bases of the Indian triangulation were measured with Colonel Colby's compensating bar of 10 ft. in length, from which it will be seen that the process is a tedious one. The selection of the position for this base line requires care, and must be on fairly flat ground. At the same time, it should be in such a position that the surrounding points to form the survey are easily obtainable. It is much better to choose a shorter base, and have it accurately measured, than a longer line where the same accuracy is not attainable. In the event of the impossibility of obtaining a measured base of sufficient length a longer one must be obtained by calculation.

In the illustration [**39**], A B is the measured base. From the points A and B angles are taken to C and D. After C and D are fixed, angles are taken from them to E and F, and by this means a base line, EF, is obtained, which can be considerably longer than AB.

It is a good practice to lay down a skeleton plan of the various points that are selected for stations in order that the best arrangement of triangles may be decided on. The equilateral triangle is the best, and the aim of the surveyor should be to arrange his triangulation so as to obtain no "ill-conditioned" triangles.

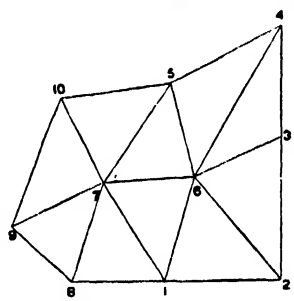
If a rapid preliminary survey be first made with a compass, sextant, or plane table, a preliminary arrangement of lines may be laid down, and plotted approximately, by which an idea can be formed as to the best arrangement of lines.

Trigonometrical Formula. The calculation of the lines is based on the well-known trigonometrical formula

$$\frac{a}{\sin A} = \frac{b}{\sin B} = \frac{c}{\sin C}$$

where a, b and c are the lengths of the sides, and A, B and C their respective angles. Having, therefore, the length of any one side, and the angles being observed, the lengths of the other sides may be calculated by the formula.

One of the simplest cases is that shown in **40**. The base line CD is chained, preferably an even number of chains. The theodolite is set up at C and D, and the angles ACB, BCD, ADC, and ADB are taken, and the lengths of the sides AC, BC, AD and BD calculated by the formula. The angles at A and B are then observed, and the distance AB calculated; the points A and B can then be used for further triangulation. A general example of a preliminary survey is shown by **41**.

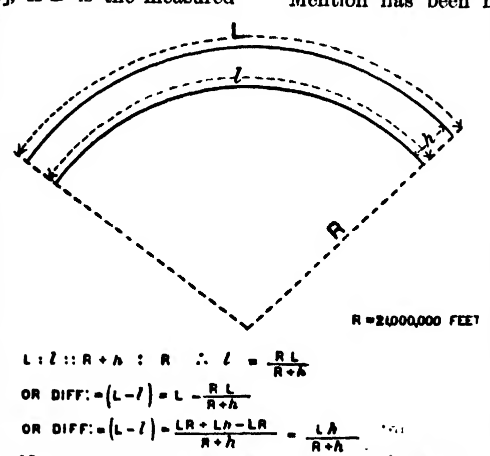


41. PRELIMINARY SURVEY

One of the lines is measured (as, for instance, 1—8), and upon it the triangulation is built. The angles at 1 and 8 are observed, and 7 is fixed. This point is the centre of a polygon 8, 9, 10, 5, 6, 1, 8, and, as explained before, the angles taken at 7 must equal 360°.

Mention has been made of the necessity of reducing the base line to mean sea-level. The illustration [**42**] gives the calculations necessary for this, assuming the earth's mean radius to be 21,000,000 ft., which is a close approximation.

In the formula, L equals the length of the base as measured at an altitude h, and l equals the length of the base reduced to mean sea-level. It is necessary to be able to fix the position of the true north in order to correct for the variation of the needle.



42. REDUCTION OF BASE TO MEAN SEA-LEVEL

LINEAR & AERIAL PERSPECTIVE

The Vanishing Point. Mathematical Devices. The Centrolinead. Shading. Aerial Perspective

By P. G. KONODY and HALDANE MACFALL

Perspective. The student should keep a rough rule of thumb over his perspective. The full laws of perspective are elaborate, but are fortunately not required for an artist's every day use; but the main laws he must use constantly, for his point of sight determines the place of things in his picture. As he draws an object, the point opposite his eye is very valuable, for from it radiates the height and breadth of all his forms. All his drawing will depend for its accuracy of position in the picture on its relation to the horizontal line drawn through this point.

The student must acquire a sound knowledge of elementary geometry [see MATHEMATICS and DRAWING] before proceeding. Take a diamond fixed at the end of a metal stick and stand with your head within arm's reach of a window. Close one eye and mark on the glass pane in outline what the other eye sees through the window, and you have an absolutely correct perspective of what is outside scratched on the flat glass.

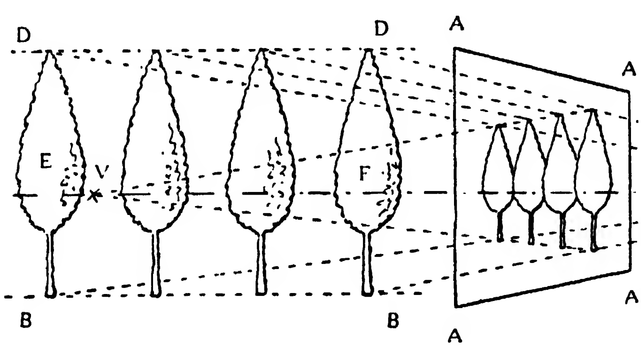
Figure 1 shows a row of trees so treated, except that the relative sizes of the features are altered for the purpose of clearer demonstration. Let $AAAA$ stand for the glass pane. It will be noticed that the ground line of the trees BB (which in reality is horizontal or level) shows on the glass a line going upwards; and, on the contrary, the top line of the trees, DD, which is equally level, shows on the glass a line going downwards. These two lines, when continued, meet always at some point, V, on a line level with the eye which has drawn the picture, and in consequence a row of trees or other similar equal-sized objects along a straight surface always look smaller as they go backward in a picture until, if continued far enough, they appear to vanish into nothing.

The optical reason for this is self-evident when we reflect that all things we see have to come into one point at the back of the eye; consequently all things above the level line HH are seen more from *beneath* them, as they advance towards the eye, and all things below the line HH more *above* as they advance towards the eye. Hence the tree at F becomes drawn on the glass pane much taller than the equal-sized tree further back at E.

This comprises the entire principle involved in perspective drawing. Once this is grasped, the rest becomes a matter of practice in drawing from visible objects; but when the object has to be designed or evolved direct from the brain, such as in architecture, the following mathematical method is pursued to get at the same result.

Mathematical Devices. First, plans and elevations are drawn isometrically to a given scale, such as one-eighth of an inch for every foot, or larger according to the amount of detail the subject contains. Figures 2 and 3 show a primitive tower so treated. Choose on the plan the spectator point S, corresponding to the position of the eye in Fig. 1. Draw from S lines SA and SB to the extreme points on each side of the object to be represented in perspective. This is called the visual angle or range of view. Bisect it—SF. Then any line perpendicular to SF, such as PP, stands for the pane of glass in the window and is called the picture plane. The nearer you make the line to S, the smaller will be the size of the ultimate picture.

From S draw SV^1 and SV^2 parallel to AG and BG respectively. These, at their intersection with the picture plane PP, give vanishing points corresponding with the point V in Fig. 1. Each vanishing point is usable in perspective for the surface or plane from which it has been thus derived, or any surface parallel to that surface.

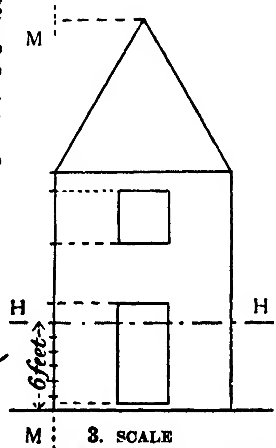


1. A PERSPECTIVE OF A ROW OF TREES SEEN AND DRAWN ON A GLASS PANE

Thus the pavement kerb in front of AG will vanish to the same point as AG.

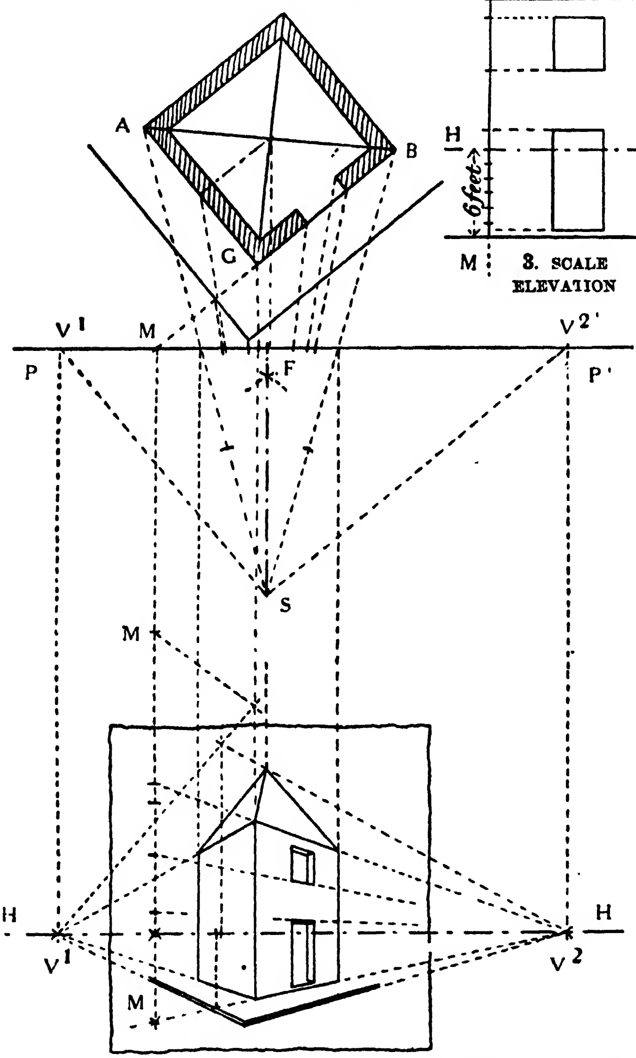
Then project BG, on plan, to M, which gives the point at which to erect the vertical " measuring line " for all heights on the scale elevation of BG shown in 3. Then draw on the perspective sheet HH, called the horizon line and corresponding with HH in 1 and 3. Tick off on it all the intersection points seen along PP on plan. Then decide how high the spectator's eye shall be when drawing the picture, say, six feet from the ground. Scale six feet on measuring line MM, from level of horizon line HH downwards, and this gives the ground line of tower. Then tick off along MM the scale heights of features on tower, got from 3. The rest of the processes becomes self-evident.

It will be noted that the nearer the spectator point S is to the plan of the building or object, the larger becomes the visual angle ASB, and the more acute is the resultant perspective. Consequently there is a limit to the size of this angle. The general rule is to keep it more or less between 30 and 45 degrees, according to the effect sought for, unless under exceptional circumstances, it being found that sometimes presentments which are too stilted to be in reality practically visible to any eye, may occasionally be required on a drawing.



3. SCALE ELEVATION

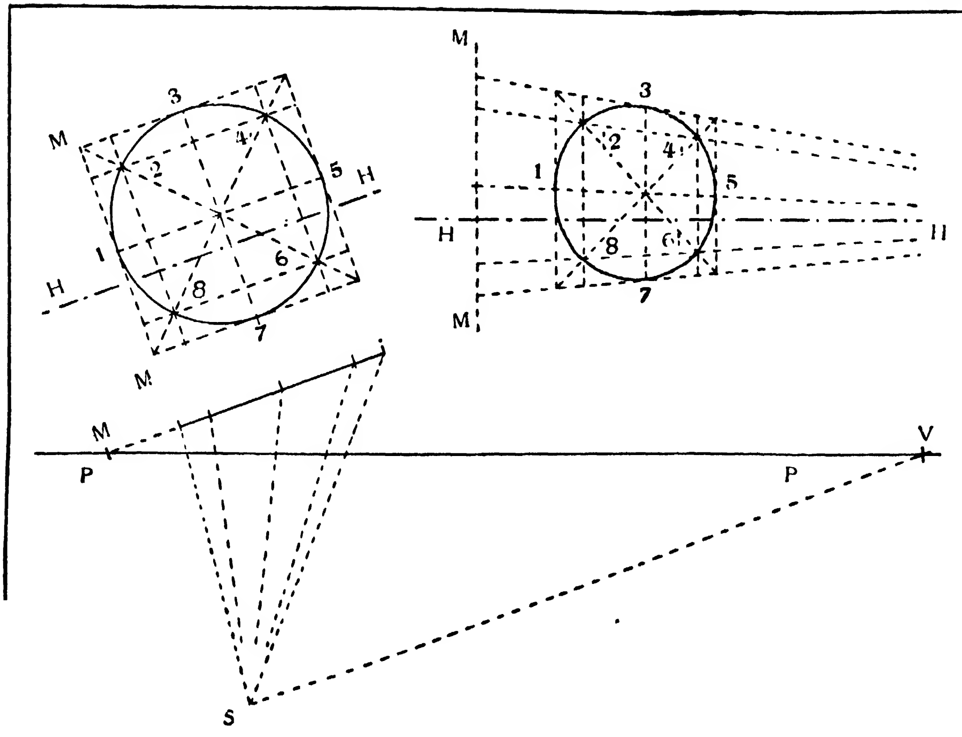
The same applies to the rule of making the picture plane PP perpendicular to the bisector [SF] of the visual angle. It is sometimes stilted as in 6. The question whether such abnormal devices are permissible must be left to trained judgment, having regard to the ultimate effect sought for in each picture.



HOW A PERSPECTIVE IS OBTAINED BY MATHEMATICAL DEVICES FROM PLAN AND ELEVATION

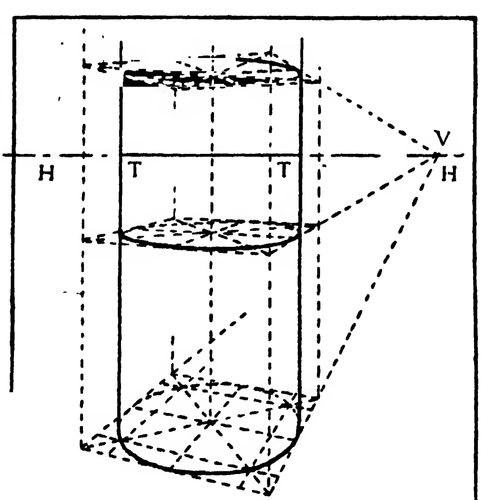
Circles and Other Curves. Up to now we have had to deal with straight lines. Circles and other curves are treated by selecting a number of points upon them and then putting these points into perspective by the same process as before; after which a line is drawn bent to pass through those points. Figure 4 shows a circle so treated, the numbers 1 to 8 being the points referred to. This is a vertical or upright circle. A horizontal or plan circle [5] is obtained in a similar way. In 5 is also shown the same circle as seen when it is placed higher up towards the eye level, or line of horizon, HH. It will be noted that the resultant oval has the same width as the lower one, but is not so deep; and this depth grows more and more narrow till, when the circle is on the actual level of the eye, TT, *it is seen as a straight line only*. The same phenomenon occurs *inversed* when this same circle is seen at any height *above* the eye or line of horizon.

When the drawings are large, one or more vanishing points are sometimes too far away to be accessible on the draughtsman's table on either side of him. In that event several methods have been devised for overcoming the difficulty. The two following are the most



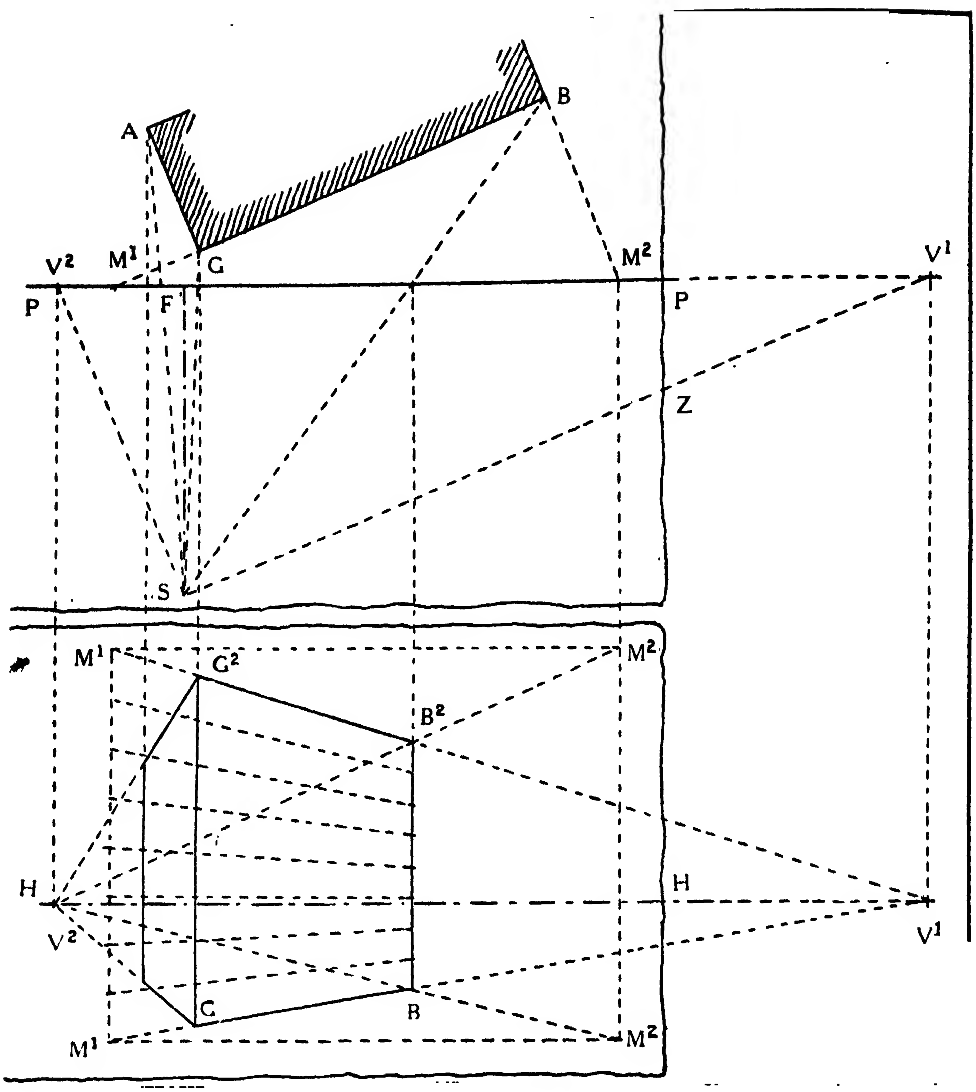
4. A CIRCLE DRAWN IN PERSPECTIVE

serviceable: Figure 6 serves when a surface, GB on plan (and all surfaces parallel to it), has an inaccessible vanishing point, V^1, but when the vanishing point of its corresponding right angle on plan, GA, is accessible V^2. As the lettering to the lines and points in 6 corresponds with those in 2, the reader will be familiar with their working till the line SV^1 is stopped short at Z by want of room to continue it. Instead of drawing SV^1 draw BM^2, which is parallel to AG, and gives a second measuring line M^2M^2. Tick off the work on the perspective sheet and draw ground line M^1M^2 and mark a convenient equal distance M^1M^1 and M^2M^2. Then draw V^2BM^2 and $V^2B^2M^2$, thus obtaining the lines M^1B and M^1B^2, which, if continued, would meet at the inaccessible vanishing point V^1. Then divide M^1M^1 and BB^2 into a convenient number of equal parts; unite them respectively, and you have a scale of vanishing lines, any intermedial lines you may require being put in by eye. At first you may require a very close vanishing scale by making the equal divisions very small, but, with training, your eye will find itself able to manage with much wider spacing.



5. A HORIZONTAL CIRCLE DRAWN IN PERSPECTIVE BELOW AND ABOVE THE LINE OF HORIZON

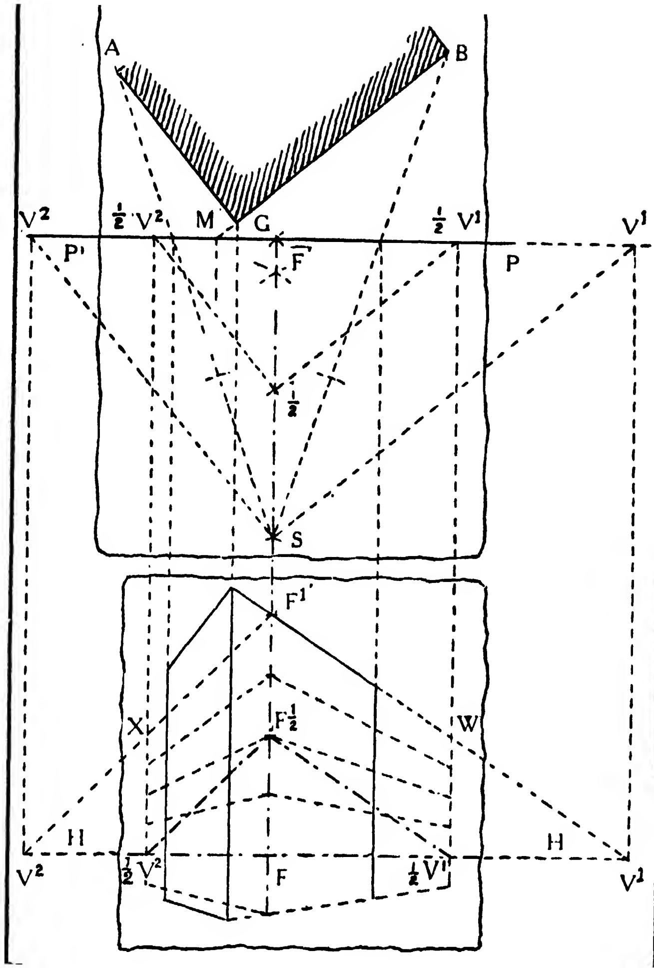
Figure 7 serves when you are hampered for room on both sides. In that event you divide SF (the perpendicular line from S to the picture plane PP) into an equal number of parts according to the room at sides you have at your disposal—say, into halves. Then connect ½ with ½ V^1 and ½ V^2 respectively parallel to GB and GA, the surfaces whose inaccessible vanishing points you are dealing with. Then it is obvious that the



6. HOW TO FIND AN INACCESSIBLE VANISHING POINT

points $\frac{1}{2} V^1$ and $\frac{1}{2} V^2$ will be respectively half way to the inaccessible points in question. Mark on the perspective sheet, along line FF^1, a convenient distance FF^1; halve it and draw $F \frac{1}{2} \frac{1}{2} V^1$ and $F \frac{1}{2} \frac{1}{2} V^2$; then from F^1 draw lines parallel to them, F^1W and F^1X; and it is obvious that these lines, if prolonged, would respectively pass through the inaccessible vanishing points V^1 and V^2. From that proceed to draw vanishing scales in the same way as the scale in 6.

The Centrolinead. There is an instrument called a Centrolinead [8] much used for drawing lines to inaccessible vanishing points after the two first lines to any inaccessible point have been obtained by the methods described. It consists of three straight edges hinged at A and fitted with screw stops whereby the three arms can be fixed at any angle to each other. Three lines so determined have a property in geometry, that when two of them (AC and AD) are placed against any two fixed points or pins (EF) and made to slide up or down against them, the third line (AB), at any place on its radial journey, will take a direction which, if continued, would meet at one centre V. The instrument is adjusted on the perspective sheet (between any two vanishing lines obtained as described in 6 and 7) by observing that the further point V is away, the larger should angle CAD be made, and the wider the pins EF be fixed. Also note that the angles CAB and DAB need not be equal. Many beginners lose patience with the centrolinead because of the time its adjustment entails,



7. HOW TO FIND TWO INACCESSIBLE VANISHING POINTS

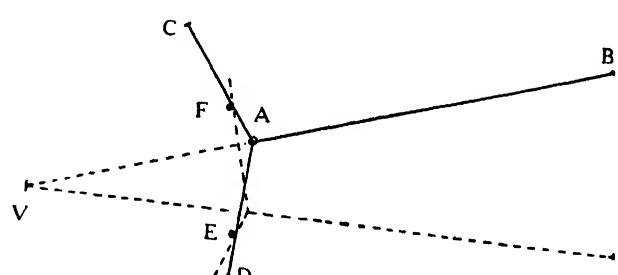
but this disappears directly a little practice has enabled the student to grasp the geometrical principle involved.

Having mastered the rudiments of perspective as applied to simple buildings or objects, the student will find, on proceeding to more complex structures, that to draw in every detail by the same mathematical process becomes complicated, and the many operations first required involve him more and more into a fog of tantalising lines in all directions. To minimise these he makes for means which do not require so much preliminary reference to the isometrical plan and elevations.

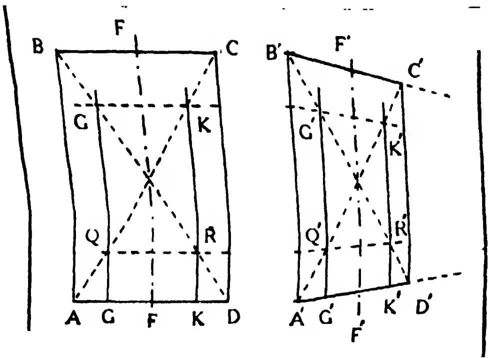
One of the main principles from which these shorter methods are evolved is the root property of a diagonal line. In **9**, $ABCD$ is the isometrical or flat elevation of a rectangular surface, and $A^1B^1C^1D^1$ is that surface put into perspective. By drawing diagonal lines the centre line FF is obtained, and the centre line F^1F^1 can be got direct by the same principle. Also, in the case of any line, such as $G\,G$, on one side of the centre, you can draw a corresponding line, KK, on the other side of the centre at equal distance from it by drawing G^1K^1 or Q^1R^1 direct on the perspective.

This principle, carried further, enables you to divide, direct in perspective, a surface into any number of equal parts. Suppose you have to draw a row of any objects such as men or trees standing equi-spaced along a straight line, say a row of 6 columns [**10**]. First get, by the plan, the centre line of the column at each end of the row, AB and CD. Divide AB into five equal parts, draw vanishing lines through each of these divisions, and draw the diagonal line AD intersecting the vanishing lines. Then mark the points where division lines give respectively the centre lines of the intermediary columns in perspective.

To find the width of the columns, note the ratio, or how many times the width of one column goes into its height. Say it is eight times. Tick off one-eighth space at EF and the same vertically at E^1F^1, draw vanishing lines through E^1 and F^1, and you get the diminishing widths of the remaining columns.



8. CENTROLINEAD



9. THE USE OF DIAGONALS

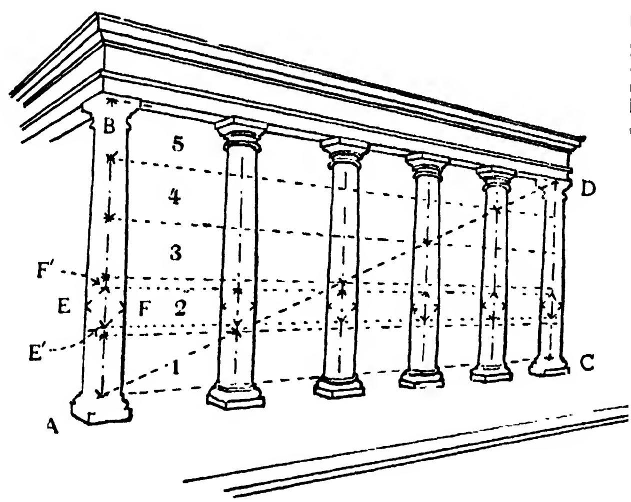
Further labour-saving processes such as these the draughtsman soon finds himself discovering, and, assisted by an ever increasing accuracy of eye, he is enabled eventually to "think in perspective." Then it is surprising how very few plan-derived lines he requires for an efficient perspective representation even of very elaborate, difficult themes, such as an ornate palace or the interior of a theatre.

Shading. After a picture has been outlined in linear perspective, its shading has to be considered. When an object stands in the way of sun-rays, any of its sides which are more or less to the back of the sun, are said to be in shade, and the intercepted rays cause a shape (derived from the outer boundary of the object) to be cast, as a silhouette of that object, on to the ground or other surfaces which may be within the field of operation. This is called the shadow. To draw in perspective the outlines of shadows, note that sun-rays are all taken as parallel lines. Therefore treat the projected shadow of any object as an isometrical projection of that object from one plane to another (see article on GEOMETRY). After this put into perspective the outlined *plan* of the shadow thus obtained—an operation done by the same perspective rules as those already explained.

Then comes the question of tones for shades, shadows, and local colours. A surface in shade has a lighter tone than the shadow it casts. The brighter the light the darker the shadow, and the more marked the difference in depth of tone between shade and shadow. Tones other than those showing shades and shadows stand for the local colours of the objects seen, and vary in depth accordingly.

Aerial Perspective. Finally, the whole of the tones are affected by what is called aerial perspective. Here the principle involved has to do with the relative density of the atmosphere through which objects are seen, by reason of that density affecting the vision through which it may be said to have to pierce. Hence, for instance, distant mountains appear misty grey or blue, though their actual colour, when seen near, may be otherwise, such as bright or dark green. Observation and practice alone can efficiently reveal the facts of aerial perspective, after the mind has been warned to look out for them.

Thus perspective and the proportions of the human figure should be mastered from the very outset. There is no better teacher of drawing than the human figure. All the time that the student is mastering the human form and drawing its anatomy stripped of the beautifying skin (not learning it by rote, like words, be it remembered), he is increasing his powers with the pencil. And in just the same way it is well to practise circular flat forms, cones, squares, and so on, above and below the eye, to get the perspective effects correctly.



10. A SHORT METHOD OF DRAWING A ROW OF COLUMNS IN PERSPECTIVE

By Gerald K. Hibbert, M.A.

Section I. GRAMMAR.

Pronouns and Adjectives: Peculiar Declensions. Some numeral adjectives, and all the pronoun-adjectives except *meus, tuus, suus, noster*, and *vester*, have the ending *-ius* for all genders of the genitive singular, and *-i* for all genders of the dative singular. The words belonging to this class are *unus* (one), *ullus* (any at all), *nullus* (none), *solus* (alone), *totus* (whole), *alter* (the other), *uter* (which of two), and its compounds *uterque*, etc., *neuter* (neither), *alius* (other, another), *ille, iste, ipse, hic, is, idem, qui*, and all its compounds. The last seven have already been declined. The first five are declined like *bonus* (except, of course, genitive and dative singular), *alter*, like *tener*, and *uter* and *neuter*, like *niger* (except genitive and dative singular). *Alius* has its neuter, nominative and accusative singular ending in *-d*.

The following rhyme may be helpful:

"Unus, solus, totus, ullus,
Uter, alter, neuter, nullus."

Examples:

Singular.

	Masc.	*Fem.*	*Neut.*
N.	alĭus	alĭa	alĭud
Acc.	alium	aliam	aliud
Gen.		alĭus	
Dat.		alii	
Abl.	alio	alia	alio

Plural.

	Masc.	*Fem.*	*Neut.*
Nom.	alii	aliæ	alia
Acc.	alios	alias	alia
Gen.	aliorum	aliarum	aliorum
D. & Abl.		aliis	

Singular.

	Masc.	*Fem.*	*Neut.*
Nom.	unus	una	unum
Acc.	unum	unam	unum
Gen.		unius	
Dat.		uni	
Abl.	uno	una	uno

Plural.

	Masc.	*Fem.*	*Neut.*
Nom.	uni	unæ	una
Acc.	unos	unas	una
Gen.	unorum	unarum	unorum
D. & Abl.		unis	

Note. *Unus* in the plural is used only with nouns whose plural denotes a singular, as *una castra* = one camp (*castrum* = a *fort*; *castra*, plural = a camp).

Before leaving the pronoun-adjectives, the following correlatives may be noticed:

Interrogative. Qualis (of what kind); quantus (how great); quot (how many).

Demonstrative. Talis (such); tantus (so great); tot (so many).

Relative. Qualis (as); quantus (as); quot (as).

Indefinite. Aliquantus (of some size); aliquot (some few).

Universal. Qualiscumque (of what kind soever); quantuscumque (how great soever); quotcumque (how many soever).

The Numerals. There are four main kinds:

1. Cardinal (one, two, three), answering the question *quot* = how many (adjectives).
2. Ordinal (first, second, third), answering the question *quotus* = which, in numerical order (all declinable adjectives).
3. Distributive (one each, two each), answering the question *quoteni* = how many each (all declinable plural adjectives).
4. Adverbial (once, twice), answering the question *quotiens* = how many times (adverbs, and therefore indeclinable).

	Cardinal.	*Ordinal.*	*Distributive.*	*Adverbial.*
1.	unus, a, um	primus, a, um prior, first of two	singuli, æ, a	semel
2.	duo, æ, o	secundus alter	bini	bis
3.	tres, tres, tria	tertius	terni *or* trini	ter
4.	quattuor	quartus	quaterni	quater
5.	quinque	quintus	quini	quinquiens
6.	sex	sextus	seni	sexiens
7.	septem	septimus	septeni	septiens
8.	octo	octavus	octoni	octiens
9.	novem	nonus	noveni	noviens
10.	decem	decimus	deni	deciens

	Cardinal.	*Ordinal.*	*Distributive.*	*Adverbial.*
11.	undecim	undecimus	undeni	undeciens
12.	duodecim	duodecimus	duodeni	duodeciens
13.	tredecim	tertius decimus	terni deni	terdeciens
14.	quattuordecim	quartus decimus	quaterni deni	quater deciens
15.	quindecim	quintus decimus	quini deni	quindeciens
16.	sedecim	sextus decimus	seni deni	sedeciens
17.	septendecim	septimus decimus	septeni deni	septiens deciens
18.	duodeviginti (two from 20)	duodevicesimus	duodeviceni	duodeviciens
19.	undeviginti	undevicesimus	undeviceni	undeviciens
20.	viginti	vicesimus	viceni	viciens
21.	unus et viginti *or* viginti unus	unus et vicesimus (*rarely* primus)	viceni singuli	semel et viciens
22.	duo et viginti *or* viginti duo	alter et vicesimus	viceni bini	bis et viciens
30.	triginta	tricesimus	triceni	triciens
40.	quadraginta	quadragesimus	quadrageni	quadragiens
50.	quinquaginta	quinquagesimus	quinquageni	quinquagiens
60.	sexaginta	sexagesimus	sexageni	sexagiens
70.	septuaginta	septuagesimus	septuageni	septuagiens
80.	octoginta	octogesimus	octogeni	octogiens
90.	nonaginta	nonagesimus	nonageni	nonagiens
100.	centum	centesimus	centeni	centiens
200.	ducenti, æ, a	ducentesimus	duceni	ducentiens
300.	trecenti	trecentesimus	treceni	trecentiens
400.	quadringenti	quadringentesimus	quadringeni	quadringentiens
500.	quingenti	quingentesimus	quingeni	quingentiens
600.	sescenti	sescentesimus	sesceni	sescentiens
700.	septingenti	septingentesimus	septingeni	septingentiens
800.	octingenti	octingentesimus	octingeni	octingentiens
900.	nongenti	nongentesimus	nongeni	nongentiens
934.	nongenti triginta quattuor			
1,000.	mille	millesimus	singula millia	milliens
2,000.	duo millia	bis millesimus	bina millia	bis milliens
500,000.	quingenta millia	quingentiens millesimus	quingena millia	quingentiens milliens
1,000,000.	deciens centum millia	deciens centiens millesimus	deciens centena millia	deciens centiens milliens

NOTE. The cardinal numbers from *quattuor* to *centum*, inclusive, are indeclinable; *unus* has been declined above; *duo* and *tres* are declined thus:

	Masc.	*Fem.*	*Neut.*
N	duo	duæ	duo
Acc.	duos (*or* duo)	duas	duo
Gen.	duorum	duarum	duorum
D. & Abl.	duobus	duabus	duobus

N.	tres		tria
Acc.	tres		tria
Gen.		trium	
D. & Abl.		tribus	

Ambo (both) is declined like *duo.*

Mille, used as an adjective, is indeclinable: but when used as a noun, it has a declinable plural *millia, millium, millibus* — *e.g., mille milites* = 1,000 soldiers; *tria millia militum* = 3,000 soldiers (literally, three thousands of soldiers).

Duo- and *un-* in composition (as in duodecentum = 98) do not change, whatever be the case or gender.

The Distributives are used:

1. To denote that the number belongs to each of several persons or things—*e.g., quinos comites adduximus* = we brought five companions each.

2. In expressions of multiplication—*e.g., bis bina* = twice two; *deciens centena millia* = a million (100,000 taken each of ten times).

3. With nouns which have no singular, or differ in meaning in singular and plural—*e.g., bina castra* = two camps. In this sense, *uni,* not *singuli,* is used (see above, *una castra*); also *trini,* not *terni*—*e.g., trinæ aedes* = three houses (*aedes* in singular = room or temple; in plural, = a set of rooms—*i.e.,* a house).

The ordinals, not the cardinals, are used in giving the date—*e.g.,* in the year 1905 = *anno millesimo nongentesimo quinto.*

Multiplicative adjectives are formed with the suffix *plex* = fold—*e.g., simplex, duplex, triplex, decemplex, centuplex.*

Every other is expressed by *alterni*—*e.g., alternis diebus* = every other day (ablative of time at which: literally, on every second day).

SCHEME OF THE FOUR CONJUGATIONS—PASSIVE VOICE

Indicative Mood.

		Singular. 1.	2.	3.	*Plural.* 1.	2.	3.
Present.							
Am-	or (I am loved)		aris	atur	amur	amini	antur

Gerundive.

amand-	us, a, um
monend-	us, a, um
regend-	us, a, um
audiend-	us, a, um

[Refer back to Table giving derivation of the verb forms, on page 244, and trace out all the passive forms.]

NOTES. 1. There is an alternative form in 2nd singular, present, indicative, passive (*ris* or *re*)—*e.g.*, *amaris* or *amare*. But the latter is seldom used, on account of the confusion with infinitive active and imperative passive (both *amare*).

2. Note how much the perfect participle passive is used. It forms all the perfect tenses, indicative and subjunctive, with parts of *sum*. It is declined like *bonus*—*e.g.*, *puellæ amatæ sunt* = the girls have been loved.

3. The gerundive is a verbal adjective; its use will be explained later.

4. There are three participles wanting in Latin:

(*a*) Act. Perf. Ptc., "having loved." We must use *quum amavisset* = when he had loved, or some similar construction.

(*b*) Pass. Pres. Ptc., "being loved." Say *qui amatur* or *dum* (while) *amatur*.

(*c*) Pass. Fut. Ptc., "about to be loved." Say *qui amabitur* or something similar.

But note carefully that *amatus* does *not* mean "having loved." It means "having been loved." The importance of this will appear later.

SECTION II. SYNTAX.

The Ablative Absolute. A participle and a substantive (or pronoun) joined together and standing by themselves, independent of the rest of the sentence, are usually both put in the ablative case—*e.g.*, The city having been captured, Cæsar withdrew = *urbe capta, Cæsar se recepit.* These things being finished, the king entered the temple = *his confectis, rex in templum intravit.*

In either of these two sentences, the two words in the ablative could be omitted without impairing the grammatical completeness of the sentence: without them we should still have complete sentences, "Cæsar withdrew," "The king entered the temple." Therefore, the words in the ablative are *absolute*—*i.e.*, independent. But in a sentence like this, "The city, having been captured, was burnt," we could not remove the words "the city having been captured" without ruining the sentence. Therefore, this is not "absolute," and "city" is nominative to "was burnt" (*urbs capta* [nominative] *incensa est*).

So the *ablative absolute* cannot be used if the person denoted by its substantive is either the subject of the principal verb of the clause (as in the sentence just given) or the object (as, "Cæsar having taken the city, burnt it" = *Cæsar captam urbem incendit*—*i.e.*, Cæsar burnt the taken city).

Other examples of the ablative absolute:

Regnante Victoria = in the reign of Victoria (literally "Victoria reigning").

Nullo respondente = no one replying.

His auditis = having heard, or, hearing this (literally "these things having been heard").

Often with adjective instead of participle:

Me invito = against my will (I being unwilling).

Te duce = under your leadership (you being leader).

Me auctore = at my suggestion (I being adviser).

Salvis legibus = without breaking the laws (the laws being sound).

Te non adjuvante = without your assistance (you not assisting).

But do not say *rege pervento*, the king having arrived. There is no passive to an intransitive verb.

SENTENCES TO BE TURNED INTO LATIN.

(Do not consult the key until you have done the work.)

1. Who was the first to hear about the death of Cæsar (say, "Who first heard about dead Cæsar?" The Romans avoided abstract nouns where possible, and used participles instead—*e.g.*, the capture of the city = *urbs capta* = the captured city)?

2. The war against the Africani having been finished (*conficio, confeci, confectum*), the soldiers returned home to Britain (return = *redeo, redivi, reditum*).

3. Our native land was conquered by the Normans in the year 1066 after the birth of Christ (say, "After the born Christ," *post Christum natum*).

4. There is no doubt that (*non est dubium quin*, with subjunctive) the sun is larger than the moon.

5. He is too brave to fear death (say, he is braver than that [*ut*] he may fear death).

6. Before us are two paths: the one leads to poverty and right, the other to wealth and shame: I ask you which of the two you choose. ("You choose" must be subjunctive, because it is in an indirect question—*i.e.*, it depends on the main verb "I ask.")

7. Be thou faithful unto death, and I will give thee a crown of life.

8. The great Bruce, having watched the spider in the cave, resolved to be *of good courage* (*bono animo*, ablative of quality).

Key to Preceding.

1. Quis primus de mortuo Cæsare audivit ?
2. Bello contra Africanos confecto, milites domum in Britanniam rediverunt.
3. Patria nostra a Normannis anno millesimo sexagesimo sexto post Christum natum superata est.
4. Non est dubium quin sol sit major quam lună (nom.), or lunā (ablative, without quam).
5. Fortior est quam qui *or* ut mortem timeat.
6. Ante nos sunt duæ viæ : altera ad paupertatem et honesta (acc. neut. plu., honourable things), altera ad divitias et dedecus ducit : rogo utram deligatis.
7. Esto fidelis usque ad mortem, et dabo tibi coronam vitæ.
8. Ille Brutius, quum araneam in antro observavisset, esse bono animo constituit.

Section III. TRANSLATION.

(The numbers at side of words indicate the order in which the words are to be taken : note them carefully. The letters in brackets refer to the notes at the end.)

"Cæsar's First Landing in Britain."

Quod (*a*)[4] ubi[1] Cæsar[2] animadvertit,[3] naves (*b*)[7] longas,[6] quarum[8] et[9] species[10] erat[11] barbaris[13] inusitatior,[12] et[14] motus[15] ad[17] usum[18] expeditior,[16] paulum[20] removeri[19] ab[21] onerariis[22] navibus,[23] et[24] remis[26] incitari,[25] atque[27] inde[28] fundis[33], sagittis,[34] tormentis,[35] hostes[29] propelli[30] ac[31] submoveri[32] jussit.[5] Quæ[1] res[2] magno[4] usui[5] nostris[6] fuit.[3] Nam,[1] et[3] navium[5] figura,[4] et[6] remorum[8] motu,[7] et[9] inusitato[10] genere[11] tormentorum[12] permoti (*c*).[2] barbari[13] constiterunt (*d*)[14] ac[15] paulum[17] modo[16] pedem[19] retulerunt (*e*).[18] Atque,[1] nostris[2] militibus[3] cunctantibus (*f*),[4] maxime[5] propter[6] altitudinem[7] maris,[8] qui (*g*)[9] decimæ[12] legionis[13] aquilam[11] ferebat,[10] contestatus (*h*)[14] Deos,[15] ut[16] ea[17] res[18] legioni[21] feliciter[20] eveniret[19]: "Desilite"[1] inquit,[2] "commilitones,[3] nisi[4] vultis (*i*)[5] aquilam[7] hostibus[8] prodere[6]: ego[9] certe[10] meum[12] reipublicæ[14] (from respublica) atque[15] imperatori[16] officium[13] præstitero" (*k*)[11]. Hoc[3] cum (*l*)[1] magna[4] voce[5] dixisset.[2] ex[8] navi[9] se[7] projecit (*m*)[6], atque[10] in[14] hostes[15] aquilam[13] ferre[12] cœpit.[11] (From Cæsar, De Bello Gallico, Book IV, chap. 25.)

Notes. (*a*) Quod : acc. of qui, governed by *animadvertit.* We say, "When Cæsar perceived this" ; the Romans said, "Which thing when Cæsar perceived."

(*b*) Navis longa = a ship of war.

(*c*) Permoti (from permoveo), is nom. pl. of perf. participle passive, agreeing with *barbari.* "The barbarians, having been influenced by the shape of the ships," etc. *Figura, motu* and *genere* are abl. after *Permoti.*

(*d*) Perfect of *consisto.*

(*e*) Perfect of *refero.*

(*f*) Ablative absolute.

(*g*) Qui = he who.

(*h*) Contestatus = calling to witness (though passive in form, it is active in meaning).

(*i*) Second pl. pres. indic. from *volo,* I wish.

(*k*) Fut. perf. of præsto, I discharge.

(*l*) Cum is another form of *quum,* when.

(*m*) Perfect of *projicio.*

Key to Above Passage.

"When Cæsar perceived this, he ordered the ships of war (of which both the appearance was more novel to the barbarians, and whose movement was quicker for use, to be moved a little from the vessels of burden—*i.e.*, transports—and to be urged forward by oars, and then the enemy to be driven back and dislodged by slings, arrows, and engines. This thing was (for) a great advantage to our (men). For, having been influenced both by the shape of the ships and by the motion of the oars and by the unusual kind of engines, the barbarians halted, and drew back (their foot) a little. And, as our men were hesitating, mostly on account of the depth of the sea, he who carried the Eagle (standard) of the 10th legion, calling the gods to witness that that thing would turn out luckily for the legion, says, 'Leap down, fellow-soldiers, unless you wish to hand over the eagle to the foe. I, at any rate, will have discharged my duty to the republic and to the general.' When he had said this with a loud voice, he threw himself from the ship and began to carry the eagle against the foe."

To be continued

ENGLISH Continued from page 447 By Gerald K. Hibbert, M.A.

PRONOUNS—continued

2. Demonstrative Pronouns. *This* and *that,* with their plurals, *these* and *those.*

When used with nouns, they are demonstrative *adjectives* [see last Lesson], as : "these sheep." But when used as nouns—*i.e.*, without being joined to a noun or requiring a noun to be understood, they are pronouns, as in the following instances :

a. When used to prevent repetition of preceding noun, as : "The army of Germany is larger than *that* of France."

b. When *this* and *that* = the one . . . the other — *this* referring to the last-mentioned thing, *that* to the first mentioned, as : "We offer you either war or peace : this means prosperity, that destruction."

3. Interrogative Pronouns. *Who, what, which,* and *whether.*

These are used in asking questions, either direct questions, as : Who is there ?, or indirect—*i.e.*, questions depending on a previous verb, as : "He asked who was there."

Who, which, and *what,* are also used as relative

pronouns [see next Section], but they were originally interrogatives.

Who is thus declined:

Singular and Plural

Nominative	Who (Anglo-Saxon *hwa*)
Objective	Whom
Possessive	Whose

Which and *what* are indeclinable. *What* is the neuter of *who* (*cf.*, *it*, *that*). *Which* = *hwi lic* ("who like," *hwi* being the old instrumental case of *hwa*). *Whether* means "which of the two?" (*who-ther*).

Who is used with reference to persons only, never to things: it is always a substantive. *Which* and *what* are used both substantively and adjectively—*e.g.*, "What did you go out to see?" (substantively); "What sneaking fellow comes yonder?" (adjectively); "Which was the braver?" (substantively); "Which way went the Spirit of the Lord?" (adjectively).

Who and *what* ask perfectly indefinitely: *which* asks for one out of a selected class or group. *What* is neuter when used as a substantive.

What (interrogative) is often used in exclamations, as: "What dreadful sufferings, with what patience, he endured!" (Charles Lamb). It is sometimes used adverbially = why?—*e.g.*, "What should I stay?"; "What need we any spur?"

Whether as an interrogative pronoun must be carefully distinguished from the conjunction—*e.g.*, "He asked whether you were in" (conjunction); "Whether of the twain will ye that I release unto you?" (pronoun).

4. Relative Pronouns. *That*, *who*, *what*, *which*. Almost all the pronouns "relate" to some previous noun, but these "relative pronouns" also connect the clause which they introduce with the former part of the sentence. In the sentence just written, for example, *which* is a relative pronoun referring to "clause" (called the *antecedent*), and connecting the clause "which they introduce" with the earlier part of the sentence.

Relative pronouns, therefore, introduce sentences which are *adjectival* to some noun or pronoun in another sentence, for in the above, the sentence "which they introduce" limits or qualifies the meaning of "the clause," and is therefore adjectival.

If we examine any sentence containing a relative pronoun—*e.g.*, "He whom thou lovest is sick," we see that but for the use of the relative, the sentence must have been broken up into two separate parts: "He is sick: and thou lovest him." This is true of no other pronoun, so that a relative pronoun is really a pronoun and conjunction combined. (This is seen very clearly in Latin: the Latin idiom for "I sent my slave *in order that he* might tell you" is, "I sent my slave *who* might tell you," and for "and when he had done *it*," Latin says "*which* when he had done.")

That is our oldest relative. As a relative, it is always a substantive, and may refer to either persons or things; it is also indeclinable—*e.g.*, "This is the house *that* Jack built." "Mark but my fall, and that *that* ruined me." It cannot always be used for *who*; we cannot say: "My father that is an old man." It is used for *who* or *which* only when the antecedent is incomplete and requires further definition—*e.g.*, "Blessed are they that mourn," "All is not gold that glitters." [Note. *That* may be (1) conjunction, (2) demonstrative adjective, (3) noun, (4) relative pronoun, (5) demonstrative pronoun. In the following sentence, "that" illustrates each of these parts of speech in the order named: "He said that that 'that' that the boy had written was that of a bad writer."]

Who passed from the stage of an interrogative pronoun to that of an indefinite pronoun, meaning "any one" (*cf.* the expression: "As who should say"). It then became an indefinite relative by the addition of -soever, and finally became an ordinary relative, the -soever being dropped. It is declined like the interrogative.

"Who" and "whom" are now used only of persons, but the possessive "whose" can be used even of lifeless things—*e.g.*, "Nebuchadnezzar made an image of gold whose height was threescore cubits" (Daniel).

What is used only of things, and never relates to any antecedent except *that* (which is always understood and never expressed); it is therefore used in the singular only. "What all desire, must be good"—*i.e.*, "that which all desire, etc." There are instances of the relative *what* used as an adjective, but they should not be copied—*e.g.*, "What time I am afraid, I will trust in Thee" (Psalms). *What* used to have other words as antecedents, but nowadays it is incorrect to say: "The man what said it, is dead."

Which is the ordinary relative referring to animals or things, as *who* to persons. It was formerly used of persons as well—*e.g.*, "Our Father which art in heaven." In the English Bible it is often preceded by "the"—*e.g.*, "In the which ye also walked." It differs from *who* in that it can be used as an adjective—*e.g.*, "which things have indeed a show of wisdom" (Colossians). "Who" and "which" can always be used where "that" (relative) is used, though, as we have seen above, the converse is not true. "Of which," "by which," "in which," etc., are sometimes written "whereof," "whereby," "wherein." Similarly "thereof" = "of this," or "of it."

Who, *which*, and *what* may each be compounded with *-ever* and *-soever*, and *who* may also be compounded with *-so* (whoso). The forms in *-so* and *-soever* are not often used now. "Whosoever" is declined—nom., whosoever; obj., whomsoever; pos., whosesoever.

Rules of Relative and Antecedent. A. A relative pronoun must have an antecedent, expressed or understood. This may be a noun, a pronoun, a noun-phrase, or a noun-clause. The antecedent of *who* and *that* is sometimes understood—*e.g.*:

" . . . Who reads Incessantly, and to his reading brings not A spirit and judgment

equal or superior . . . Uncertain and unsettled still remains." ("Paradise Regained.")

(Here "he" is understood before "who.")

"That thou doest, do quickly." (Here *that* = "the thing which.")

B. The relative agrees with its antecedent in number, gender, and person; but its *case* is determined by its own clause—*e.g.*, "I, *who* erewhile the happy garden sung" (*who* is first person, singular, masculine, agreeing with antecedent "I"; its case is determined by its own clause, it being nominative because subject to "sung").

"Those (nom.) whom (obj.) the gods love die early" (*whom* is plural, common gender, agreeing with *those*; but it does not agree with "those" in case, being objective after "love").

"To those who ask how kind thou art" (here *those* is objective and *who* nominative).

Important Note: *Who*, both as relative and interrogative, presents endless difficulties to "the man in the street," and there are comparatively few Englishmen who are always sound in their grammar on this point. Even the Authorised Version of the Bible breaks down here, a very rare thing indeed. In Mark viii. 27, we read: "Whom do men say that I am?" This, of course, should be "who," as we see if we alter the form of the sentence: "Who am I, do men say?" If we keep "whom," we must say: "Whom do men think me to be?" All such expressions as "Who did you see?" "Who did you speak to?" "I know who you mean," "The man who I saw" should be avoided.

Omission of the Relative. The relative is often omitted, but only when if expressed it would be in the objective case—*e.g.*, "The thrifty hire I saved under your father" ("As You Like It"), where "which" is understood. This is very common in colloquial English: "The book he gave me is lost." It is said, however, that in the English Bible the relative is not once omitted.

We sometimes omit a preposition as well as a relative, as: "the way he walks" (for "the way in which he walks"). This is very slipshod.

The relative should never be omitted—

a. When, if expressed, it would be in the nominativ .

b. When th relative sentence, instead of defining or restricting the antecedent, states some further circumstance attending the antecedent, and is continuative or ampliative rather than restrictive. If we compare the two sentences: (1) "He broke the pen which I lent him," (2) "His eldest son, whom he had lost many years before, had always been his favourite," we see the difference. In (1) *which* defines limits, restricts the meaning of *pen*; in (2) *whom* amplifies and enlarges on "his eldest son."

The *which* in the first sentence could be omitted, but *whom* in the second could no be left ou .

"*Than whom.*" For some unknown reason, the relative is always put in the objective after "than," even in cases where any other pronoun would be in the nominative—*e.g.*, "Which when B elzebub perceived, than whom, Satan except, none higher sat, with grave aspect he rose." ("Paradise Lost.")

As is often used as a relative pronoun, after "same" and "such"—*e.g.*, "This is the same as that," "'Tis still a dream, or else such stuff as madmen tongue" ("Cymbeline").

In old English the genuine relative was used after *such*—*e.* .,

"Such an enemy
Is risen to invade us, *who* no l ss
Threatens than our expulsion down to Hell!"
(Milton.)

As *such* meant "so-like," *which*, meaning "what-like," naturally followed it; and so with the other relatives, "who" and "that."

5. Indefinite Pronouns. *One, none, aught, naught, any, other, another, some.*

One: a. Adjectively, meaning "some," "a certain," as: "I shall one day perish."

b. Substantively, meaning "a certain person," as: "One in a certain place testifieth" (Hebrews). It is often used in the plural, as: "I have also called my mighty ones" (Isaiah). It is also used like the French *on* and the German *man*: "One can never say what will happen."

None is used for *no* when the noun is omitted, as: " . . . those kindnesses that I have done for you. I know of none."

Aught is from the Anglo-Saxon *a* = ever, and *wiht* = thing. *Naught* is its negative (sometimes spelt "nought"), and *not* is a contracted form of this. They are n t often used now, "anything" and "nothing" usually take their places.

Any is derived from ne, and was originally spelled *ony*.

Other means "one of two." (*cf.* the *-ther* in "whether"). It is used as an adjective and as a pronoun; in the latter case it is declined:

	Singular.	*Plural.*
Nom. and Obj.	other	others
Poss.	other's	others'

"The one . . . the other" are used when only two are spoken of; "one . . . another" when more than two. Similarly, the expression "one another" is not correct when used of only two persons: we should then use "ea h other."

6. Distributive Pronouns. *Each, every, either, neither.*

Each denotes all taken separately; it can be either adjective or pronoun—*e.g.*, "Each morning sees some task begun" (adjective); "The kings sat, each on his throne" (pronoun).

In the phrase "each other" the two pronouns

were originally independent, but the two words are now treated as a compound. Strictly speaking, in the sentence, "They killed each other," *each* is nominative, and *other* objective ("they killed, each killing the other").

EVERY (ever-each) is very similar to *each*. It is usually an adjective ("every man to his tent"), though originally it stood as a pronoun by itself.

EITHER; NEITHER = one of the two (but not both); not one of the two. "Either" and "Neither" should be used only when there are two alternatives: "either of the three" is wrong.

Each, every, either, neither should be followed by a singular verb, as they are always singular —*e.g.*, "Each man knows what suits himself."

EXERCISE ON PRONOUNS.

1. In the following passage pick out and classify all the pronouns:

"There was once a dog who was crossing a bridge, carrying a bone in his mouth. Looking into the water, he saw another dog, that also had a bone in his mouth. 'I should like that,' he thought to himself, 'better than this.' So he dropped his own bone to seize the other, and lost them both. Who could believe that any dog could be so foolish as he?"

2. Correct the following sentences:

a. Who is there? It is me.
b. Let each esteem other better than themselves.
c. I have a brother is condemned to death.
d. I won't say who I mean.
e. Everybody has their faults.

KEY TO EXERCISES ON PAGE 447.

Faulty sentences:

1. Omit "the rest."
2. "Best" should be "the better."
3. Omit the second "a."
4. If one man fills both these offices, this is correct; otherwise insert "the" before "Treasurer."
5. Insert "other" before "poet."
6. Insert "a" before "green."

VERBS.

A verb is a word which says something about a person or thing, or groups of persons or things —as "time *flies*," "dogs *bark*." It was called verb (Latin *verbum* = a word) because it is the most important word in a sentence.

Every grammatical sentence must contain at least two words, the one naming a person or thing (or groups of persons or things), the other telling us with regard to the first that it does something, or is in some state, or has something done to it. The first is a noun and is called the Subject, the second is a verb and is called the Predicate.

TRANSITIVE AND INTRANSITIVE VERBS.

1. A transitive verb (Latin *transire* = to go across) is a verb of action which affects an object; the action "goes across" from the doer to someone or something else. Therefore every transitive verb must have an object—*e.g.*, "*Fear* God: *honour* the king," "The captive *broke* his chains."

2. An intransitive (or neuter) verb cannot affect an object; it denotes a state or condition, or an action confined to the doer—*e.g.*, "Men die," "The top spins."

Many transitive, verbs are sometimes used intransitively—*e.g.*, "He *burst* his chains" (trans.), and "The bubble *burst*" (intrans.), "He *cut* his finger" and "This knife *cuts* well."

Transitive verbs can be used reflexively, with the reflexive pronoun either expressed or understood—*e.g.*, "He *wounded* himself," "Planets *move* (themselves) round the sun."

INFLEXIONS OF VERBS.

Voice. There are two Voices, Active and Passive. A verb is in the Active Voice when its subject stands for the *doer* of the action. A verb is in the Passive Voice when its subject stands for the *object* of the action. Examples: "I *killed* Cock Robin" (active); "Cock Robin *was killed* by me" (passive). In these two sentences the same action is expressed—*viz.*, that of killing; but whereas "Cock Robin" is object in the first sentence, it is the subject (grammatically) of the second.

Intransitive verbs have no passive voice, as they pass over no action to an object.

The Passive Voice is formed by prefixing to the past participle of a transitive verb the different tenses of the verb "to be"—as, "I shall be *praised*," "Thrice was I *beaten* with rods." Be sure, however, that the past participle is that of a transitive verb; if it is that of an intransitive verb, the voice is active, not passive—*e.g.*, "He *is* dead," "I *am* come." We could equally well say, "He *has* died," and "I *have* come."

Mood. When a verb makes a direct statement or asks a direct question, we say it is in the *Indicative* Mood (Lat. *indicare* = to point out). When a verb conveys a command it is said to be in the *Imperative* Mood (Lat. *imperare* = to command). When we wish to express, not so much a fact (in which case we should use the Indicative) as our conception of the fact, we are said to use the *Subjunctive* Mood. These are the three Finite Moods, called "finite" because the action or state denoted by them is "limited" by considerations of number, person, and time.

There is a fourth Mood, the *Infinitive*, in which the notion expressed by the verb is absolutely "infinite," unlimited by number, person, or time—*e.g.*, "I cannot *speak* for tears" (*i.e.*, "I am not able *to speak*"). Some grammarians deny that this is a "Mood" at all.

QUALITIES OF GOOD SERVANTS AND SERVANT LAW

By A. Eunice T. Biggs

A SERVANT has been defined as "a person who is subject to the command of his master as to the manner in which he shall do his work," and such a person becomes a domestic or menial servant when he "lives in his master's house and attends to the personal wants and pleasures of the master or his household."

At present there exist several means of obtaining domestic servants, all more or less unsatisfactory. As a general rule the master, or more commonly the mistress, has recourse to a registry office. Here she registers her wants—the kind of servant she is seeking, giving full particulars of the age, salary offered and duties to be performed by the person engaged. These details are recorded by the keeper of the registry-office, whose duty it now becomes, on the payment of a fee, to place the would-be mistress in communication with suitable servants, disengaged at the time, who have also registered their names as persons seeking such employment. The servants who place their names on the books at a registry-office are often not required to pay a fee, or, at all events, they may defer the payment until after they have been "suited" with a situation.

The Engagement. During recent years abuses have arisen in connection with the keeping of registry-offices. They have frequently been conducted by unscrupulous persons who pocket the fees of the mistresses and servants who have believed their promises, and then make not the slightest effort to suit either class of applicant. In other cases incompetent, dishonest, and generally unsatisfactory servants are sent to mistresses seeking servants: the result being considerable discomfort and annoyance to both parties.

Lately an effort has been made to establish registry-offices on a more businesslike basis. Properly qualified persons competent to ascertain and judge of the qualifications of intending servants, and supported in their endeavour by the co-operation of mistresses, are now undertaking the work of bringing into communication the intending employer and the servant whose character and competence bear close investigation.

The Registry-office. Failing the assistance of the registry-office, both mistress and servant must endeavour, by advertisement in a daily newspaper, to obtain the desired end. But the disadvantage of such a method is obvious. It is troublesome to a mistress, since in answer to her advertisement she will probably get numerous letters from illiterate persons, many of them quite incapable of executing the duties of the post offered, or of stating their qualifications and experience clearly and with accuracy. On the other hand, the mistress who answers advertisements purporting to be those inserted in the newspaper by servants requiring work, will find that, in most cases, such advertisements emanate from registry-offices, and are merely baits to ensnare the unwary and secure a fee.

Thus it will be seen that at the present time the means by which servants and mistresses can get into communication with each other are in a very unsatisfactory state. It is therefore to be hoped that during the next few years the attempts now being made to place matters on a more satisfactory and legal basis will meet with success, and so obviate much of the annoyance at present experienced by both parties concerned.

Desirable Characteristics. The comfort of a household is indissolubly associated with the character and competence of the domestic servant. This being the case, it is not surprising that the mistress attaches the greatest importance

to the evidence of the past career of the servant she engages. It is a serious matter to introduce into a household a person of whom little is known, whose previous service will not bear full investigation, or who cannot produce evidence of good character and a certain amount of skill from those with whom he or she has been previously associated.

In engaging a servant the mistress should be on the look-out for certain moral characteristics which are most important. On the other hand, those who wish for success in the capacity of domestic servant will do well to consider the value of such qualities and endeavour to acquire and exercise them.

Cleanliness of person and habits of neatness and method in general cannot be overrated. An untidy, slovenly cook, working unmethodically in a dirty, ill-kept kitchen, affords an object-lesson of what unsatisfactory domestic service may be. Good work cannot be done without neatness and method, and untidy habits and uncleanly utensils double the work of the servant and naturally give much annoyance to the mistress. Personal neatness is also of great importance. The neat print dress and cap and apron of the maidservant and the livery of the manservant, if properly cared for, contribute greatly to their satisfactory appearance; and with due attention to such details as neat hair, personal cleanliness, etc., the dress of the domestic servant is at once becoming, suitable, and by no means unattractive.

A Code of Honour. Characteristics which are, of course, indispensable to a domestic servant are honesty and truthfulness. It is of supreme importance that the mistress should be able to trust the servant she engages. The relationship between mistress and servant is very personal in its character, and the servant will have countless opportunities, not only of defrauding the mistress, but also of displaying strong moral character and trustworthiness. Temptation to appropriate the employer's goods is pretty sure to occur—in fact, is almost unavoidable, and the comfort of the mistress will depend to a very large extent on the degree of confidence she can place in her servant. She should be able to trust implicitly in her servant's word, and know beyond all doubt that the servant will not abuse the confidence so entrusted. Many servants who are absolutely reliable where money, jewellery, or such-like valuable matters are concerned, are not irreproachable with respect to food, notepaper, and other small matters. To read an employer's private letters, to be over-curious as to the mistress's private affairs—these are characteristics which should not be found in a desirable servant. The servant who has the highest standard of honour will treat his or her master's goods with the economy and respect he would use towards his own possessions. A dishonest servant creates discord in a household; suspicion is awakened and the spirit of generosity and confidence which makes for happiness is entirely lost.

Good temper and willing service are very desirable in a servant. Grudging service loses half its value, and a bad-tempered servant will be tempted to disrespect and discourtesy. A cheerful demeanour and obliging manner lend a charm to all service that cannot be overrated, and in adding to her mistress's comfort the servant secures her own happiness.

Good health is a desirable asset from the servant's point of view. A delicate person cannot perform his duties satisfactorily, and the attempt leads to much discomfort to both himself and his employer. Domestic service demands good health as a first essential, and is not suitable except for those who are well equipped for it by a liberal endowment of health and strength.

The Value of Punctuality. Punctuality is another important characteristic of a good servant, and, we may safely add, of a good mistress also. The characteristics of a good master and mistress and their duties towards their domestic servants we shall, however, consider carefully later. A servant should endeavour, for her own sake as well as for the sake of others, to cultivate habits of punctual rising. The peace of many a household has been lost by the irritating delay of a late breakfast or an unpunctual dinner. Nothing is so wearing to the temper, or so trying to the patience, as unpunctuality in the domestic service. Mistresses will do well to remember that the punctuality of the servants depends to a large extent on themselves, and that an unpunctual mistress makes an unpunctual servant.

Lastly, the servant must bear in mind that an essential duty is obedience and loyality to the master and mistress. The servant has no right to consider whether the order given is unreasonable or inconvenient. It must be executed, provided it is lawful, and within the scope of the servant's employment. Refusal to obey justifiable orders may give cause for "immediate dismissal," which we shall consider in detail later in this course. The servant should exercise forbearance and restraint in speaking of the master or mistress to fellow-servants or other persons. The talking over of a grievance often magnifies it to an alarming degree, and much may be said in haste that will be repented of at leisure. A loyal servant will not allow himself to belittle any member of the household, but will as far as possible identify his interests with theirs.

A respectful manner towards an employer is very desirable, and a servant will do well to cultivate habits of politeness both in speech and action. There is a great distinction between respect and servility, and in giving due respect to master or mistress the servant does no violence to his own independence and proper pride.

The Giving of Testimonials. In order to protect a mistress when engaging a new servant, it is customary for a written statement called "a character" to be given by a previous employer. A mistress is, however, under no legal obligation to give the servant a character. It is, nevertheless, customary to

do so, and refusal is generally very prejudicial to the servant concerned, implying, as it does, that the late employer is unable to testify to his good qualities. If a mistress consents to give a character, she must be careful to state the truth, and nothing but the truth. There must be no exaggeration either of the servant's qualities or imperfections. The "reference" should be an unprejudiced statement of the servant's characteristics, and should give a correct impression of the servant's abilities. Such a statement so made, whether by word of mouth or in writing, is held in law as "a privileged communication," and the master making such "privileged communication" does not render himself liable for slander or libel. This security of the master holds good even if the statements made in giving the "character" be untrue, unless it can be proved that the statement was made "maliciously."

Privileged Communications. In order to bring successfully an action for libel or slander against a master, the servant must be able to prove not only that the statements made are untrue, but also that they were made "with malice." Should the servant be able to show that the master made certain statements with regard to the servant's character, *knowing them to be untrue*, evidence of malice could be proved. Supposing that a mistress gives a servant on leaving her service a good character, but afterwards ascertains that the servant had forfeited her right to such a testimony of good conduct, the mistress is then justified in communicating with the servant's new employer. Such a communication will also be "privileged," and the new employer may ask questions and be answered by the former mistress.

Thus it is very obvious that in giving a servant a character the greatest care should be taken to make only accurate statements, and to choose carefully the words used in expressing such statements. All trace of exaggeration should be scrupulously avoided. Words should be carefully chosen in giving a character, and particularly in speaking of the servant's shortcomings. In giving such particulars, the mistress should be just, remembering that she should, as far as is compatible with justice, set forth the servant's good qualities, rather than any faults he may have. On the other hand, in justice to the new employer, grave faults should not be concealed, although it is only kindly to set forth to the best possible advantage any qualities and evidences of competence the servant may have shown in the execution of his duty.

The Mistress's Liability. It is not generally known that a master or mistress who wilfully gives a false character incurs a grave liability. Should the new employer incur loss or injury as the result, the mistress giving the false character renders herself liable. If the new employer finds that the servant does not deserve, or in some way forfeits, the good character given previously, the new employer should not allow others to be imposed on by a false character. But the utmost care must be taken, in adding any disparaging remark to such a statement, that nothing but the truth be added, and that *without malice*.

It is an offence against common law to forge a character in order to deceive and obtain a situation by false pretences. Heavy penalties are incurred by those who "falsely personate a master or mistress," or who wilfully make misstatements with regard to length of service, or the capacity in which the servant has been hired; or who alter or efface any word or other detail given in a character by a former master or mistress.

When a Servant may be Dismissed. If a servant is engaged temporarily for some definite period, say a week or a month, no notice need be given her, since she will leave at the expiration of her engagement. In ordinary cases of domestic servants it is customary—and the custom is recognised by law—to give one month's notice, or a month's wage in lieu of notice. In the case of the first month it is sometimes held that the mistress or servant may terminate the engagement by notice given at or before the expiration of the first fortnight. The first month is, in such cases, taken as one of "trial" in the absence of any special agreement to the contrary.

If a domestic servant is guilty of wilful disobedience to a lawful order she renders herself liable to dismissal without notice; but trifling acts of disobedience are not always sufficient to justify such summary dismissal. Misconduct is the most usual cause of his or her dismissal without notice. If a servant be guilty of habitual drunkenness, or drunkenness even on one occasion, which unfits him to execute his duty; if the servant be guilty of immorality, violent conduct, theft, or insolence, instant dismissal is warrantable. Gross and habitual negligence of duties may meet with similar treatment; while a servant who is quite incompetent to perform the duties undertaken may be dismissed without notice, since he cannot perform his part of the contract. Lastly, illness of a permanent nature on the part of the servant justifies the master in dismissing him. But the dismissal must be in definite terms, and the wages up to the date of dismissal paid, otherwise the master will be liable.

When a Servant may Leave without giving Notice. If the mistress denies proper food to the servant, or exposes the servant to unnecessary risk, the servant may leave her situation at once. Also if infectious disease breaks out in a house, the servant may (but there may be exceptions to this) leave without giving notice. If the servant leaves her situation in this way, and is justified in doing so, she may claim her wages up to that date, and may also be awarded damages.

The whole question of the legal relationship between servant and employer is of the utmost importance, and should be studied with the greatest attention. Once it is thoroughly grasped, we may proceed to study in detail the duties of various domestic servants, and the duty they may reasonably expect an employer to exercise towards them.

It is of the greatest importance that both master and mistress should understand exactly what their duties are towards their domestic servants. For the servant has his or her "rights," and these are no less stringent than those demanded by the master. Consideration of the servant, and proper care of his welfare, will encourage him to serve his employer with the utmost zeal The master will, moreover, enjoy a feeling of satisfaction that cannot be overrated in the knowledge that he has done his duty by those dependent on him. We have already dealt with the qualities most desirable in a servant, and we must now consider the characteristics of a good employer—whether master or mistress—and the duties that are owed to a servant.

A Cause of Dissension. Perhaps it will be well first to notice one chief cause of dissension between mistress and servant. In many households, especially those in which there are many grown-up daughters, the servants, and the maid-servants in particular, are given orders by a variety of persons. This is a mistake to be avoided whenever possible. All sorts of little orders and counter-orders worry the servant and hinder her in the proper execution of her regular duties. And this is not the only disadvantage of such a system. Nothing is less desirable than grudging service, or work that is done with a bad grace. On the other hand, there can be no objection to an occasional request from some member of the family that some special work should be done, and the servant would be sadly wanting in generosity who would object to execute some little additional task which adds to the general comfort of the household. The mistress, for her part, should, as far as possible, endeavour to give her orders first hand. It is the greatest mistake to give an order through another servant when this is avoidable; although, of course, in many cases it is natural and customary.

Characteristics of a Good Mistress. A good mistress exercises an important influence over her servants. If she is energetic, good-tempered, and pleasant to live with, her servants will, as a rule, take their tone from her. A mistress with whom it is difficult to live peaceably will make it difficult for even the most painstaking of servants to serve her satisfactorily. Certain qualities in a mistress are pretty sure to reflect themselves in the servants' conduct; and the mistress who wishes to ensure the highest degree of household happiness will do well to cultivate these qualities.

One of these essential characteristics is punctuality. In a well-organised household there will be fixed hours for every meal and every item of the daily routine. These fixed hours should be rigidly adhered to by every member of the family. The children will take their cue from their elders, and to be late for a meal should be regarded as a grave offence. The household should be aroused at a fixed hour, and breakfast should be served punctually. It is well for the discipline of the kitchen if every member of the family can put in an appearance at the breakfast-table. In middle-class families, and in homes where expenditure has to be carefully considered, much unnecessary waste will be avoided by this punctual breakfasting. Bacon will not get cold or burned, eggs will not get hard and indigestible, and endless relays of fresh tea and coffee will be unnecessary. If the mistress is at all self-indulgent in the matter of lying in bed late in the morning, the whole organisation of the kitchen is bound to suffer. Even a punctual cook will see the futility of serving a meal at its appointed hour, after she has seen the long delay before the food is eaten. The mistress should insist on the punctual serving of each meal, and should personally see that her orders are properly executed. We all know the discomfort of the type of household in which, when seven o'clock dinner is needed, "Cook must be told to have it ready at 6.30 p.m., then it will be on the table by seven!" Such methods at once reveal the fact that something is lacking in mistress as well as in servant.

Useful Habits. Habits of tidiness should always be insisted upon by the mistress, and she should seek to instil the same appreciation of neatness and the same love of order into the younger members of the family. An untidy bedroom gives an infinitude of trouble to the maid who is responsible for sweeping and dusting. In little matters such as these a good mistress will show all possible consideration for her servants, giving no unnecessary trouble, and endeavouring to lighten their duties and make their work pleasant.

In giving her orders for the day, the mistress should state definitely and clearly what her wishes are, otherwise there may be some misunderstanding, leading to difficulties that might have been avoided by the exercise of a little care. Once her orders have been given, the mistress should try to avoid countermanding them. Of course it will sometimes happen that some unusual and unexpected turn of events will cause the change of all her plans. This may necessitate a complete alteration of all the orders she had given for the day. But it is obvious that these departures from routine are worrying to the servant and should be avoided whenever possible.

The Giving of Directions. When a mistress requires some particular service from a servant, she should give her directions firmly and avoid the semblance of making a request. It is quite possible to give an order with absolute politeness and yet with indisputable firmness, and this is the preferable attitude of the mistress towards the servant. Of course a dictatorial tone is most objectionable, but a wavering order that admits of questioning leads to quite as much annoyance. Discussions between mistress and maid should not be tolerated. Familiarity of tone should also be avoided, and both mistress and servant will find that it will answer far better in the long run to maintain an attitude which, though perfectly amiable and friendly, is entirely lacking in familiarity.

This word of warning is very necessary to young wives whose husbands of necessity leave them much alone with maidservants during a long day. The temptation to talk to someone may be very great, and, failing the presence of a friend, the young housewife may find herself embarking on a too familiar conversation with her maid. This is often a mistake. On the other hand, a good mistress will take a real and personal interest in her servants, who will not be afraid to talk quite freely to her, knowing that she will give them ready sympathy, and, if possible, help. Ladies, and especially young ladies, are too prone to make confidants of their maids, and to make them the recipients of information which had far better be withheld. Unless the lady's maid is very trustworthy, she is more than likely to regale her fellow-servants with the confidences she has received, thus bringing about an undesirable state of affairs.

The Danger of Mischief-making. One of the chief causes of dissension in a household where more than one servant is kept is the readiness with which the individual servants find fault with each other to the mistress. This affords the latter an opportunity for exercising the greatest tact. Under no circumstances should the mistress show herself ready to listen to mischief-making remarks. Jealousy or spite are often at the root of the matter, and in any case it will be far wiser for the mistress to be on the alert to detect wrongdoing herself than trust to its discovery by another servant. Matters cannot become very seriously wrong if the mistress is really observant. She should know so thoroughly each item of the daily routine that no little omission will escape her.

We are for the present considering more particularly the attitude of the mistress of a middle-class household, who keeps the reins of household management in her own hands. In a larger *ménage*, where this work is left to a housekeeper, the latter will need to acquire all the qualities that should characterise a good mistress. The housekeeper in such a case represents the mistress, and the servants will depend on her to a very large extent for their welfare and proper control. But whether the responsibility rest with mistress or housekeeper, the essentials are the same.

Necessity for Supervision. The servants should feel that their work is well under supervision; that well executed work will be noticed and meet with reward; and that neglect of duty will be also observed and incur blame. This supervision is particularly necessary with young and inexperienced servants. Their youth gives them but a small sense of responsibility and duty, and their inexperience makes it at times a little difficult for them to carry out their share of the household work satisfactorily. Such young servants will profit greatly if placed for a time under the tuition of an older and really trustworthy maid. In a small household the mistress herself will find it well worth her while to take some trouble and expend a good deal of time in showing her maid how she likes the work done. Then in the future, if the maid is conscientious and intelligent, there will be fewer difficulties to contend with.

Recreation. Lastly, a good mistress will take a really personal interest in the recreations of her servant. She will allow time for adequate rest, and will so arrange household matters that once on Sunday, at least, each servant is given a chance of attending a place of worship. The mistress has no power to insist that any particular service shall be attended, but if kindly and tactful she will endeavour to meet the requirements of each servant. In the matter of recreation and exercise, however, the mistress has a definite duty towards her servants. In the discharge of their daily duties most servants get a good deal of indoor exercise, but this is not sufficient to ensure good health. A short walk in the open air is desirable, if not absolutely essential. In a large establishment, one or two servants can in turn be spared for the purpose; and in a smaller household, where there are fewer servants, or even only one, an opportunity can generally be made by a little contrivance.

Then, in the matter of recreations and pleasures, if a mistress can now and again offer her servants some little treat—a concert or entertainment of some kind—her thoughtfulness will be much appreciated. Again, a mistress can often contribute to a servant's happiness by the loan of magazines and newspapers. In a large household some such literature is generally provided for the servants, and in a smaller house it will be well for the mistress to consider her servants in this way.

The Characteristics of a Good Master. In the main, those qualities mentioned as essential to a good mistress are as desirable for a master. In a small house, where only maidservants are kept, the master will have few orders to give, and will have little to do with the management of the household. In giving orders a good master will show consideration and politeness when addressing the maidservants, and at the same time avoid all semblance of familiarity. The master should be careful not to run counter to any orders previously given by the mistress, and he should endeavour, as far as possible, to avoid any interference with the mistress's wishes. Lastly, every member of the household should remember that matters of a family, personal, or private character should never be discussed in the presence of servants. And in the same way all disagreements and all suggestion of quarrelling or ill-temper should be hidden from the servants. To witness a "scene" is bad for both parties concerned, since it undermines all feeling of respect and authority.

Food and Lodging. It is the master's duty to supply food to his domestic servants. This right is secured to the servant by law, and the servant has a right to demand adequate food and suitable lodging. In most households the meal-times and the actual food served to the servants differ slightly from that supplied to the members of the family. This difference in the time of serving meals is more convenient, and the difference in food is also advisable. Servants are generally called upon to do a good deal of

work which involves muscular exercise. Thus flesh-forming foods are necessary.

In a large household the servants usually breakfast about an hour earlier than the family. This leaves them free to prepare the breakfast and have everything in readiness at the appointed hour. In order that the house may be comfortable, and some of the rooms cleaned and dusted before breakfast, it is necessary for most of the servants to rise in good time. They are therefore glad of an early meal. When the family are at breakfast, the maids responsible for the bedrooms will throw back the bedclothes, stripping the beds so that they may air well before remaking. In many houses a light lunch of bread and cheese is provided about eleven o'clock for those servants who desire it, and at about one o'clock a substantial middle-day dinner is served. In households where there are young children this dinner will coincide with that of the nursery.

Meals. Between 4 and 5.30 tea of the "school-room" type will be served, including bread-and-butter, and sometimes jam or cake. Then, in the evening, after the late dinner of the household is served, the servants take their last meal—supper. The character of this meal varies considerably in different classes of household. In a large home it is fairly elaborate, and in a smaller one may merely involve a cup of cocoa and bread-and-butter, or cheese. If many servants have to be catered for the supply of food must be carefully checked or there will be unnecessary waste. In such cases the system of "allowancing" is employed, and a definite quantity of tea, sugar, etc., given out from the stores each week. This will be left in the hands of the housekeeper, or the mistress herself will supervise the matter, and we shall consider the question in detail when we deal with the duties of the housekeeper and cook.

Hours. In the matter of lodging the master has also a duty towards his servant—to provide him, with a properly-equipped bedroom and room in which to take meals. The master must allow certain hours and definite times during which the servant may absent herself. Should she, however, fail to return at night, the master is not compelled to wait up for her beyond a reasonable hour. On the other hand, should a domestic servant absent herself without permission during a whole night, the master is justified in dismissing her without notice. But he must avail himself of the right at once, as soon as the offence has been committed, for he cannot afterwards bring forward that act of disobedience as a ground for dismissing the servant without notice. The mistress is bound in the same way as the master to feed her servants properly and to provide them with suitable lodging. If she is married and living with her husband, he will be responsible for the treatment of the servants—unless it can be shown that he supplied the necessary food, and it was wilfully withheld from the servants by the mistress. In such a case he will be exempt from blame, but the mistress is liable to an action by the servant. Quite apart from the duty involved towards a fellow-creature, a master and mistress will find it essential to their own legal safety to consider carefully their duties to their servants. Should a master or mistress so neglect a servant and withhold from him proper food until he becomes enfeebled and unfit for his duties, and should such a servant die, his death being accelerated by the master's neglect, the master exposes himself to the risk of conviction of manslaughter or even of murder.

Criminal Liability. The obligation of the master to provide adequate food and lodging is emphasised by law. For it is provided by statute that—

"Whosoever being legally liable either as a master or mistress to provide for any servant necessary food, clothing, or lodging, shall wilfully and without lawful excuse refuse or neglect to provide the same so that the life of such servant shall be endangered or the health of such servant shall have been or shall be likely to be permanently injured, shall be guilty of a misdemeanour, and being convicted thereof shall be liable to be kept in penal servitude for any period from three to five years or imprisoned for any period not exceeding two years with or without hard labour."

"Where a master, being legally liable to provide for his servant necessary food, clothing, medical aid, or lodging, wilfully or without lawful excuse refuses or neglects to provide the same whereby the health of the servant is or is likely to be seriously or permanently injured, he shall, on summary conviction, be liable either to pay a penalty not exceeding £20, or to be imprisoned for a term not exceeding six months with or without hard labour."

Clothing. In the matter of clothing, the master is not ordinarily bound to provide his servants with clothing, unless some special agreement to that effect has been made. In some cases a particular livery is given to menservants, and in individual cases it becomes the absolute property of the servant after a certain length of time. In the case of maidservants some mistresses prefer to provide them with dresses of a particular colour and material. In the case of caps and aprons, cuffs and collars, and similar details, the mistress may prefer to choose the particular kind her maids shall wear, and in such cases it is more generous to provide them. The mistress may select a particular kind of apron that is more costly than the one the maid would select were the choice left entirely to her. In small households, where only one or two maids are kept, some mistresses will invest in large and particularly strong housework aprons for wear during the performance of rough and dirty work. Strong gloves should also be provided for the servants to wear when cleaning grates, polishing silver, and on other occasions when without such special protection the hands would become unnecessarily dirty.

Illness. If the servant be laid up with a short illness the master is not justified in dismissing him without notice. If, on the other hand, the servant develops a serious complaint, the master may at once give him notice, paying

his wages up to the date of dismissal. It is not sufficient to send the servant to a hospital. In such a case the master is liable for the servant's wages during the time he is ill (unless in the meantime he gives him a week's notice); nor can the master deduct anything from wages to recoup himself for the time that the servant was unable to serve him. The master is not bound, unless he has made a special agreement to that effect, to supply his servant with medical attendance. If, however, when the servant falls ill, the master calls in his own medical man, he will be liable for the fees incurred, and he cannot deduct them from the servant's wages except by the acquiescence of the servant in question.

Board Wages. If for any reason it becomes necessary for the servant or servants to be left at home while the rest of the family are away, it is usual to place them on what are termed board wages. This is a sum of money paid in addition to ordinary wages, and intended to be spent on the food and other necessaries to which the servant would be entitled if the master were at home. The actual sum paid will vary according to the style of household in which the servant is engaged, and it will also vary with the sex of the servant for whom such provision is being made. Thus, a minimum sum paid to a maidservant as board wages would be 10s. a week in addition to her ordinary wages, the amount being increased in a wealthier establishment, or when paid to a manservant.

In a large household where many servants are left on board wages, each will be paid his or her allowance individually, but as a general rule the servants will add the small independent sums together for current expenses. Under this arrangement, by good management, each servant will live exceedingly well, and a surplus will probably be left over from the total sum of board-wage money, which can then be divided among them. It is a well-known fact that it is always proportionately cheaper and more economical in every way to cater for several persons rather than for one. There need be very little waste, greater variety in the actual food provided is possible, and small initial expenses become infinitesimal when shared by several, whereas such expenses amount up to an alarming total when met by one person alone.

Alternative Methods. Occasionally a mistress will consider it desirable to dispense with the system of paying board wages, and arrange that the servants shall purchase necessities for themselves at the various shops at which she deals. In this case the accounts for all such commodities will be sent in to the mistress on her return. Such a system does not generally commend itself, and the objections which can be raised to it are obvious.

To begin with, servants generally prefer the board wages. This gives them perfect freedom in the selection of their food, and, moreover, should they be of an economical turn of mind, enables them with perfect honesty to save a small margin of profit on their weekly allowance. The system of arranging for all expenses to be entered in an account has very many disadvantages. The servant feels that each item of expenditure may be examined and criticised by the mistress, who, on the other hand, will probably find the whole system very expensive and unsatisfactory. Of course, providing the servants are reasonably economical and conscientious, the accounts need not be extortionately large; but then, again, the mistress may feel a little uncomfortable lest, through over-conscientiousness, her servants have stinted themselves in her absence. And even the most contented of servants may not be able to resist the feeling that they might have been treated more liberally.

Thrift. A mistress who has her servants' well-being at heart will take care—particularly if her servants be young—to instil into them the idea of the necessity for thrift. A young and inexperienced servant, coming, perhaps, for the first time into service from school and home, has no idea of the most advisable use to which to put her money. Her essential expenses are met for her—food and lodging are already provided for. She has, however, to keep herself well equipped in the matter of clothes; and a certain sum will be essential for travelling expenses, pocket-money, stamps, etc. Many domestic servants have to send regular help to their family, and this considerably lessens the total wage. But every mistress should, as far as possible, urge on her servant the necessity for thrift, and encourage them to set aside at any rate a small proportion of her wages yearly.

Kitchen Etiquette. Kitchen etiquette varies widely in different households, and with the number of servants employed. Where only two or three maids are kept, there will probably be no separate room for the servants' meals, when they will take them together in the kitchen. Their preparation, and the duty of laying the table, will fall to the share of the cook, or of the kitchenmaid should one be kept. If one of the servants is the children's nurse, she will, in all probability, take her meals upstairs in the nursery at the same time. In this case, it will be a matter for the mistress to arrange with her servants at the time of engaging them—whether the nurse is to fetch her meals from the kitchen, or whether they will be brought up to the nursery by one of the servants. It will be well for the mistress to make this point quite clear, for, unless she does so, there may be some friction between the nurse and the other servants, on the ground that they may object to waiting on her as a fellow-servant.

Housekeeper's Room and Servants' Hall. The housekeeper's room is furnished as a sitting-room, and is used by the housekeeper and other servants for their meals. Here the butler, lady's-maid, and valet take their meals with the housekeeper. Should there be guests staying in the house, accompanied by maids, these ladies'-maids will also take their meals in this room. All the other servants presided over by the cook have their meals in the servants' hall, a large room furnished comfortably but plainly as a sitting-room or dining-

room. The servants' hall is generally quite near the kitchen, and is used by them as a sitting-room in the intervals of their duties. In small households there will be no servants' hall, but the kitchen is used instead. Even in a very small establishment an effort should be made to make the servants' room as comfortable as possible. The cheerful surroundings of well-polished saucepan-lids and dish-covers, the neatly arranged dresser and shining range, all contribute an air of comfort to the room.

A thoughtful mistress will make the room still more cosy by providing it with a floor-covering. A square carpet, for instance, is very suitable, if not too large, since it can be taken up during the busiest part of the day when cooking operations are in full swing, and replaced when the servants have practically finished their day's work. Then the table should be furnished with a cloth also, which can be put on one side until the ordinary kitchen routine is over. Every kitchen which serves also as the servants' dining or sitting-room, should be provided with two or three comfortable chairs and a bookcase containing a selection of books. By these simple means, the servants who have met with much consideration, are much more likely to be satisfied with their lot, and to remain faithful in the service of such a mistress.

Smaller Households. The number of servants kept will vary with the position of the master. In a simple ménage, where the income of the master does not exceed £200 a year, one servant only will be kept—a general servant—who will be responsible for all the housework, with the assistance of the mistress, and perhaps that of grown-up daughters also. In some households, a cook and a housemaid will be kept, and with the gradation of income more servants will be employed. In many middle-class households women-servants only are kept, but in larger establishments men retainers are essential. A footboy or page is often kept, in addition to maidservants, where no manservant is kept; and in wealthier households the number of menservants kept will, to a certain extent, be regulated by the number of women-servants. Occasionally, preference is given to additional maidservants instead of menservants; for example, a kitchenmaid may be engaged to assist the cook, her other duties being mainly those which would be performed by a page.

Large Households. In a large household the four chief servants are the housekeeper, the butler, the lady's-maid, and the valet. They take their meals together and their duties bring them more in contact with their master and mistress than the work of any of the other servants. Thus, it is important for these upper servants to be particularly careful in their manner and bearing towards their employers—to be invariably respectful in their presence, and unflinchingly loyal in their absence. These points are of the very greatest importance. The housekeeper has abundant opportunity of influencing the women-servants of the household for good, who will all take their cue from her.

The butler is similarly responsible for the tone prevalent among the menservants. One of his duties will be that of securing faithful service from the under menservants. He must be conscientious and painstaking in the execution of his own duties, for he will find it difficult to obtain satisfactory service for his master from others should he in any way be remiss himself.

In their bearing towards their employers the manner of upper and lower servants should entirely coincide. The most perfect civility and politeness is accepted as an essential characteristic in the execution of duty. The servant should never sit down in the presence of the master or mistress unless expressly told to do so; for example, a mistress may tell her sewing-maid to remain seated while she herself is busy in the room. The servant should also be careful not to offer an opinion unless invited to do so, and never to attempt conversation unless at the instigation of her mistress. If this attention to manner and deportment is observed carefully by the servants the master and mistress will be spared the necessity of making any unpleasant complaint on this score, and the servant will escape the disagreeable necessity of listening to it.

THE STORY OF THE MAKING OF THE EARTH

By W. E. Garrett Fisher

GEOLOGY, as its Greek name indicates, is "the science of the earth." It deals with the *structure* and the *history* of the planet on which we live, and with the *natural processes* which have moulded it. It endeavours to show how the world around us may have developed out of the gaseous *nebula*, or fiery haze of clashing atoms, which represents the earliest form in which the materials of the earth can be pictured by the scientific imagination. It teaches us to read the wonderful record which is written in the folds of the rocks and stamped upon the surface of the earth, and so to form an idea of the various stages through which our planet must have passed before it could be the fitting abode of human civilisation. Finally, it enables us to look with the eye of science below the smiling surface of fields and parks, or the sandy desolation of the desert, and to predict the places in which it is likely to be worth while for the miner, the railway engineer, and the well-sinker to begin their operations with a hope of successful results.

The study of geology pre-supposes some knowledge of *geography*, or the superficial features of the earth, which it is the function of the geologist to explain and interpret. It is further necessary to assume an elementary acquaintance with *chemistry* and *physics* when the student begins to inquire into the mineral constituents of the *earth's crust*. The student will obtain these from the special courses on the subjects. But the special charm of this science is that the best place to study it is in the open air, and that the most essential piece of apparatus for the scholar is a good pair of eyes and a strong pair of legs.

The main *laws* of geology can be studied within the range of a holiday walk, though it may be necessary to travel far afield in order to witness their application on a larger scale. We propose in this course of study to set them forth much as an intelligent lad might be able to deduce them from a series of rambles with a practical geologist, saying as little as may be about those branches of the science which can be properly learnt only in a well-equipped laboratory and under the direct supervision of a teacher.

The Geologist's Walk. The first thing which strikes the would-be geologist with open eyes, in the course of such a country ramble as forms the best introduction to this science, is that the *features* of the earth's surface always differ, and yet are always recurring. Every turn in the road introduces a slightly different *landscape*, which, nevertheless, depends for its formation on a comparatively small number of details variously combined. The study of these details, with their unison in the several types of scenery, is the subject-matter of *Descriptive Geology*. The study of the natural processes which modify them is the subject-matter of *Physical Geology*, and the study of the changes through which they have come to exist in their present form is the subject-matter of *Historical Geology*. All the numerous sub-divisions which learned inventors of names have suggested come under one or other of these main classes. We can, in short, study only the present and the past—what is, and how it has come to be.

First of all, our pedestrian will notice a difference in the *materials* of which the earth's

surface is composed. He starts his walk on the street pavement, we will suppose, which is made of granite blocks, or of flagstones, which may be composed of compacted sand or the shells of very ancient sea-creatures, of asphalt, or concrete, or some other material which man finds it convenient to walk on. As the streets merge into the country, perhaps this pavement changes into a path of cinders or compacted earth, until it disappears altogether, and our pedestrian is stretching his legs on the macadam of the roadway, which he can easily see to be made up in a different fashion of small fragments of stone closely packed together—and too often coated with their *detritus* in the shape of dust and mud. All these materials, however, do not present the natural surface, but only what has replaced it at the bidding and for the convenience of man. Thus, the urban geologist learns—as his first lesson—that the crust of the earth has been modified in parts by the existence of life.

Soon we leave the road and follow a footpath through the fields. Here the variety of materials composing the earth's crust is still better illustrated. One field is *sandy*, another of heavy *clay*, another of that admirable *loam* which is a mixture of the two. The path leads through a little copse, and we notice the rich *leaf-mould* that has accumulated under the trees. Here and there a heap of stones has been gathered out of the ploughed soil, and the most cursory glance will show us that they are of several different kinds.

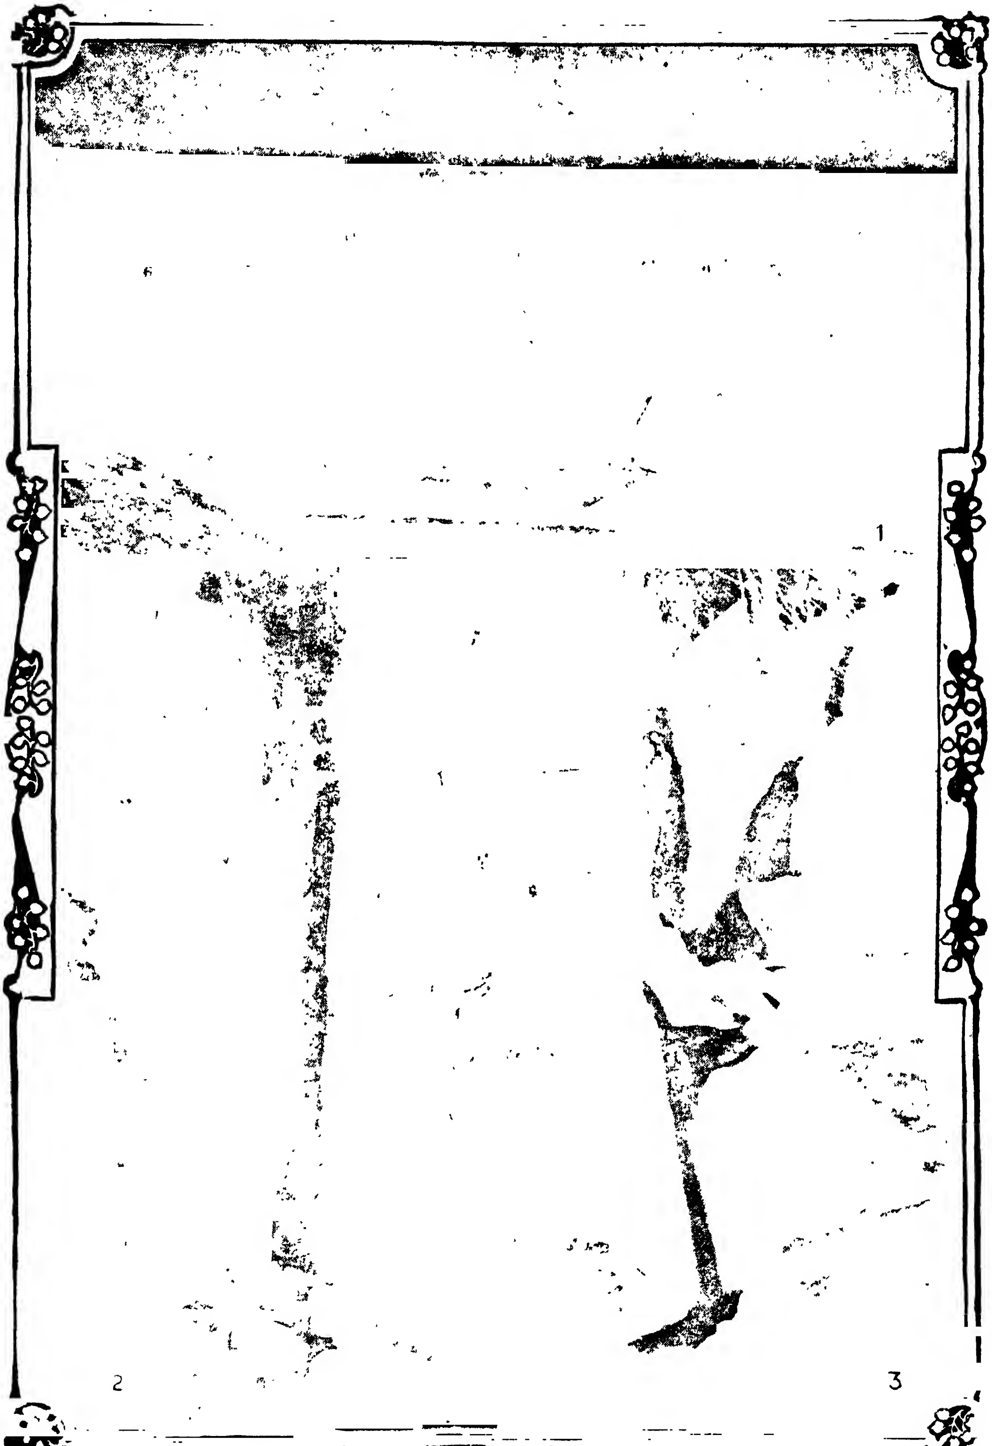
Rivers in Landscape. The path brings us to the side of a little *stream*, and we follow it upwards. It leads us towards the hills which are the usual object of such a ramble, and we note the gradual change in its fashion of running. Down in the open fields it flows along slowly and equably, only a foot or two below the bank on which we are walking. But as we ascend its course it becomes at once smaller and more lively. Here and there the banks rise suddenly, and we cannot fail to notice that the stream is cutting them away, and perhaps we go on to the just conclusion that the whole valley down which it flows was once carved out of the hills by a stronger prehistoric stream. We notice, too, that where the land is cultivated and the soil is soft the stream winds about and makes broad, fantastic curves; but where, nearer the hills, the banks begin to show rocky walls, it runs straight, swift and narrow, in little glens or ravines. It begins to dawn on us that rivers have something to do with the shape of the land. When we go home we take down an atlas, and see that everywhere, on the large scale as on the small, rivers run down from the hills in intricate but ever widening valley-systems to the sea; and it becomes apparent that this is not a mere truism, but a geological fact which helps to explain how the land has been carved into its present shape.

As we continue to ascend our stream, we come to a tumbling *waterfall* [2 and 3]; and if we study it carefully, we shall find that just here the water is coming over a ridge of *solid rock*, much harder than anything which we have seen yet. The running water, which comes down thick with sediment and mud after rain, is constantly wearing away the land; but it cannot act upon the rock nearly so fast as on the softer soil, though it does act upon it, and so the rib of stone has made a kind of wall over which the stream has to plunge. Probably the young geologist has tried on occasion to dig a really deep hole in some garden, and he knows that sooner or later he comes down to this solid rock, which nothing short of dynamite seems able to break up. Yet the running water has made a breach in it: for the centre of the stream is far below the rocky banks that stand up on each side. So two more lessons are added: one, that the soil which covers the earth in most civilised parts is only a skin a few feet thick over the rocky skeleton which underlies it; the other, that even this "eternal rock," as poets call it, is liable to be worn away by running water, apparently the softest and least destructive of things.

How the Land is Moulded. Well, the walk has now brought us up right among the *hills* that were blue on the horizon when we started. The cultivation has come to an end, and we can wander about as we choose. Clearly there must be something to keep the farmer away. It is partly a difference in *soil*, as we can see readily enough when we investigate among the roots of the heather, or pull up some of the short, wiry grass, very different from the luscious pasture down in the valley. Partly it is the change in the *contour* of the land, which is all ups and downs—no place for the harvest cart or the plough. It is the business of geology to tell us what has produced this variation in the outlines of the land. And one of the chief ways in which the question is answered is by the comparison of various places which are in different stages of the same kind of development.

Thus, we go to Beachy Head and watch the waves busily attacking that tremendous coast, eating into the softer parts of the cliffs and leaving the harder places to stand boldly up. If, on the way back to London, we pause on the top of Reigate Hill, and look abroad over the rich valley that stretches away for miles below us [1], we can hardly fail to ask ourselves if the sea did not once wash the foot of the hill on which we stand; and the answer is that it did. We see a range of hills, again, of which all the lower parts are smooth and rounded, whilst the higher summits are fretted into sharp and picturesque crags. We tell ourselves that some vanished agency must have been at work to produce this well-marked difference, and it needs hardly the evidence of the pebbles that we find scratched into long striations on their surface to tell us that all but the high summits were once covered with a sheet of ice, filing down inequalities and leaving a smooth contour.

The Fossil Record. So the *fossil* fishes which are found in the midst of the sandstone blocks quarried high up on the hillside assure us that once the sea rolled over the inland spot on



HOW WATER HAS CARVED THE LAND

1. An old arm of the sea: From Reigate Hill. 2 and 3, Typical waterfalls (2, Scale Force, Crummockwater; 3, Stock Ghyll Force, Ambleside)

which we stand, no less than the discovery of tree-trunks and ferns in the seams of coal [4] assures us that we warm our rooms and drive our engines with the remains of prehistoric forests. We notice some curious little pits on the surface of a sandstone slab which is going to be built into a new house, and they remind us of the day when the material of that slab was a bed of sand by the seashore, just firm enough to receive the marks of a shower of rain which it preserved, under the shelter of the next layer of sand brought in by the waves, through uncounted ages. The footmarks of extinct birds or reptiles tell the same story. The reproduction of the belemnite fossil [5] is interesting as a reminder of the growth of our knowledge in this branch of geological science. Various ages have attributed this fossil to various origins. In pre-Christian civilisation it was held to be a product of a mammal. Later, belemnite fossils were called "fingers from Mount Ida," or "Devil's fingers," with origin undecided. Then the theory was advanced that they were produced by lightning, and was followed by the supposition that they were stalactites. At length investigation proved them to be organic remains, the internal shells of curious gregarious animals that frequented shallow water. A bit of chalk, seen through the microscope, is made up of tiny shells and spicules which once formed part of the minute organisms that basked in the warm waves of a primeval ocean. Everything about us almost may thus be impressed into the service of the geologist, to throw some light upon the strange problems of the building of our world.

The science of geology, then, deals with the *structure and history of the earth*. It must be studied in the field and the quarry, no less than in the lecture-room and the museum, if it is really to tell a vital story. Here it is possible only to give an outline of the chief facts which are known with certainty about the materials of which the earth's crust is made and the natural processes which have built them up into the fair and fertile earth on which we live.

THE MAKING OF THE EARTH

Geology deals chiefly with the *crust* of the earth, because it is the most important part of our planet—the part on which we live. It is also the only part which we really know. Man has done little more than scratch the surface; his deepest borings go down little more than a mile—one four-thousandth part of the distance to the centre. We can, indeed, infer a good deal as to what lies lower down, but we soon come to the intensely heated *interior*, as to the physical condition of which geologists are not yet quite agreed. It is almost solely the crust that we shall study, and chiefly that part of it which lies within a few feet of the surface. First, however, we must take a glance at the history of the earth as a whole. This belongs as much to *astronomy* (the course on which may be consulted for further details) as to geology, but some acquaintance with it is an essential preliminary.

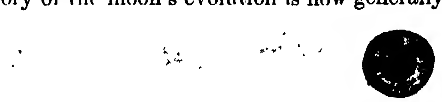
The Earth as a Blaze of Light. The earth was once "a fluid haze of light." The whole *solar system*, in which it is one of the smaller *planets*, was originally a vast *nebula*, or swarm of fiery dust and gas molecules, roughly spherical, and more than 5,000 million miles in diameter. This nebula was all rotating about its centre; it was also cooling, by the radiation of heat into space, and contracting. As it contracted it shed a series of rings at varying distances from the centre, each of which, with one exception, gradually coalesced into a planet revolving round the central portion, which formed the comparatively small star which we call the sun The four outer rings gave birth to the major planets—Neptune, Uranus, Saturn, and Jupiter—which are still in a more or less nebulous condition. The next ring never coalesced, but broke up into a large number of asteroids or minor planets, of which more than 500 have been discovered already. There were still four other rings left behind as the nebula slowly contracted, which formed the four inner and smaller planets—Mars, the Earth, Venus, and Mercury.

Our First Glimpse of Earth. Thus our first distinct glimpse of the earth shows it as a *nebulous star*, still intensely hot, and with no solid nucleus, rotating on its own axis, and at the same time revolving round the sun in a nearly circular orbit. The brilliant researches of Professor G. H. Darwin have illuminated this dawn of terrestrial history in a most curious and interesting fashion. The earth at present revolves on its axis in 24 hours—the artificial measure of time into which we divide the natural unit of the day fixed by the earth's rotational period. But it is steadily losing time. The tides which are diurnally caused by the joint attraction of the sun and moon, sweeping round the earth in the direction opposite to that of its rotation, form a friction-brake precisely analogous to that which is used on the wheels of railway carriages or motor-cars. The retardation thus caused is so small as to be imperceptible in an ordinary lifetime; it amounts only to a lengthening of the day by one second in about a thousand centuries. But in the vast periods of geological time even a tiny change like this accumulates to a serious quantity. And when the earth was still plastic, or even liquid—as it must have been in the process of cooling down from its nebulous state—the tides produced by the sun and moon in its actual substance must have operated as a far more powerful brake.

Calculating this secular retardation backwards, Professor Darwin showed that there must have been a time when the day was only two or three hours in length. The effect of tidal friction also operates on the *moon*, since, by Newton's Second Law of Motion, action and reaction are equal and opposite. The moon is constantly travelling away from the earth, and at the same time revolving more slowly. Working this problem also backwards, Professor Darwin was able to show that there must have been a time when the earth was rotating in a period of between two and three hours, and the moon was revolving round it at the same period, at a distance almost inappreciable.

The Origin of the Moon. Another step in this luminous research was to show that when the earth was a liquid spheroid, rotating rapidly about its axis, it must have been in a state of dangerously *unstable equilibrium.* We do not know the exact speed with which it began to rotate after the nebular ring had coalesced, but we do know that at first, under the influence of solar gravitation, that speed must have tended to increase. Thus the liquid globe of the earth was exposed to two contending forces — that of gravity, which held it together, and that of the so-called centrifugal force, which tended to make it break up, as a grindstone or a fly-wheel bursts when spun too fast. It can be shown that when the period of the earth's rotation had decreased to about two hours and twenty minutes, these two forces were exactly balanced. The least increase in speed would overcome the force of gravity, which of course remained constant, and something must give way.

"The Moon Flung Off From the Earth." It cannot be a mere coincidence that the calculation of the moon's motion, when it was all but in contact with the earth, shows that it must have made a complete revolution in something between two and two and a half hours. The conclusion is irresistible. Originally the moon formed an integral portion of the earth. But as the speed of the earth's rotation increased under the gravitational pull of the sun, it crept up to the critical velocity at which the earth could no longer hold together. There was a vast cataclysm, beyond anything which we can imagine, and the moon was flung off from the spinning earth—possibly in the form at first of a meteoric ring, which eventually condensed into our satellite. As soon as the moon had an independent existence, it set up vast tides in its parent earth, which acted as a powerful brake. The earth's rotation began to slow down again, and the moon began to travel outwards in a widening spiral. This beautiful theory of the moon's evolution is now generally

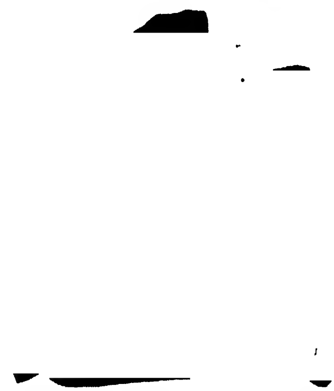


5. BELEMNITE FOSSIL FROM OXFORD CLAY

accepted. Thus we can read the history of the first, and still the greatest, geological cataclysm of which there remains any record.

The Earth and its Envelopes. The earth, as we know it, is an *oblate spheroid* [6] a globe, that is, which is slightly flattened at its poles, which are the ends of the axis about which it revolves. Its equatorial diameter is about 7,926·59 miles, and its polar diameter about 7,901·47 miles. The cause of this departure from the perfectly spherical form—which would have been assumed by the earth if its materials had coalesced under the sole influence of gravity and cohesion—is the earth's rotation combined with the solar tide. Calculation shows that the present shape of the earth is that which would have been assumed by a liquid globe rotating at its present speed, whence we conclude that the earth solidified at a time when its rotational period was practically the same as it is to-day.

The earth consists of shells, like an onion. It is a globe covered by a solid crust—the *lithosphere*—which is surrounded by an envelope



4. FOSSILS OF FERNS IN COAL SEAM

of air—the *atmosphere*—and in part by an envelope of water—the *hydrosphere.* It is the lithosphere, and especially the crust by which it is bounded, with which geology is mainly concerned. The outer envelopes are chiefly of interest from the effect which they have on the surface of the crust.

Atmosphere and Water. The atmosphere, or outer envelope of the earth, consists chiefly of the air we breathe, a mechanical mixture of the gases oxygen and nitrogen, in the proportions by volume of about 1 to 4—exactly 20·6 O to 79·4 N—with a small, varying amount of carbon dioxide and water vapour, and traces of rare gases like argon and helium. It extends perceptibly to a height of at least 150 miles, though more than half of it is compressed by gravity to within three miles of the surface. It is equal in weight to an envelope of water covering the whole earth to a depth of 34 ft., and exerts a pressure on all substances at sea-level of rather less than 15 lb. to the square inch (one atmosphere). Its geological effects are very considerable, as the rocks of the lithosphere are superficially modified by wind—laden with dust—rain, hail and snow.

The *hydrosphere,* or surface water of the earth, also plays a great part in the work of geological change. This water is sufficient, if the surface were a dead level, to cover the whole earth to a depth of nearly two miles. But the various forces which have been at work in the course of the last hundred million years or so have modified the earth's surface so that it presents considerable inequalities of level, ranging from five miles above the mean level in the highest Himalayan summits to six miles below it in the deepest abysses of the ocean. Consequently, the water of the hydrosphere has chiefly collected itself into the seas which occupy the depressed

portions of the surface, and which cover nearly three-fourths of the whole area of the earth—about 145,000,000 square miles. A considerable part of the water is always suspended as *vapour* in the atmosphere, and a complete system of circulation is set up under the solar influence. [See the Course on GEOGRAPHY.] The water evaporates from the seas, falls as rain on the land, and is returned to the sea by the rivers which it thus forms. It is one of the most effective agents in the geological operations which are constantly altering the surface of the earth.

The Solid Earth. The great bulk of the earth consists of the *lithosphere*, or solid globe of rocks, with which geology properly deals. It is on the part of this lithosphere, composing a little more than a quarter of the earth's whole area—55,000,000 square miles—which rises above the seas and is called land, that mankind lives. Practically the whole of its surface is exposed to the study of the geologist, who is also acquainted with its interior structure, as displayed by mines and bore-holes, to the depth of something over a mile. It is his business to form inferences as to the condition of the parts which he cannot directly explore. He has also to tell us why the land is diversified so much, by plain and table-land, mountain-range and valley-system; why the rivers flow through it, and what dominant force has traced their courses; why one kind of soil is better suited than another to the purposes of agriculture; and how the miner can best prospect for the shafts with which he hopes to tap the mineral resources of the earth's interior. Only a long and thorough course of study can enable him to do all this; but the principles on which he depends will be outlined in the following chapters.

Astronomy has already taught us that the earth was once so hot as to be a mere nebula, composed either of fiery gases or of glowing particles of matter such as we now call meteorites. We know, by common experience, that its surface is now cool and hard, and mostly composed of solid rocks, with a mantle of soil varying from one or two to hundreds of feet in thickness. How has this great change been brought about?

Influence of the Earth's Motion. We know that three different agencies have been at work on the original nebula. It was originally in motion, rotating around its own axis, and this motion has been preserved and handed on to the earth. It was intensely hot, and has been losing heat ever since. And it was made up of some sixty or seventy different substances—the so-called elements of the chemist—which have since entered into numerous kinds of combination with one another.

First let us consider the influence of the earth's *motion*. Everyone knows that a rotating body tends to take a circular or spherical form. If you whirl a skipping-rope round your head, its handle moves in a circle; if you spin a chain-bracelet, it stiffens into a circle as it moves; a lump of snow rolled along the ground takes a roughly spherical shape. Further, a drop of liquid always takes a spherical form, even when it is not in motion, under the influence of other forces. [See PHYSICS.] Thus the nebulous mass which was to give origin to the earth speedily assumed the globular shape which characterises every star or planet or satellite that we have yet discovered. But, as we have seen, it was also under the influence of the sun's attraction, and this combined with its rotation to make it bulge a little at the equator—though, for practical purposes, we may consider it as a perfect sphere. If we represented the earth by a globe five feet in diameter, the flattening at the pole would be less than one-tenth of an inch.

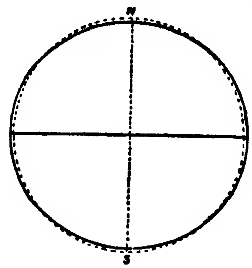
The Earth Cooling. Secondly, the nebulous earth has constantly been losing *heat* by radiation out into space. All bodies, with some negligible exceptions, contract as they cool. A considerable volume of steam liquefies into a few drops of water, which change into solid ice with very slight alteration in bulk—this, by the way, is one of the exceptions, since water expands in freezing. The great mass of nebulous matter which once formed a sphere 5,000 million miles in diameter, has solidified into the sun and planets, which all put together would form a sphere of only about one five-thousandth of that diameter. Thus the nebulous earth steadily contracted as it lost heat, until finally it began to change from glowing gas into a very hot liquid—a globe of molten rock—from which, as we have seen, the moon was shot off under the influence of the centrifugal force.

The exact steps of this *liquefying process* are still in doubt. We can never hope to trace this far-off part of the earth's history with any great accuracy; it is so much a question of inference and hypothesis. Some hold that the liquefying process began at the centre of the nebulous mass; for though the heat may have been greatest there, so was the pressure, amounting perhaps to 3,000,000 atmospheres, or 20,000 tons to the square inch—and we know that the melting point of nearly all substances rises in proportion to the pressure exerted on them. Others assert that it began at the outside, where cooling was fastest. What is certain is that it did begin somewhere, and continued until the whole vast nebulous bulk had shrunk into what we may for brevity call a liquid or plastic globe some 8,000 miles in diameter.

The Solid Crust. Meanwhile, *chemical changes* have been going forward. At the high temperature of the original nebula it is probable that all the elements existed by themselves, being too hot to enter into combination. [See CHEMISTRY.] But as they cooled they began to form compounds; the iron and the oxygen rushed together, producing some oxide of iron; hydrogen and oxygen gave birth to water-vapour, silicon and oxygen produced quartz, and so on. At this stage the history of the earth belongs rather to chemistry (*q.v.*) than to geology.

The geological story really begins with the formation of the *solid crust* on the surface of

this liquid globe. As the secular cooling went on, the outer parts of the liquid mass must have begun to harden and solidify, just as the lava from a volcano or the slag from a blast-furnace hardens when exposed to air. At first, no doubt, the hardened portions sank into the fiery liquid, and were dissolved again, but in time they began to become thicker and larger, and to adhere together, until at last the



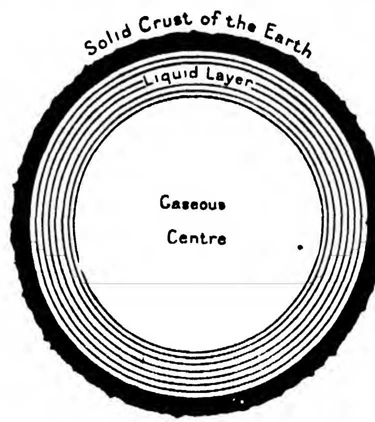
6. AN OBLATE SPHEROID ILLUSTRATING FLATTENING OF THE EARTH AT THE POLES

whole globe was covered with a skin of solid, though still intensely heated, rock. The atmosphere meanwhile shrouded this globe, and began to check the rate at which heat was lost; it contained not only the air which we breathe to-day, but all the water of the oceans and rivers in the shape of superheated steam, as well as vast quantities of carbon dioxide, much of which is now fixed in our coal-measures.

Heat of the Earth Within. An important evidence of the formation of this solid crust is to be found in the well-known fact that the earth is still *hotter within* than it is on the surface. The phenomena of volcanoes, geysers, and hot springs bear witness to the existence of some internal reservoir of heat. That this is not merely local, but universally distributed, is shown by the fact that wherever we bore into the earth's crust we find the temperature steadily increasing as we go down. On the average, the increase is 1° C. for every 90 ft. of descent. The actual rate varies widely according to the local conditions, but that is about the mean of numerous observations. If this rate were kept up, the temperature at the centre of the earth would be over 200,000° C. Probably the rate of increase does not remain so great; it must be remembered that we can follow it for only six or seven thousand feet. But there is no doubt that the interior of the earth is exceedingly hot. At a depth of 100 miles the temperature would be 5,700° above that of the surface, and no known substance would in the ordinary course remain solid. Thus the earlier view of the earth held it to consist of a solid crust, 50 to 100 miles thick, floating on a molten globe, which served as the common reservoir for volcanoes.

Condition of Earth's Interior. But this view has been seriously modified by the progress of knowledge. Astronomers have shown that, if the earth's interior were really fluid, the sun and moon would cause vast tides in it which would seriously perturb the motion of our satellite. Nothing of the kind takes place, and it has been calculated with entire certainty that the earth, as a whole, must be far more rigid than if it were a globe of solid steel. The earlier geologists omitted to take account of the immense pressures which the weight of the superincumbent strata exerts upon the materials of the earth's interior, and which greatly raise the melting-point of the ordinary rocks. [See Course on PHYSICS.] Thus, the modern view is that the interior of the earth is practically solid all through, in spite of the immense temperature which must prevail in it. The best theory is that of Professor Arrhenius, who has put forward the view that the earth is a vast bubble, consisting of a solid crust [7], perhaps 30 or 40 miles thick, resting on a liquid magma of 60 to 100 miles, which shades off into a globe of gas.

But this gas is very different in physical properties from any which we know in our laboratories. That it is gas we argue, because the temperature at this depth must be higher than the critical temperature of any known substance —*i.e.*, the temperature at which a substance can remain solid or liquid under any pressure. [See PHYSICS.] But it is gas under a pressure so vast that its density is two or three times greater than that of any known rock, and its rigidity and incompressibility



7. SECTION THROUGH THE EARTH

are greater than those of steel. Probably at least half of this gas consists of iron and other metals. It is almost impossible to realise this condition of matter, but a number of arguments—such as those based on the speed with which seismic waves are transmitted through the substance of the earth, and on some anomalies of volcanic action, as well as that derived from what we know of the behaviour of substances at high temperatures and under great pressure—make it equally difficult to get away from its necessity.

The Earth as it is. The earth, then, which geology has to study, consists of *a series of shells of matter* in different states [7]. The *central core* is a globe of about 7,600 miles in diameter, which

is composed of iron and other elements, probably not forming compounds, in the gaseous state, but exposed to such tremendous pressure that it behaves as a solid and extremely rigid body. Outside this core is a *shell of liquid matter* which consists of all the rocks which we know at the surface in a state of fusion, perhaps 100 miles in thickness. Upon this magma floats the *solid crust*, 30 or 40 miles thick, which is composed of the various rocks which we have now to study, breaking down at the surface into soil. Three-fourths of the surface of this crust are covered by the *water of the oceans*, the hydrosphere, the rest being dry land. Outside all comes the *atmospheric mantle*, chiefly composed of air, which supports life, acts as a blanket to keep the earth warm and a shield against the blows of meteorites, and extends to a perceptible height of about 150 miles.

The Materials of the Earth's Crust. Before we can proceed to consider the later history of the earth, and to ask how the hot, bare rocks, of which the surface was originally composed, have given birth to the habitable earth on which we live, with its varieties of soil and contour, we must study the materials of which they are composed. Within our limits it is possible to take only a brief survey of the more important of these.

Minerals and Rocks. We shall first consider the *minerals*, which are the chief constituents of the earth's crust, and shall then pass on to inquire how, and under what conditions, they have given birth to the *rocks* which build up the earth's surface. Two definitions may be given here, but it must be noted that they do not bear the weight of definitions in chemistry and physics.

A *mineral* is a naturally-formed non-living substance which is composed of one or more chemical substances, and has certain definite physical properties by which it may always be recognised.

A *rock* is "a mass of matter composed of one or more simple minerals, having usually a variable chemical composition, without necessarily symmetrical external form, and ranging in cohesion from mere loose débris up to the most compact stone." (Geikie).

Examples of familiar minerals are diamond, iron pyrites, quartz or rock-crystal, calcite or Iceland spar, common salt, mica. All constituents of the earth's crust are known as rocks, in the geological sense, when they occur in mass. Mud, sand, and loam are rocks, as are granite, lava, sandstone, limestone and coal.

We shall begin with an account of the chief *rock-forming* minerals, and the elements which compose them.

Chief Elements which form Minerals. The earth's crust is composed of some sixty or seventy *elements*, or bodies, which cannot as yet be analysed into simpler substances. [See CHEMISTRY.] Most of these are found in the sun and other stars, as is obvious from the nebular theory, which presupposes a common origin for bodies which form part of our system, or, indeed, of our universe. The larger number of these elements, however, play so small a part in the constitution of the earth that they may be neglected by the elementary geologist. The following list includes the elements of which 99 per cent. of the earth's crust, as known to us, is composed, with their relative proportions, as indicated by Clarke's laborious analyses of a very large number of typical rocks:

Element.	*Chemical Symbol.*	*Percentage of earth's crust which it forms.*
Oxygen	O	47·02
Silicon	Si	28·06
Aluminium	Al	8·16
Iron	Fe	4·64
Calcium	Ca	3·50
Magnesium	Mg	2·62
Sodium	Na	2·63
Potassium	K	2·32
Hydrogen	H	0·17
Carbon	C	0·12
These ten elements form of the earth's solid crust.		99·24%

Hydrogen, of course, is of importance as one of the constituents of water, which enters largely into the composition of many rocks. *Nitrogen* (N), which forms no appreciable part of the crust, should be added to the list on account of its presence in the air. For an account of the properties of these and other elements, the reader is referred to the course on CHEMISTRY. The various minerals which we have to study in geology are compounds of these elements. About 800 of these are known, and distinguishable wherever they occur by their permanent characteristics. We need only make acquaintance here, however, with a comparatively small selection of the more common minerals. Some minerals, such as coal and the ores of the various metals which enter so largely into our industries, have a practical importance which is out of all proportion to their place in the general geological scheme, and the course on MINING will deal with many which we must here be content merely to mention.

A RAPID SURVEY OF THE WORLD

The World Near the Poles. The Tundra. Cool and Warm Lands. The Deserts. Vegetation. Government and Races of the World

Continued from page 558

By Dr. A. J. HERBERTSON and F. D. HERBERTSON, B.A.

The Shaping of the Coast. The coast, or margin of sea and land, is an area rapidly wearing away under the ceaseless influence of the waves and of the sand and shingle they are perpetually hurling to and fro. Coasts may be either flat or high, composed either of hard or soft rock, and either drowned or raised. A drowned coast is one where the land has sunk or the sea has risen, so that the low grounds and valleys are flooded. A raised coast is one where the land has risen or the sea has retired, so that what was formerly the sea bottom is exposed.

A flat coast is usually sandy, often bordered by sandhills and lagoons. It may be carved into cliffs, as in the clay cliffs of Norfolk. A raised coast is usually flat from the long-continued action of the waves during the period when it was submerged. Flat coasts have no good harbours.

A submerged, or drowned, coast differs according to the nature of the submerged region. If this was hilly or mountainous, with valleys running parallel to the shore, the coast will be ironbound and harbourless unless the sea-level has risen sufficiently to give access to the valleys behind the first range of heights. If this happens T-shaped gulfs are formed. Where the valleys open at right angles to the sea they become bays, usually with excellent harbours. The hills between the valleys rise as peninsulas, or islands. If the land was flat before drowning took place a flat coast is the result.

Glaciated valleys, which have irregular floors and steep sides, form fiords when submerged, of the type seen in Norway and in the west coast of Scotland.

Where the land is composed of soft rocks a more uniform coast-line results than where it is composed of harder rocks, or of hard and soft rocks mixed. The waves in eating out the softer rocks often form magnificent sea caves, natural arches, and pinnacles.

THE LIVING WORLD

We have concluded our survey of the various forces which are continually at work on our planet. Let us briefly summarise the results. The rotation and revolution of the earth, together with the inclination of the axis, tend to equalise the distribution of temperature over the whole surface of the globe. This is further promoted by the great systems of winds and ocean currents, which cause an interchange between the hot and cold air and the hot and cold surface waters of differently heated parts of the earth's surface. In the cycle of changes which raises a drop of moisture from the ocean, carries it through the vast whirls of the atmospheric circulation, to fall at last as rain, and be ultimately restored to the ocean through the agency of rivers, we have a beautiful provision of Nature for furnishing that constant supply of moisture without which plant life, and with it animal and human life, would vanish from the earth. Our study of the rainfall system showed how this supply of moisture is distributed in the form of rain as uniformly as may be over the globe. Finally, we saw how a whole set of forces, heat, cold, and water in the form of rain and river, are working on the irregular outlines of the land surface, wearing down the heights, filling up the hollows, and tending to bring about a surface of uniform elevation over which movement in all directions would be easy. While we cannot say that all these forces are contrived to fit the earth to become the home of man, there is at least no doubt that such is their outcome.

The Far North. We have distinguished six climatic regions—the polar regions, the cool temperate lands, the warm temperate lands, the hot deserts, the hot inter-tropical lands with a summer rainy season and a winter dry season, and the equatorial lands with constant rains. Well-marked vegetation zones correspond to these.

For a varying distance round the Poles the land is so completely buried beneath ice and snow that we do not know with certainty whether it consists of land or sea. Beyond this comes the *tundra*, a poor moorland, frozen always to the depth of many feet, and covered with snow for most of the year. It has a brief summer, when the snow melts and the hard ground thaws on the surface for a few inches. A dwarf vegetation struggles into life, consisting of tiny berry-bearing bushes—cranberries and the like—and of "lichens and mosses of every conceivable colour, from the cream-coloured reindeer moss to the scarlet-cupped trumpet moss, interspersed with brilliant Alpine flowers." The only tree, if such it may be called, is the dwarf birch, dwindled to a bush a foot or two high. Towards the margin of the tundra it begins to increase in size, and dwarf pines and firs appear. The trees increase in number and size, and the tundra passes gradually into poor, thin forest.

Forests of Cool Temperate Lands. On the margin of the tundra farthest from the Poles we have a scanty forest of stunted birches and firs, gradually becoming denser till they form vast forests of noble trees. The whole of the cool temperate lands in both the Old and the New Worlds were once entirely covered with forest, consisting in the north of trees with needle-shaped evergreen leaves—the coniferous pines

and firs—and in lower latitudes of trees which lose their leaves in winter—*deciduous* trees—such as the oak, elm, beech, etc. These forests still cover hundreds of thousands of square miles in North America and Asia, but they have been cleared in Europe, except in the north and east and on the highlands of the centre. In the Southern Hemisphere they are found in the forests of Chile and Southern New Zealand.

Forests of Warm Temperate Lands. The warm temperate lands lie in less rainy latitudes than the cool temperate lands, and, except on the margins, are too dry for forests. New species of trees, better suited to warmer climates and drier, appear. In Europe the Spanish chestnut is a link between the deciduous forests of Central Europe and the evergreen forests of Southern Europe and Northern Africa, in which the commonest trees are evergreen oaks, including the cork oak, and species of pine never seen in the colder North. In the Southern Hemisphere warm temperate forests are found in the southern part of Brazil, in South America, in Natal, South Africa, and in New South Wales and Victoria in Australia. In the Australian forests the chief trees are acacias, or wattles, and different species of eucalyptus or gum-trees, with their leaves hung sideways to reduce evaporation from the surface. Over most of the temperate region however, the rainfall is so scanty that forests are replaced by steppes or grasslands.

The steppes are found towards the interior of the continents in the warm temperate belt. The climate is extreme and the rainfall scanty. After the severe winter the ground thaws and becomes very moist, while the sun is powerful, so that vegetation comes on with a rush. Plants which quickly come to maturity do best in such conditions, as may be easily imagined by those who have watched the unequal race between perennial plants and quick-growing annuals in any garden. Trees require many seasons for growth, while grasses germinate, bloom, and die in a few weeks. On the steppes the latter shoot up with great rapidity, and with a few weeks of hot sun and thunder-showers they grow to the height of a man. Trees have no chance against them. Little saplings a few inches high struggle for life every spring, but they are quickly choked in the sea of grass, and cut off from light and air. Bulbous plants, which root easily in the loose soil and come into bloom before the grass is too high, also do well. They form a beautiful feature of the steppes in spring.

An Ocean of Green and Gold. "Boundless tracts," writes a traveller, "are resplendent with tulips—yellow, dark red, white, white-and-red. Immediately after the tulips come the lilies. They completely dominate wide stretches. Usually each species is by itself, but here and there blue lilies and yellow are gaily intermingled." Another writer, describing the steppes later in the year, says: "The steppe was nothing less than a green-gold ocean, whose surface seemed besprinkled with millions of different coloured flowers. Here, through the tall, thin grasses, were to be seen purple, blue, and violet cornflowers; there the pyramidal top of a yellow vetch shot up suddenly; there the umbrella-shaped heads of clover shone like so many white spots; some ears of wheat, brought Heaven knows whence, were slowly ripening among the grass." Early maturity is followed by early decay By July the steppe is parched and brown, and the animals are dying from thirst in a treeless land, where shade is unknown. Autumn finds a barren, desolate land.

In the Southern Hemisphere steppe lands are found in Patagonia, in South America. The grasslands of the karoo and veld in South Africa are a transition type to the savanas described below.

Where the rainfall diminishes, as it does towards the Equator and away from the sea, the vegetation of the steppes becomes poorer, and they pass gradually into desert or semi-desert.

The Hot Deserts. The hot deserts lie in the trade-wind area, or in their lee, as we saw in studying climate. They are, like all the vegetation zones, most extensive in the Northern Hemisphere, and particularly in the Old World, where the land is broader in the latitudes of the trade winds than in the New World, or in the Southern Hemisphere. The Desert of Sahara, which is continued by the deserts of Arabia, Persia, and Central Asia, forms an almost continuous belt, the most extensive desert area in the world. In the New World we find the deserts of the western United States in the Northern Hemisphere, and the deserts of Peru and Chile in the Southern. The other deserts of the Southern Hemisphere are the Kalahari desert of South Africa and the desert in the interior of Australia, the second largest in the world.

The surface of a desert may be either flat or hilly, and composed either of sand, stones, or white alkaline deposits. The character common to all is the more or less complete absence of vegetation, due to the lack of rain, and not necessarily to any natural infertility of the soil. What vegetation exists is of hard, prickly plants, whose leaves are adapted either by their shiny, leathery surface or by their small spinelike character to lose as little moisture as possible by evaporation from their surface. [The mode in which plants breathe and perspire is described in NATURAL HISTORY.] Aloes and cactuses are the characteristic plants of the American deserts, gum acacias and tamarisks of the Sahara, the wait-a-bit thorn and other prickly plants of the South African desert, and the dreaded spinifex and mulga of the Australian deserts.

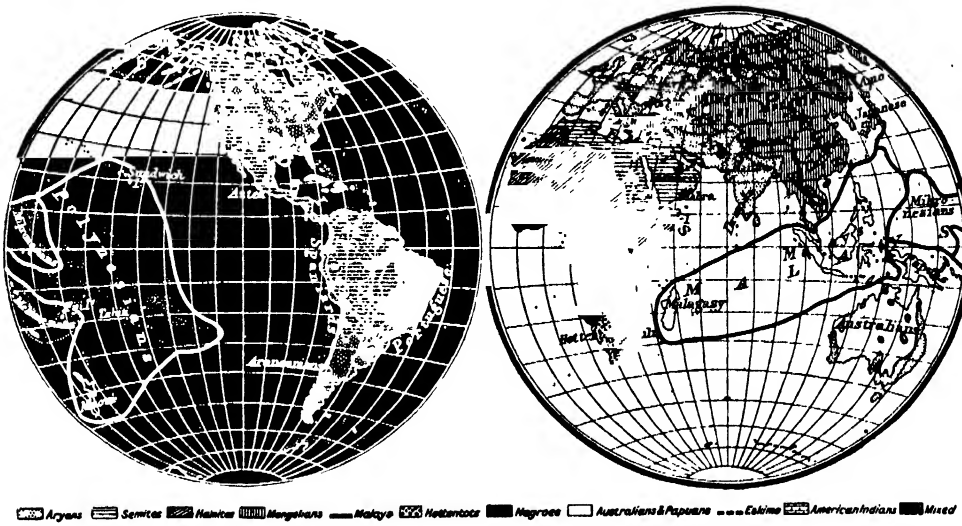
How Water is Stored in the Deserts. Many desert plants possess the power of storing up water, generally in their roots. The natives of Australia are skilful in obtaining water from the long roots of the mallee, a desert eucalyptus. A plant of the North American desert is known by the expressive name of the "well of the desert." By cutting out its centre a bowl is formed which quickly fills with excellent water. In the Kalahari desert the water-root has saved hundreds of dying from thirst. The ground round its large oval bulbs is generally so baked

that it has to be hacked away with a knife. Its bulbs are eagerly sought by both man and the lower animals.

The desert is infertile because it is too dry for vegetation. Rain falls at rare intervals, and then usually in torrents, filling the dry river-beds for a few hours with a raging torrent. In various parts of the desert springs occur, and then fertile spots, or oases, break the monotony of the scene. The waters of the springs are carried by means of canals to every part of the oasis, the size of which depends on the quantity of water available for this purpose. This mode of supplying cultivated lands in the dry regions with water from a spring or river is called irrigation. In the oases of the African and other Old World deserts the date palm is the chief product; but other fruits, as well as cereals and cotton, are cultivated. In many of the drier regions of the world use is made of the great stores of underground water. Very deep wells are sunk till these are reached, after which irrigation becomes possible. Thousands of such wells have been sunk in the drier parts of Australia and the United States.

Vegetation of Hot Lands with a Summer Rainy Season. Such hot lands are found on both sides of the wet equatorial belt, extending as far as latitude 35° or 40°, according to the height, exposure, and configuration of the country. The cause of the summer rainy season has already been explained. This savana region, as it is called, consists of grasslands with clumps of trees which do not form woods or forests. The trees are of kinds unknown farther north. They have massive trunks, with thick bark, and many spread out their branches in umbrella fashion. Many of them store up water against the dry season, which, though winter, is still hot. Lands of this type, with fine trees dotting a grassy landscape, are often called parklands, from their resemblance to the scenery of an English park. They are found in the northern part of South America, where they form the llanos of Venezuela and Guiana, and south of the Equator in the campos of Brazil and in the pampas of Argentina. They occur in Africa, north and south of the Congo forests. In Australia the Darling Downs, and other grasslands of the north, are in the savana region, which is restricted in area by the widespread drought of that continent. Parts of India, South-East Asia, and the East Indies, usually at some elevation, are also savana lands. Savana lands due to elevation are found on mountains in the equatorial belt at the height of a few hundred feet.

The Equatorial Forest. On each side of the Equator are regions of constant heat and moisture, forming a sort of natural hothouse. Nowhere else does vegetation develop in such luxuriance. Trees known in other latitudes as dwarfs become giants, and new and colossal species appear. Dense forests cover many thousands of square miles in the basin of the Amazon in South America, in the Congo basin of Africa, and in South-East Asia and the adjacent islands. Many of the Pacific islands are also densely forested.



51. THE RACES OF THE WORLD, AND THEIR HOMES

Perhaps the best description of the equatorial forest is by Stanley, in his description of the forests of the Congo. "Imagine a space," he writes, "four times the size of England, Scotland, and Wales crowded with colossal trees 200 ft. in height, with their thick, glossy foliage so interlaced that the hot, glaring sun of the tropics is quite shut out. Each tree is seemingly lashed to every other by endless lengths of numberless cables ranging from tender, thread-like creepers to others of the thickness of the old hempen hawsers of a line-of-battle ship. Underneath the thick, impervious shade is the impenetrable undergrowth, so close that you could

travel easier above the top of it. Imagine the forks of each tree crowded with little conservatories of orchids and ferns, and their great horizontal limbs burdened with grey-green lichens with leaves as large as prize cabbages, and with drooping epiphytes, or air plants, as well as hosts of tendrils swinging ceaselessly about, and here and there great swaying walls and nodding towers of vines, round the flowers

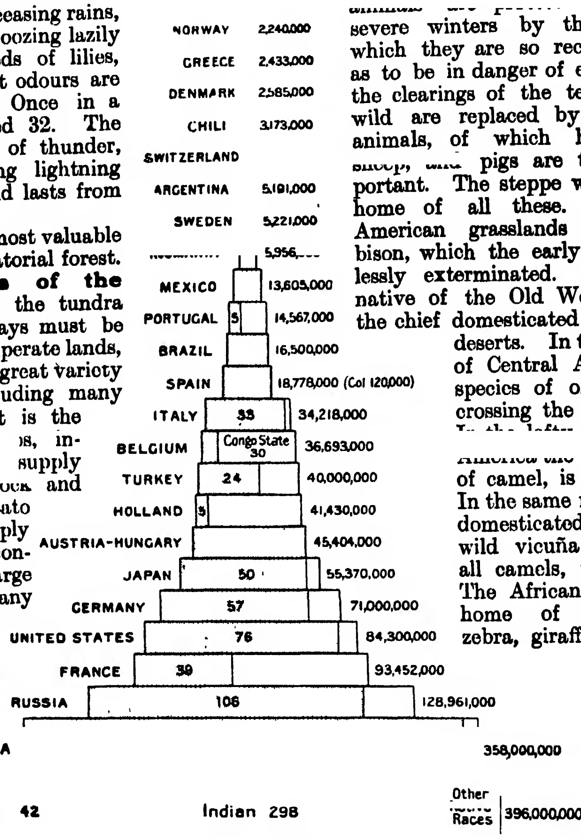
palm along the shores, the bread fruit, and roots such as the yam are grown.

Animals. The wild animals of the world disappear rapidly wherever man penetrates, and domesticated animals are introduced by him wherever he makes permanent settlement. In the Polar seas the seal and walrus are hunted for their furs. In the tundra the reindeer has been domesticated. Its hoof is specially fitted for moving over the boggy ground in summer, in winter beneath.

bank, and fed by never-ceasing rains, coursing impetuously or oozing lazily from under floating beds of lilies, while the sickening-sweet odours are almost overpowering. Once in a 10-mile march we crossed 32. The rain comes after bursts of thunder, with displays of dazzling lightning and raging tempests, and lasts from four to fifteen hours."

Rubber is among the most valuable wild products of the equatorial forest.

Cultivated Plants of the Various Zones. In the tundra agriculture is and always must be impossible. In the temperate lands, warm and cool, we get a great variety of useful products, including many cereals, of which wheat is the ... is, in- supply winter fodder for live-stock and those which, like the potato and sugar beet, supply articles for human consumption; a very large range of fruits, and many industrial plants. The range of products is, on the whole, greater in the warmer lands, as the plants of cooler latitudes can be grown at suitable elevations. In the warm temperate lands maize and millet become the most important cereals. Rice and cotton, which are sub-tropical plants—that is, belong to latitudes near the tropics, are grown in the hottest parts. The steppes are grazing lands, but where not too dry are very suitable for the cultivation of cereals. In the savanas the banana becomes an important article of food, and coffee, sugar, ... At elevations most temperate products do well. In the equatorial forest belt there is little agriculture, except of a primitive type in the clearings. In the forests of Eastern Asia the sago palm is a staple food. In the Pacific islands the coco-nut



52. POPULATION OF THE CHIEF STATES OF THE WORLD

The population of the Home Country is shown by the shaded area. The figures inside the rectangles give population in millions

severe winters by thick furs, for which they are so recklessly hunted as to be in danger of extinction. In the clearings of the temperate lands wild are replaced by domesticated animals, of which horses, cattle, sheep, and pigs are the most important. The steppe was the original home of all these. The North American grasslands teemed with bison, which the early pioneers recklessly exterminated. The camel, a native of the Old World steppes, is the chief domesticated animal of the deserts. In the higher parts of Central Asia the yak, a species of ox, is used for crossing the highest passes. In the lofty Andes of South ... of camel, is similarly used. In the same region the semi-domesticated alpaca, and the wild vicuña and guanaco, all camels, may be noted. The African savana is the home of the elephant, zebra, giraffe, lion, leopard, rhinoceros, and innumerable antelopes, while the hippopotamus haunts the rivers. In the tropical forests of Asia the tiger lurks, but large animals are not numerous in the equatorial forest anywhere. The animals of South America differ considerably from those of Africa. The largest beast of prey is the puma, or South American lion. Australia, when discovered, was very poor in animals. The most remarkable was the kangaroo. Of animals introduced by Europeans the rabbit has bred till it is a dangerous pest.

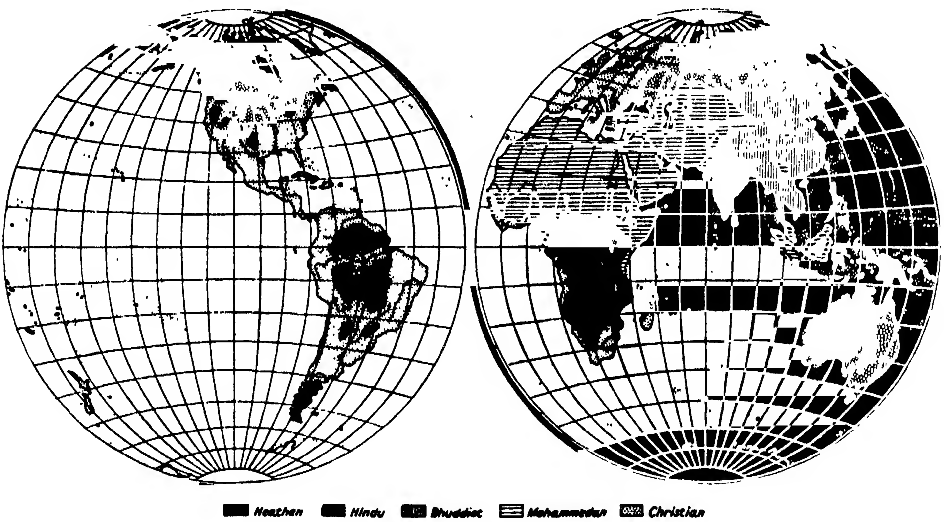
A word must be said of creatures hostile to man. The mosquito is supposed to be the means by which malaria is spread, and if so, many parts of the world will continue dangerous till it is exterminated. The tsetse fly of Africa

prevents the keeping of animals where it is found, and unfits large areas for settlement.

Man. Man is the most widely distributed of all animals, being found from the polar seas to the equator. This he owes to the possession of superior intelligence, which enables him to suit himself to his surroundings. It is often said that man conquers Nature—a difficult task. It is truer to say that he co-operates with Nature, adapting himself to her imperious laws. He becomes hunter, fisher, keeper of animals, farmer, as the character of his home suggests, and thus he can live almost anywhere. His great discoveries have been the making of fire and the practice of agriculture.

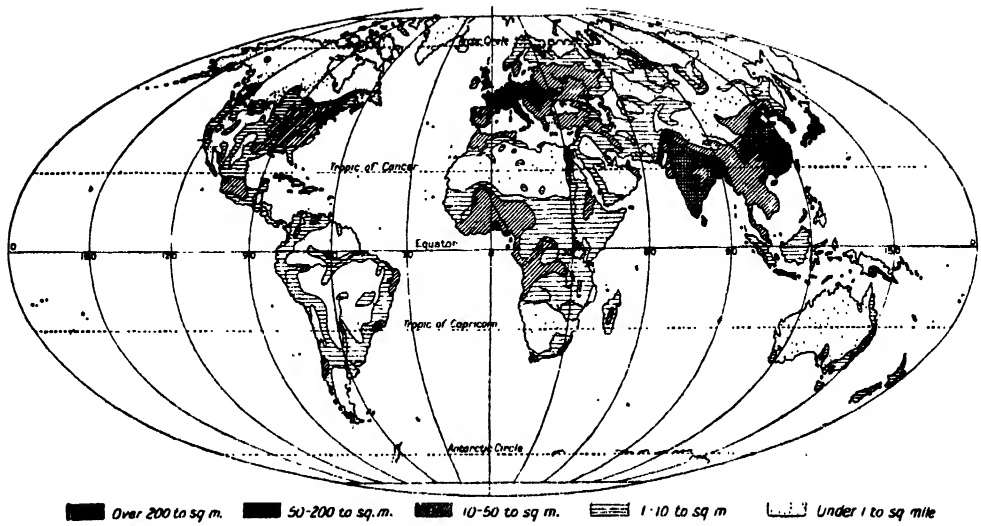
Races. There is no general agreement as to the number of races in the world [**51**], and experts cannot agree whether all have developed from one, nor what was the place of origin. The white, or Caucasian race, many branches of which are very dark in colour, occupies most of Europe, and a great part of Asia. Its members have also colonised all the New World, South Africa, and Australia, and are now trying to settle in the tropics. The yellow, or Mongolian race, occupies Eastern Asia. In South-east Asia is the Malay, or brown race. A great part of Africa is occupied by the black, or negro race. There is a large negro population in the southern parts of North America and in Brazil, descended from slaves imported from Africa. Peoples of negro blood are also found in Southern Asia, and the Malay Archipelago, and in the islands of the Pacific south of the equator, and west of 180°. The inhabitants of the other Pacific islands are probably of very mixed blood. The aboriginal inhabitants of the New World, or Indians, are sometimes classed as belonging to the Red Race, and are probably descended from the Yellow races. Certain peoples, like the Pigmies of the Congo forest and the Bushmen of South Africa, seem to belong to a primitive dwarf race, perhaps the earliest type of man [**52 and 54**]. The different races regard each other with dislike. The white race, in particular, declines to intermarry with the others, though irregular unions have produced a fairly large half-caste population. It is doubtful if this attitude can long be maintained. Japan, now a first-class Power, will conceivably claim to intermarry with European reigning houses, and it is difficult to see how the privilege could be refused. This would introduce a new principle into the world, and might naturally lead to the formation of a composite race combining the best qualities of each.

Religion. In Europe, and countries colonised from Europe, the prevailing religion is Christianity in one or other of its great forms—Roman Catholicism, Greek Catholicism, and Protestantism, the last-named including many sects [**53**]. In Turkey the religion is Mohammedanism, a creed which finds a following from the Atlantic to the Pacific, but is especially powerful in the desert and semi-desert lands of Africa and Asia. Only Buddhism, largely professed in Central and Eastern Asia, can be compared with these two in universality. Brahminism, a philosophical Nature worship, has millions of adherents in India. Confucianism in China, and Shintoism in Japan, are both primarily ethical. The African savana and forest lands and the islands of the Pacific produce many varieties of degrading and cruel religious beliefs.



53. THE RELIGIONS OF THE WORLD

Government. In early stages of society there is probably no choice between anarchy and despotic government. A relaxation of despotism comes with advance in civilisation. Despotic government is still the rule, except among the white races. In Europe the government of Russia is practically despotic. Turkey, though nominally a European Power, preserves the despotic ideas of her Asiatic origin. With the exception of France and Switzerland, which are republics, the countries of Europe have



54. DENSITY OF POPULATION ALL OVER THE WORLD

hereditary rulers, whose power is more or less limited by constitutional safeguards. The characteristic form of government of the modern world is a federal republic under an elected president. It is universal in the New World, except in British, Dutch, and Danish Colonies.

World Powers. The nineteenth century witnessed a revolution in the conditions of transport. This has brought all parts of the world to within a few days or weeks of each other, and has led to the growth of world Powers, with colonies and dependencies in many parts of the world. The British Empire, the greatest in population and area, stretches through all latitudes, and is equally powerful in both the Old and the New World. Its constituent parts, where of white blood, are, with rare exceptions, permitted full self-government. Elsewhere the government is despotic, but extremely just. The Russian Empire extends across Asia to the Pacific, and is throwing out feelers towards the Persian Gulf. It is everywhere despotic. France has colonies in Eastern Asia and Northern Africa, and shows great organising power. Germany is creating an empire by acquiring territory in Africa and important interests in South America and Asia Minor [55]. Finally, the United States and Japan have both within the last few years acquired territory outside their own borders.

55. THE EUROPEANISATION OF THE WORLD

A striking example of the influence of Europe, which, though one-fourteenth of the land in area, controls six-sevenths of this. The word European is obviously used in its comprehensive sense, embracing races of European descent.

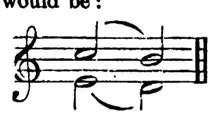
FIGURED BASS & COUNTERPOINT

Theory of Figured Bass. Choosing Harmonies. Counterpoint. The Fugue. Books to Study. Conclusion of "Musical Theory"

By J. CUTHBERT HADDEN

IN the old-fashioned pedagogic study of harmony, vast attention was paid to what is called "Figured Bass"—a kind of shorthand used by musicians, wherein the intervals which the notes of a chord form with its bass are expressed by figures. It is really of little practical value, for no composer begins by writing a bass to be fitted with harmonies; he begins with a melody, and sets harmonies to *that*. Nevertheless, the system of figured basses is still much used for students' exercises, and it is necessary to know something of the principles upon which it is founded.

Stated in a word, these figured basses are simply a system of interval measurement from the lowest note of the chord. Thus, a bass note to be accompanied by a common chord (eighth, fifth, and third) would be figured $\substack{8\\5\\3}$ or $\substack{5\\3}$. In practice, however, the common chord, being *so* common, is left unfigured, it being understood that an unfigured bass note is to bear a common chord. First inversions are figured $\substack{6\\3}$ or simply 6, second inversions $\substack{6\\4}$. A discord of the seventh is expressed by the essential figure 7, its inversions, in their order, by $\substack{6\\5}$, $\substack{4\\3}$, and $\substack{4\\2}$. A discord of the ninth (including a seventh) is figured 9, and the inversions 7, $\substack{6\\5}$, $\substack{4\\3}$, and $\substack{4\\2}$. The latter figures correspond with those for the inversions of the seventh, but the student can always distinguish a seventh from a ninth by the root note and generally by the resolution. When the same bass note is to bear two separate chords, the figures indicating these are always given. For example, if $\substack{6\\4}$ $\substack{5\\3}$ were placed below the bass note G, the result would be:



When accidentals are to be introduced, the necessary indication (sharp, flat, or natural) is placed before the figure representing the note to be affected, an accidental without a figure invariably referring to the third from the bass. Such are the foundation principles of figured bass. It is a very complicated system when taken in all its details, and in a work of this kind no good purpose would be served by a more extended exposition of it. Ninety-nine students out of every hundred want to "set" melodies, not basses.

And it is really much more difficult to choose appropriate harmonies for a given melody than to fill up a figured bass, which at best is a mechanical exercise. In setting about the harmonising of a melody, the student should give preference to the fundamental chords of tonic, dominant, and subdominant, either in root positions or inversions. It is by these major chords that strength and substance are imparted to a composition. But the three minor chords of the scale afford an agreeable relief, and these should be used along with the major chords as contextual and other conditions will allow, giving preference to the chord of the supertonic, next to that of the submediant, and last of all to that of the mediant. In the choice of inversions, be guided to some extent by the progressions of the bass itself regarded as a melodic part. Secure contrast whenever possible in the progression of the two most prominent parts of the harmony, so that if the melody moves by large intervals the bass shall move by small ones, and *vice versa*. A judicious mixture of discords will give still further variety, and the same may be said of passing notes, when the character of the composition will allow of their introduction. At first the student will often hesitate about the particular chords to use for the notes of his melody, for every melody may be fitted with a great variety of basses.

On this point we quote the late Dr. John Hullah. He says: "In the choice of roots for the several principal notes of a melody, its division into sections should first be ascertained; then the keys in which these severally end, and (as a necessary consequence) the cadences, perfect, imperfect, or plagal, of which their penultimate and ultimate notes form part. . . . In harmonising passages which modulate, or imply modulation, care should be taken, at the moment the modulation is about to be made, to use only such chords as belong both to the scale about to be quitted and to that about to be entered." In at least all his earlier attempts at harmonising, the student should always take means to put what he has written to the test of actual sound. Only in this way, and by a liberal use of manuscript music paper, can he hope to attain facility and success in the fitting of parts to a melody.

Counterpoint. The word *counterpoint* has a flavour of antiquity about it. And counterpoint is, indeed, a very ancient science, for it came before harmony strictly so called, and governed the art of musical composition well-nigh to the close of the sixteenth century. Nowadays the student who is well grounded in harmony often shirks counterpoint altogether, regarding it as superfluous. In any case it is customary to teach

harmony before counterpoint. The late Sir George Macfarren urged that students should reverse the process; that they should "master the laws of counterpoint, and so approach the fundamental or massive harmonic school by the path of history." This would be pedantic. The more usual method of teaching counterpoint presupposes a knowledge of harmony.

But what *is* counterpoint, and wherein does it differ from harmony? The word means literally "point against point" (*punctum contra punctum*)—that is, in modern terms, note against note. Notes were formerly termed "points," and adding a counterpoint meant setting one point or note against another. To combine notes—rather let us say melodies—one with another is the essence and aim of counterpoint. Every part must be of equal interest. This is how counterpoint differs from harmony. In harmony a melody is accompanied without special reference to the inter-relation of the parts. As a French theorist puts it, there is a material ready made to begin with—namely, chords. These the harmonist combines, modifies, links together; but they are always chords. Counterpoint recognises nothing of this kind. The chord is not a personality to the contrapuntist; he takes no heed of its name or its existence, and considers notes only in respect of their reciprocal distances, their consonance or dissonance, and their affinities. In a word, counterpoint is the art of combining *melodies*.

Simple and Double Counterpoint. Having thus cleared the ground, we proceed to a concise review of this somewhat abstruse art. The first thing to be noticed is that counterpoint is classed under the two broad divisions of "simple" and "double." When the parts are to be performed as they stand, the counterpoint is "simple"; when they are capable of being inverted, so that the higher part may become the lower, or *vice versa*, the counterpoint is said to be "double." Next, observe that counterpoint is divided into five distinct orders or "species." A "subject," technically called the *canto fermo*, is taken, and according to the manner of treating this subject, so is the particular "species" of the counterpoint. Here are the five kinds or "species":

First species. Literally "note against note"—*i.e.*, every note of the *canto fermo* accompanied by a note of equal value in the counterpoint.

Second species. Two notes—in triple time, three—against each note of the *canto fermo*.

Third species. Four, six, or eight notes against each note of the *canto fermo*.

Fourth species. With syncopations and suspensions.

Fifth species. Florid or figurate counterpoint, in which all the previous kinds are combined, with additional ornamentations.

Notice, next, that there is a *strict* counterpoint and a *free* counterpoint. In strict counterpoint (the older form) diatonic progressions are chiefly employed, discords being admitted only as suspensions or passing notes. In free counterpoint, on the other hand, all sorts of dissonances and progressions unknown to the strict style are allowed. Practically, it is part-writing in the modern style, for it is founded on modern harmony. In all counterpoint the means, compared with harmony, are vexatiously limited. Thus the only concords recognised are the octave (or unison), the perfect fifth, and the major and minor third and sixth. All other intervals are discords, including the perfect fourth when it stands between the lowest and one of the upper parts. Add to all this that each of the five species of counterpoint is written in any number of parts, from two to eight or more, each form (as regards the number of parts) regulated by its own special laws, and it will be seen how futile would be an attempt to encompass the subject in a work of this kind. Perhaps the best way will be to take two-part counterpoint of the various species, show by musical notation its actual nature, and state some of the rules which govern each particular species.

We have then the *first species*, where the added part is note against note of the subject. This is illustrated here by Cherubini:

In this species only consonances are used, the beginning being a perfect consonance, unison, octave, or fifth; the end a unison or an octave, preceded by the leading note.

In the *second species* we have two notes against one.

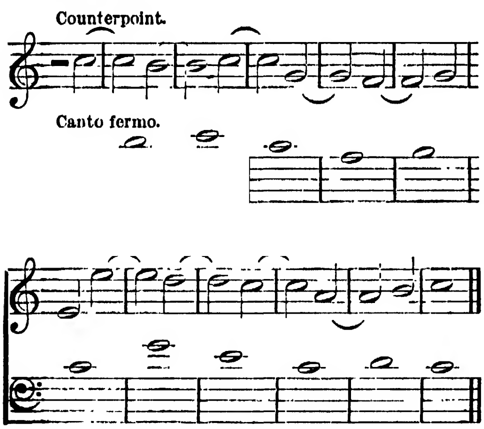
Here, again, the beginning should be with a perfect interval, and it is considered better to

start the counterpoint after a minim rest. The last bar but one should contain the leading note, preceded by the submediant if the counterpoint is in the upper part; by the dominant if in the lower.

The *third species* shows four quarter-notes in the counterpoint to the whole note of the *canto fermo*, as in the following example from Albrechtsberger:

In this species the first bar usually begins with a crotchet rest, and in the last bar the counterpoint note must be of equal value with the *canto fermo*.

In the *fourth* species the added part is in syncopation (tied notes) to each note of the *canto fermo*. Thus, in an example from Ernst Pauer:



The unaccented part of the bar, which always carries a consonance, becomes here, by the rhythmic displacement, the accented. The first measure of the counterpoint must contain a half-note preceded by a half-rest. The close is made by the suspended leading note, in the penultimate bar, and the tonic, a whole note, in the final bar.

The *fifth species* (florid counterpoint) is, from the composer's point of view, the most interesting of all. It is an absolutely free mingling of the four species preceding, to which may be added, for further variety, dotted half-notes and eighth-notes joined two by two. The following is an example:

These, then, are the five kinds of simple counterpoint. We have not quoted a third of the rules regulating each individual species. The first species, for example, is bound by something like a dozen separate restrictions, and if some of these are relaxed for the other species, new restrictions immediately take their place. The student, in short, will find counterpoint a very severe form of exercise. A French writer sympathetically describes the student of music as "feeling singularly hampered at first, and for some time scarcely able to move at all." But he will become accustomed to this, and later take great pleasure in what had at first appeared quite insupportable. The most exhaustive and up-to-date treatise on the subject is Professor Prout's, but the student will find Sir Frederick Bridge's primers in Novello's series of great practical value; also Dr. Pearce's "Student's Counterpoint" and "Composer's Counterpoint."

The Fugue. The *fugue* is the highest form of composition in counterpoint. All the "species" are employed in it, and a special "build" is imposed, from which there is no escape. The term is derived from the Latin, *fuga*, meaning "flight"; and the characteristic of a fugue is that the parts seem to be constantly flying from or pursuing each other. This was emphasised by the remark of a cynic, who regarded the fugue as a dry form of composition, that the parts "flew away from each other, and the listener from them all." The constructive elements of a fugue are made up of: (1) The *subject*, or principal theme; (2) the *answer*, at the fifth above or the fourth below; (3) the *counter-subject*; and (4) the *stretto* (Italian, meaning "narrow," "drawn together"), in which the subject and the answer are brought as close together as possible for the purpose of heightening the interest. There are accessory elements—episodes, counter-expositions, etc.—which, however, cannot be dwelt upon here. It will do the student greater service to quote the German theorist and composer Fux, who gives concise directions

for the construction of the fugue in its simplest form.

How to Construct the Fugue. "First (he says), choose a subject suitable to the key you intend to compose in, and write down your part in that part wherewith you intend to begin. This done, and having first examined your subject, to see that it be conformable to your key, repeat the same notes in the second part, either in the fourth or fifth; and while the second part imitates the first wherewith you have begun, put such notes in the first part as will agree with your imitating part, according to the directions given in the figurative or florid counterpoint; and after having continued your melody for some bars, regulate the parts thus that the first cadence may be made on the fifth of the key. Then resume your subject mostly in the same part you have begun with, but by another interval, after having first put a rest of a whole or half bar, which, however, may be omitted in case there should be a great skip instead of it. After this, endeavour to bring in your second part, after some rest, and that before the first part draws to a conclusion; and having carried on your subject a little longer, make your second cadence in the third of the key. Lastly, introduce your subject again in either part, and contrive it so that one part may imitate the other sooner than at first, and if possible after the first bar, whereupon both parts are to be united, and the fugue finished by a final cadence."

Examples of the Fugue. These are abundant in classical music, for every composer has written something in this form. The greatest of all fugue writers was Sebastian Bach, whose "Forty-eight Fugues" and other numerous organ and choral fugues, monuments of constructive genius, ought to be familiar to every student of this most scientific branch of musical composition. Bach, as an acute critic remarks, understood how to unravel all the scientific and artistic mysteries, to throw life, fluency, grace, and charm into his fugues; and he alone was able to present an almost unceasing variety of subjects, while he possessed inexhaustible means of enriching the beauty and power of his themes. There is an admirable little work on Fugue by Mr. James Higgs (Novello), which the student will find helpful.

Musical forms can be dealt with only very briefly. The *sonata* is the most important of the instrumental forms. According to modern use, it has generally four separate movements—the first in the elaborate so-called sonata form; the second in some slower time; the third a minuet; and the fourth (the finale) usually a rondo. The second and third movements are interchangeable. Each movement may be said to form a separate composition, and yet possess a connection with the other movements. "A certain unity of feeling must pervade the whole." The masterpieces in this form are chiefly the work of Beethoven, Haydn, and Mozart. The structure of the sonata applies also to the *symphony*, in which a certain number of instruments are united "to produce a poetical representation of a series of emotions of the soul." It has a broader and grander treatment than the sonata, as witness Beethoven's "Pastoral" or "Eroica" symphonies, compared with any of his sonatas. In the *concerto* we have a piece in three movements, in which one particular instrument (piano or violin) is regarded as the solo instrument, and is accompanied by a small or larger orchestra. The *overture* stands half-way between pure symphonic art and musical dramatic art, and is derived from both. Its object usually is to "prepare the spectator for the emotions of the drama which is about to be performed in his presence by placing him in the mood most suited to receive the impression vividly." Hence it is often constructed out of the material of the work itself, or filled with allusions to its principal themes.

Books to Study. Such are the leading instrumental forms. It would be impossible to describe in detail the form of the chant, the chorale, the anthem, the part-song, glee, and madrigal, the march, the various dance forms, the suite, the rhapsody, the string quartet, the fantasia, and the variation, to say nothing of extended works like the opera, the oratorio, the mass, and the cantata. Some of these are briefly described in the glossary on page 42. For fuller details the student should consult such works as Ernst Pauer's "Musical Forms" (Novello), or the articles under the various headings in Grove's "Dictionary of Music and Musicians."

We thus conclude our survey of the theory of music. With the more advanced branches of the subject it has necessarily been a case of merely placing the student on the road leading to the heights. Much that a Beethoven and a Wagner knew has perforce been omitted. But the foundations have been laid, and with the aid of the more exhaustive works of the theorists the student can readily rear his superstructure. Professor Prout, our greatest living master of theory, has completely covered the subject in a series of works which are unrivalled in any language. To these the student aiming at the very highest attainments must be referred. The musical theory books are legion, but none are better, none more exhaustive, than those of Professor Prout.

THE FARMER'S SEEDS

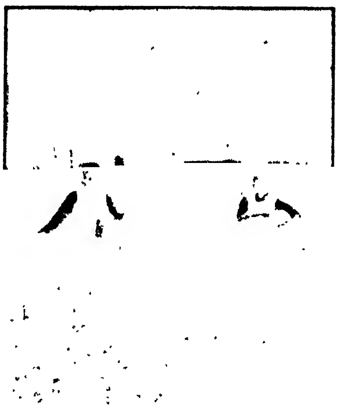
Construction of Seeds. How to Sow. Efforts for Light and Air. Effects of Wet and Cold. Weight of Seed. Increasing the Crop

Group 1
AGRICULTURE
5
Continued from page 590

By Professor JAMES LONG

SUCCESS in agriculture in the future lies in the application of scientific method. The young farmer who would succeed beyond his fellows will do well to ascertain, by confirming facts for himself, and by simple methods of observation and experiment rather than by reading or hearing, how seeds are constructed, and how the embryo plant within the coat is enabled to germinate, to feed, and to grow. The remarks which follow will, it is hoped, not only afford him some assistance in these directions, but enable him to carry out some such process of acquiring knowledge at first hand, although they are necessarily limited.

The Plant's Start in Life. A seed has been described as a miniature plant, although it is something more, for it contains sufficient food to give the tiny living organism a start in life, until, indeed, by the development of its roots and its leaves, it can shift for itself. The seed is developed from the flower, and it is as interesting as it is instructive to watch this development from day to day. Seeds differ in form, size, and structure; they differ also in that while some germinate at a relatively low temperature, others will not. The range of temperature, which applies to the seeds of farm plants, is broadly between 40° F. to 100° F. Thus, while 65° F. to 70° F. may be regarded as the most generally suitable on the farm—although germination is more rapid at the higher temperature—it fails altogether beyond the extremes mentioned. The germination of seed, too, depends much upon the depth at which it is sown. Few seeds will grow when deposited six inches below the surface, while the deeper they are sown within this range the longer they are in making their appearance, and the larger the number of failures.



BROADCASTING THE SEED

Seeds should be sown as nearly as possible at a specific, and always regular, depth—the depth depends upon their size and their variety. It is quite common, for example, to broadcast very small seeds, such as those of the grasses and clovers, on the surface, and to cover them with the harrow. The result is that many remain uncovered, and, being induced to germinate or sprout by contact with the moist soil, many are subsequently malted or killed by the sun. This is an important point to note. Such seeds should be covered by at least half an inch of fine soil, and subsequently pressed with the roller to provide them with a compact bed.

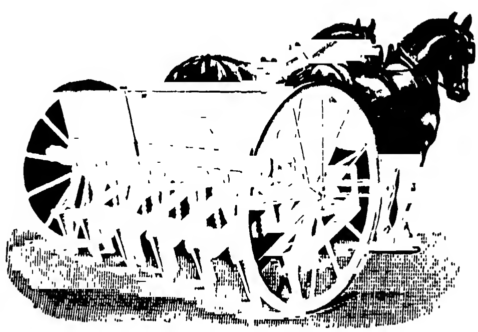
The Behaviour of Seed. Farm crops are nearly all grown from seed, much of which is impure or so lacking in vitality that it fails to germinate or to live. The process of germination and subsequent growth may be observed by the adoption of one of many simple methods. A hundred seeds, preferably those of barley or oats, may be placed upon a porous tile or saucer—preferably one of those employed in a seed-testing station—which is allowed to stand in a larger saucer well supplied with water. As the water rises and comes into contact with the seed, the latter swells and sprouts, thus proving that moisture is essential to germination. This, however, is not all; the seed must be in contact with air, which must be sufficiently warm—as in the living apartment of a house—for, as we have seen, it will not germinate at a low temperature. In a few days it will be possible to count the number of worthless seeds, and, consequently, to ascertain the percentage of germination. By observing the process of growth, the *radicle*, or root, and the *plumule*, or stem, will be recognised, while in due course the leaves will appear.

An Instructive Experiment. A still more instructive experiment may be made, and this time by the aid of seeds of much larger size. We take the broad bean, which for this reason is usually employed in demonstration, and we plant a number of seeds side by side in fine deep soil, at various depths, ranging from 1 to 6 in., several seeds being planted at each depth. From day to day we take up one seed at each depth, and examine its progress. We note the temperature of the soil, and subsequently the rapidity of germination. We find that, as before, the root and stem appear, but that, unlike the oat, the entire contents of the husk or shell of the bean is practically composed of what we subsequently recognise as seed-leaves, but which are known as cotyledons. These leaves provide nourishment for the young plant, whereas in the case of the oat and other cereals, this food is found in the flour which forms the bulk of the seed, and which is known as starch. Plants, however, being unable to feed upon solid materials, Nature provides a method, through

the medium of a ferment known as diastase, of converting the starch into sugar during the process of germination. Sugar being soluble, is therefore easily appropriated.

Influence of Light and Air. It will be noticed that however the beans are laid in the soil, the stem grows upwards towards light and air. If we exclude air, growth is prevented, while if we exclude light, we shall find the leaves retain the whiteness of colour which always distinguishes them before they emerge from the soil. The green colour of the leaf is owing to the presence of a colouring material known as chlorophyll. It has been remarked already that the plant, after germination, is fed by food stored within the seed. This food is quickly exhausted, but it so far enables the seedling to develop its plumule and leaves, and its radicle, that it may be placed in a position to obtain food for itself from both soil and atmosphere.

We have seen that the seed is stored with starch, upon which, after conversion into sugar, the seedling is fed. Starch, like sugar, is known among feeding materials as a *carbohydrate—i.e.*, it is a compound of carbon, hydrogen, and oxygen, the two latter elements existing in the compound in practically the same proportion in which they are combined in water—*i.e.*, two parts of hydrogen to one part of oxygen. Starch, like sugar and other carbohydrates, is thus air-derived, the elements of which it is composed being appropriated by the leaves of plants. If a piece of sugar or starch be burnt, nothing remains; the elements of which it is composed have returned to the atmosphere.



SEED DRILL

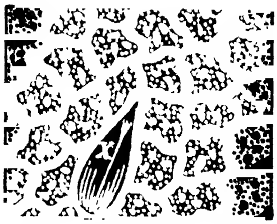
The Plant's Food Supply. If a seed has germinated, and is allowed to remain exposed upon the tile or saucer to which we have referred, the seedling will die when its food supply has been exhausted. Similarly, if we deposit seed within pure sand which has been calcined to destroy any nutritious matter that it may contain it will germinate and grow until, having exhausted its store of food, it withers and dies. On the other hand, if the sand be mixed with small quantities of the minerals with which plants are normally supplied by the soil, together with a small portion of fertile soil, which will convey the necessary bacteria, a leguminous plant will flourish, for it will then be able to obtain its nitrogen from the atmosphere. When seed is deposited in fertile soil, germination following, the plant grows because it is supplied with food; but its size, vitality, and growth depend upon the soil being furnished with a regular supply of food, and especially in that the soil has, by cultivation, been brought to such a fine condition that the tiny plant rootlets are able to seek and appropriate it.

Thus, if we compare the beans which have been planted as an experiment with others which have germinated in a saucer, we shall not only be able to ascertain the influence of depth and of temperature, but we shall observe that the growth of the former is owing to something which they find in the soil, and which is not available to those growing apart from it, only to die when they have exhausted the food which the seed provides. If seed be deposited in cold, wet soil, the temperature being below germinating point, it may remain intact, especially in the case of oily seeds, like those of the weed known as charlock, or wild mustard; or it may die and rot.

When wet and cold weather follows early winter sowing, it frequently happens that a large proportion of the seed fails to germinate, and is spoiled; hence the importance of draining and improving the porous character of heavy soils. It is proverbial that where seed is sown unusually early or late, a larger quantity is required to ensure a normal crop. This may be partially owing to failure to germinate, but it is chiefly owing to the depredations of birds and vermin, which make greater inroads upon a seed-bed during these seasons than during the main sowing season, when a much larger area is available to them.

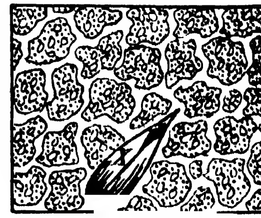
How to Recognise Good Seed. It is important to learn how to recognise a good sample of seed. Without an actual test it is often impossible to distinguish fertile from infertile seeds, and in some cases a farmer of experience may fail to differentiate between pure and impure seeds. It is, however, of primary importance to distinguish between a good sample and a bad sample from bulk, whether in hand or in the sack; and in order to do this there is nothing like practical experiment—actual comparison between known fine samples and known impure and imperfect samples. If comparison be made in the presence of an expert who points out the differences in colour, size, and general characteristics, so much the better for the novice.

It is important that seed should not only be pure, but full of vitality, and consequently that it should be new and in good condition. The brownish imperfect colour in the oat, for example, indicates that it may have heated in the rick, and its vitality destroyed. All grain should be bright, pure in colour, clean, sweet under the nose, and up to weight. There should be a minimum or, indeed, entire absence of thin, small grains, which are quite common in samples



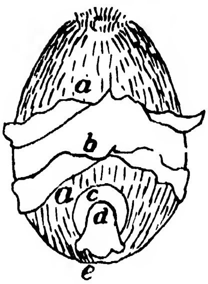
1. Seed in soil with water but without air.
x Seed. Black: Water. White: Powdered soil.

2. Stony and cloddy ground. Seed. *y*. Hard clods. *z*. A stone.



3. Seed in soil with air but without water.
x. Seed. Dark spaces: Air-filled pulverised soil. White: Air.

4. Seed in soil with air and water.
x. Seed. White: Air. Shaded parts: Powdered soil. Black spots: Water.



5. Wheat grain.
a. Outer skin.
b. Inner skin.
Scale or Cotyledon.

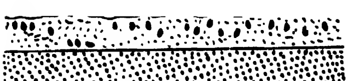
7. Wheat germinating.
a. Shoot leaving its sheath.
b. Shoot evolved.
c. Unevolved shoot.
d. Rootlets.

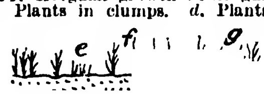
8. Seeds in furrow.
a. In hollows. *b*. On tops and sides of furrows.



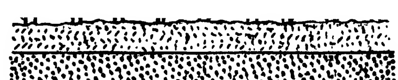
9. Seeds on badly-ploughed furrow.
e. Clustered seeds, shallow covered. *f*. Clustered seeds, buried deep. *g*. Scattered seeds, shallow covered. *h*. Scattered seeds, deep covered.

10. Seed sowed by drill at regular depths.

11. Irregular growth on irregular furrow.
c. Plants in clumps. *d*. Plants scattered.



12. Irregular plants on ill-ploughed furrow.
e. Late plants. *f*. Early plants. *g*. Regular plants.



13. Regular growth from drill-sown seed.

SEEDS AND SOILS
Showing the result of scientific method in modern farming

of second-rate oats. No better object-lesson than the seed classes at an agricultural show, such as Birmingham, which may be studied with great advantage, can be suggested. Clovers and grasses are in particular liable to impurities and adulteration, and special care should be taken in their selection.

Buying Seed. In buying seed it is wise to deal with the best firms, and to obtain guarantees with each purchase. That the price is a little higher than that charged by seedsmen without reputation is not to be considered. A buyer must expect to pay for the extra trouble which a guarantee of purity involves. Suppose we count a hundred seeds, and find 20 per cent. of the sample to be impure. And suppose, further, that of the 80 per cent. of the seeds remaining we find on testing for germination that 25 per cent. fail. In such a case we obtain only 60 per cent. of good seed, the cost of which may have exceeded that charged by the seller of a guaranteed sample. The cost of seed which is both impure and wanting in vitality is oftentimes enormously greater than that of apparently costly guaranteed seed. If it be inconvenient to make a test of a purchased sample, the buyer should communicate with the Secretary of the Royal, or some other important agricultural society, that a test may be made for him by the expert retained for that purpose, and he will have the advantage of a semi-official report at a very nominal cost.

Weight as a Guide to Value. Weight of seed is a guide to its value. For instance, oats weighing 36 lb. to the bushel are more or less common on the market; but, apart from the impurities they contain, there are many small oats almost entirely or quite devoid of kernels. The mere husk is useless, while small seed with a tiny kernel is next to useless, for it cannot produce a fine prolific plant. Oats for seed should weigh from 40 to 42 lb. to the bushel. Weight is significant, inasmuch as it means that the seeds are robust, and if well saved, full of vitality, and that they contain abundance of food for the nourishment of the seedling plant. The weight of seeds will, however, be referred to in the chapters dealing with agricultural plants. The testing of seed has long been conducted at the Swiss station at Zurich, by Dr. Stebler, whose work on the subject is of the first rank. There are also public stations in Denmark, Sweden, and the United States, and it is significant that in the absence of a British official station, the station at Zurich has been long and largely supported by British growers.

The Life of Seed. It is important to notice that the life of seed varies considerably. While the seed of the cabbage and the swede retain vitality up to six years, or even more, it is unsafe to sow the seed of oats, spring wheat, or barley which is over two years old. Much depends upon how seed has been kept, but in practically all cases the number of seeds which germinate after sowing diminishes with each year of its age. It is, therefore, the safest plan to insist on new seed. With reference to germination, it is necessary to point out that the best seed may fail in a bad seed-bed. The soil should, therefore, be fine, deep, and well compressed after sowing. A coarse bed may leave some seeds lying in open spaces, where, after germination, they are liable to die. In order to be well equipped with facts relating to the behaviour of seeds during and after germination, the learner should make experiments with cereal, clover, mangel, turnip, and grass seeds, similar to those to which we have referred in the case of the bean, always remembering to avoid a wet soil—in which the seed may be damaged or destroyed—and a very dry soil, in which it may long lie before germination.

Uses of Seeds. The seeds of plants commonly supply food for men and animals, as in the case of cereals and pulses, linseed and cottonseed, the two last named supplying oil for industrial and other purposes, while the residue remaining after pressure provides food for farm stock. All seeds contain the nutrients known as the carbohydrates—chiefly sugar and starch—fats and oils, also remarkable for their richness in carbon, and the proteids, which, in addition to the elements already named, contain abundant nitrogen. The seeds of plants, therefore, play a double role; they are responsible for, and essential in, the production of crops, while they provide the most valuable and concentrated foods which are supplied to the animals consuming those crops.

The majority of farmers regard a change of seed from time to time as essential to the success of their crops. The work of the experts employed by the Government of Canada has practically proved that this change is not essential, and that the only method of increasing the crop from the point of view of seed influence is to breed—*i.e.*, to produce seed on the principle of selection. The method which has now been adopted for some years is practically as follows:

Increasing the Crop. The strongest plants of the most suitable variety known on the farm on which it is grown are selected before harvesting or cutting. The ears of these plants are separately collected, and in the case of grain the corn is threshed and dressed, the heavest grains alone being retained. These grains are subsequently sown on a specially prepared seed-bed, enriched with manure with the object of producing fine strong plants which will bear equally fine and robust seed. Before harvest arrives the best plants are again selected, and subjected to the same treatment, the finest seed alone being retained for sowing, and so from year to year the seed, instead of being saved from the main crop, is produced from the best seed grown upon the best ears sown in a special seed-bed.

The principle is applied equally to pulse, clovers and potatoes, with the very best results. These results are superior to any obtained in any other way, and they can be confidently followed, inasmuch as they are based upon the clearest of scientific principles.

THE VAST FORTUNES OF TO-MORROW

Continued from page 521

Where they will be Made. Waste Utilisation. Cheap Ozone. Artificial Silk. Forestry. Photography. Food-stuffs. Entertainment

By ERNEST A. BRYANT

THE man whom we call the greatest creative genius is in reality the most versatile plagiarist. He reads the book of Nature, and in a thousand ways applies her wonderful lessons. He gives practical effect to cardinal principles; he utilises concrete examples. The greatest lesson of all he is still learning—the lesson that in Nature there is no waste. The credulous native who venerates a plant or rock as embodying one of his departed ancestors has more of fact on his side than is commonly credited.

The idea was well expressed by Lord Playfair when he said: "The economy of the chemistry of art is only in imitation of what we observe in the chemistry of Nature. Animals live and die; their dead bodies, passing into putridity, escape into the atmosphere, whence plants mould them into forms of organic life, and these plants, actually consisting of a past generation of ancestors, form our present food."

The New Meaning of Waste. Man, then, taking this lesson to heart, is evolving a new meaning for the word "waste." The refuse of yesterday is the potential wealth of to-morrow. Sawdust, which anciently had no use except as pack ng for unsatisfactory dolls, is now made to yield alcohol; or to form, when mixed with blood from the abattoir, imitation ebony, wheels for roller skates, and other useful articles. One patient speculator seeks to convert it, by compression, into planking. Coal-smoke has in it the elements of wealth; from it there may be extracted industrial alcohol and other marketable products. One firm has already made it return 10 per cent. of lead which was previously precipitated into the atmosphere.

There is undreamed wealth in the refuse-heaps which disfigure the neighbourhoods of blast-furnaces and collieries. Lovers of the countryside are attempting, by planting them with trees and shrubs, to obliterate these hideous blemishes by which the landscape is scarred. But the day may come when the trees now being planted will be uprooted in order that wealth may be extracted from the heaps now despised.

Power from Blast Furnaces. Every year some 18,000,000 tons of slag are produced by the blast-furnaces of Great Britain. Already an industry has grown up around these miniature mountains. But the possibilities are not nearly exhausted when, so far, we get only ballast and slag-wool. The blast-furnaces themselves permit the escape of enormous volumes of energy which we must learn to conserve, so that it may furnish such districts with artificial heating and lighting, and with power to drive the machinery of the towns, their trams, and trains. An example of what may be accomplished in this direction is afforded by a great firm in the West of Scotland. Fifty per cent. of the coal which they consumed, it was found, was permitted to escape in waste; gas was dissipated in sufficient volume to light a dozen towns. Ingenious minds devoted to the problem devised plant whereby now they derive power for driving all the machinery to collect the tar and break it up for use as fuel oils; pitch for use as fuel; ammonia to the extent of half a ton a day. Altogether, what was absolute waste is converted into a net profit of over £20,000 per annum.

A Pure Water Supply. If it be true that dirt is matter in the wrong place, it is equally true that waste is waste only to those who have not brains or sufficient energy to resolve its elements into useful form. One of the problems by which scientists of to-day are faced is the treatment of sewage and the purification of water supply. Yet it is acknowledged by the highest authorities that the most noisome residuum with which we have to deal is the very product necessary for the maintenance of fertility in the soil of Europe.

And we must be upon the eve of solving the question of pure water supply. While the present paper was being written London was still considering the statement of one of its Medical Officers of Health to the effect that we must no longer look to the Thames as a supply of water for drinking purposes, as the river has become hopelessly polluted. It is a statement of this kind which gets things done. Not until members of Parliament were threatened with fever from the stench of the Thames did we get the Embankment in place of the malodorous foreshore which was slowly poisoning London. When the Thames is pronounced impossible of purification we may hope to see it purified.

Nice sets us a brilliant example. Its water supply has long been a danger to health. Now, while this paper is in course of preparation, the authorities there have embarked upon a scheme for the ozonisation of their drinking water—9,000,000 gallons of water per day are to be ozonised. No drink is purer than ozonised water. The process kills every deleterious organism in the fluid. Setting at defiance cholera, typhoid, diphtheria, it promises to give us from the Thames water of which the most delicate may safely drink. But the benefit does not end here. By its aid the atmosphere of the hospital ward, the sick-room, the public hall and theatre may be purified.

Cheaper Ozone. What we want now is a cheaper process of ozonisation. Cost is at present the only barrier. When the man with

an economical method comes forward there will be no reason why every tram and train, every office and shop, every establishment in which we eat our meals, should not have its due supply of invigorating ozonised atmosphere. But, even now, only the fringe of the subject has been touched. The commercial possibilities of ozone are infinite. Ozone, when we get this cheap process, may banish chemicals from the bleaching-house. Cotton and paper will be bleached by its aid. Delicate fabrics inevitably suffer by chemical bleaching; there is at present nothing to equal the primitive old method of bleaching by the aid of the sun. The country housewife shows her knowledge of this when she lays out washed linen to dry in the sun on hedgerow and grass-bank. Ozone will bleach as effectively as the sun, but in one-thousandth of the time.

The need for a new process of paper manufacture for art work has already been considered. It may be added here, at the suggestion of a noted chemist, that in the course of the next 20 years the surface of the highly-glazed art papers at present in use will be practically destroyed. Paper-making is an industry more and more claiming attention. Rag paper for newspapers is too costly; certain grasses now in use yield too brittle a result; the forests to which we look for wood-pulp as a source of supply are rapidly disappearing. A new supply is badly needed; it is coming already from Newfoundland. The stalk of Indian maize, so long a curse to the cultivator, is now being successfully employed for the purpose. Millet, of which enormous quantities are grown, serving already to its cultivators as many purposes as the reindeer serves to the Eskimo, may have yet another value as a base for paper manufacture.

The Butcher's Laboratory. Nature is an insistent mistress. When we cast aside residual products as useless, she has a habit of making the refuse so intrude upon our attention that out of very vexation and despair we are impelled to take note with a view, not so much to utilisation as to disposal. The cotton seed was long the plague of the planter's existence; to-day it is a gold-mine to him for conversion into oil and cattle-food. So it was with the refuse of the slaughter-house. But what a miracle of adaptability the modern scientific butcher has become! He makes the bullock yield from by-products so many articles of value that now we are assured by the Beef Trust that the bullock is not worth cultivating as beef; that the profit comes only from materials which, but the other day, were a waste and an offence to our olfactory nerves.

Those who will may believe it, but just as Manchester, by the intelligent application of unpleasant matter to its proper use, has converted a sterile bog into a smiling estate, yielding food for the many, so the butcher takes the carcases, element from element, and metamorphoses them into combs, buttons, pipe-stems, handles, tooth-brushes, powder-puffs, billiard balls, meat extracts, tonics, sugar, gelatine, oil, soap, pepsin, and fertilisers.

Lord Masham's vast mills at Manningham are an even more attractive example of the application of brain-power to the mastery of commercial problems. It cost him only a penny per pound to buy the great mass of sticky, dirty waste left after the cocoons of silk had been unwound; but he had spent a quarter of a million sterling before he had mastered the secret which that filthy heap contained. That quarter of a million, and all the time he devoted to it, have since then yielded fortune upon fortune to him, and prosperity and relative wealth to a large population at Manningham.

A Romance of Textiles. We want more of these scientific men in commerce. The great masters in the textile trades have done practically all that is possible with the materials at their disposal. They want now new fibres for clothing and other textile purposes; ramie, it is said, is to become a chief textile of the future. Distillers want new processes, enabling them economically to utilise all their residual products. Scientists want the man who, with a mental divining-rod, will guide them to refuse heaps or natural deposits whence they may extract radium. Some day the Queen of England may wear a dress of silk spun, not by the worm, but by human hands. There are three processes already in operation in England, and increasing attention is being given to the subject.

Centuries ago James I. endeavoured, unsuccessfully, to acclimatise the silkworm here; now, after the lapse of all these years, there seems a possibility that we may challenge France in the production of silk. Those who are working at it modestly disclaim the hope of rivalling the natural product, but there is good reason to believe that the man may come who will give us an article so beautiful and durable that the proudest lady in the land will not be ashamed to wear it. This, of course, would open up quite a new industry for England. And that is an important consideration. Every discovery which makes its mark upon the commerce of our country means addition, not only to the wealth of the individual, but to the earnings and comfort of the community.

Two Industries from an Experiment. It has been already noted how the approximation of various branches of industry, hitherto regarded as widely separated, is creating wonderful developments. Lace, muslin weaving, netting, and hosiery are coming together. It is fascinating to trace the development of industry from industry; to note how two or three come together, and then others branch out in wholly unexpected directions. How important these developments may be can be seen from this very question of the artificial production of silk. One of the processes mentioned was the result of experiments tried with a quite different end in view. The object was a solvent for cotton, whereby the latter might be converted to various uses. The cotton having been changed to liquid form, the time came when it was found possible to spin it, in its new form, just as the silkworm spins. But the wonder did not

end here. When the liquid set, it was found to provide an excellent filament for incandescent gas-mantles! Here, then, are two new industries from one and the same experiment. Need we, after this, despair of converting a ball of worsted into a navigable airship?

Fortunes to be Made in the Forest. A subject of national importance to this country is forestry. It is, of course, a sound argument that where forests are, crops for the food of man cannot be. But, then, those who advocate afforestation do not plead their cause at the expense of arable and pasture land, any more than those who advocate the multiplication of pretty toys for children would care to destroy the manufacture of mathematical instruments. We spend between £20,000,000 and £30,000.000 annually on imported timbers. Some little share of that might go into the pockets of thousands now leaving the land in this country were it possible to conduct a scheme such as they have, say, in Germany. Their forest industries represent excellent wages to several hundred thousand families, aggregating in all some three or four million people. These find employment in wood-turning, carving, coach-building, match-making, wood-pulp manufacture for paper, drum and cask hoop-making, the manufacture of wooden rivets, spoons, shovels, and toys in endless variety.

The afforestation of catchment areas in Great Britain has an important bearing upon pure water supply; and the attention of the student may be directed to the experiments of Liverpool and of some other corporations now in progress.

Toys. Apropos of toy-making, there is no reason why great firms in whose premises carpentry, cabinet-making, and the like are carried out on a considerable scale should not add to their income by establishing departments for the manufacture of toys and bric-à-brac; the débris from the lathe and bench is just the material, now wasted, which would serve for the purpose. Birmingham ought to claim a larger share in the home market for mechanical toys, of which hundreds of thousands are annually imported at prices ranging from a penny to a half-crown. America is setting up her toy-works in conjunction with larger enterprises; and she has no monopoly of the executive skill necessary for the work. Here, however, as in many other directions, she gives the lead to the Old Country, where, so long have we enjoyed commercial ascendency that we are averse to adopting new schemes or new implements. Yet it is only by assimilating new ideas, instead of condemning them untried, that we shall reassert ourselves anew in the markets of the world.

Mention of toys suggests other possibilities for the children. An American firm finds it worth while to place on the market a contrivance for the rapid blowing of soap-bubbles. If that, in the judgment of acute men of business, be a sound investment, other ideas of a similar character might safely be tried in this country. Of the millions of children who go each year to the seaside, all, rich and poor alike, have at their disposal only the same old sources of amusement. Adults complain of the deadly dulness of the seaside; for the children the conditions are still worse.

A New Seaside Industry. Spade and bucket serve to-day as spade and bucket served when our grandparents were children, Castle-building, with moat and trench, are the joy of the children on the sands. Spade and bucket are but primitive tools for the work. A simple implement for "mining" sand—something which would make a trench at a stroke, if need be—is the thing wanted for the beach. There is a whole armament of new toys for the seaside to be made by the man who cares to undertake the thinking. Another phase of seaside life affording openings should appeal to what we may term "the children's Grossmith." Pier entertainments are not, as a rule, for children; and too often the "niggers" and pierrots are recruited from the ranks of itinerant vocalists who, out of the seaside season, wail for pence at the doors of public-houses, and take their pot-house "humour" with them for the summer to the sands. An entertainment on the beach or the pier which would appeal to children and be absolutely free from offence would be a boon indeed.

An All-day Entertainment for London. The same style of entertainment is needed for children in London. And older children would welcome harmless amusement. London with its ever-swelling throngs of pleasure seekers should support at least one place of amusement at which visitors could drop in for an hour at any time of the day. We have many theatres and variety halls, but where, east of Charing Cross, can entertainment of the character indicated be obtained, and where, even in that part of London, save at one hall? Sight-seeing palls upon even the most eager seeker after knowledge; he would pursue his way with the greater avidity after an interregnum devoted to rest and recreation in a hall where for an hour he had listened to good music and laughed at a really humorous song. The experiment of giving four performances a day has been tried at one London establishment, but discontinued after a few months. In conditions demanding less expense in production the venture ought to prove successful. It costs no more to have open a hall in which is a concert-platform than to keep it closed. And where there is entertainment to be had, London visitors will go—and be thankful. London should provide fortunes for many Grossmiths if they would afford her the opportunity. After this digression the matter must be left, while attention is given to more material considerations.

We have a tremendous object-lesson before us in the story of aniline dyes. There is still living in our midst, in this fifth year of the twentieth century, the man who has given incalculable fortunes to the world. Dr. W. H. Perkin was experimenting with a refuse—coal-tar—when he discovered the first aniline dye. Science knows no country, it is pleasantly said; but, unfortunately, one country knows science a good deal better than

another. And the discovery of this great Englishman was seized upon by the German chemists. The secret had been laid bare in England, but our system was not capable of developing it, and almost entirely the millions upon millions sterling which it represented have passed into German keeping. We export the raw materials for the work, and the Germans sell us the finished article!

An English Idea Which Made Germany Rich. All the most exquisite essences, all the dainty perfumes for the toilet-table, all the delicate odours for our best soaps; saccharine, hundreds of times sweeter than sugar and realising a fabulous price; carbolic acid, and all our best disinfectants; with, of course, all our finest dyes, result entirely from the discovery made by this English savant. He placed us first in the field, and the incalculable wealth which his discovery portended might have been ours exclusively but for the characteristic inefficiency of those who should have been ready to seize and develop the idea. It is questionable whether a nation has ever before been so vastly enriched by the discovery of an individual as Germany has been from the discovery of Dr. Perkin. They deserve their gains just as they deserve the success which attends their manufacture of artificial indigo; deserve it because they systematically sought to develop and best turn to account the new idea. But they have killed India's indigo trade, and they make England buy German essences and dyes.

In the same way Great Britain, whose coal-beds are the finest yet discovered, has had within the last two years reluctantly to follow where the Continent and America have led in the matter of mining coal by machinery. Many mines have been shut down here as no longer profitable because seams had run thin or the coal was too hard to be profitably mined. The coal-cutting machine can work at a rich profit seams which could not have been touched by the labour of man except at a heavy loss to the mine-owner.

Photography in the Future. Another respect in which we have lagged behind is photography. Great as is the advance made within recent years in England, the art is still only in its infancy. The world is still awaiting the advent of the man who shall photograph colours, and print them from one negative. There are a thousand and one appliances which the photographic operator wants. He wants simpler methods of developing and printing and fixing. Delightful work as it is, the time now required for the developing of a series of negatives in the dark-room is too long, as well for one's limited leisure as for his health. Daylight developing is now practicable with a certain outfit; it is wanted for all. It should not always remain impossible to develop by "dry" methods. The wet plate has long been improved out of existence; the time has come for liquid developers to follow suit. The same remark applies to toning and fixing. These processes are at present too slow and irksome. The man in the roadside booth manages in a few minutes to produce a permanent portrait—of a sort; but the first-class photographer cannot. Speedy work, especially for the illustrated press—a goldmine to the photographer—is a feature of increasing importance. Photography in future will be much more common for commercial purposes. It will be more and more used in the office as an adjunct to machine-drawing, a circumstance which should be borne in mind by the student. There is also a future for photography, experts declare, in advertising.

Food-stuffs claim the attention of the chemist. A thousand things are rejected as waste from industrial establishments which can be made digestible and nutritious for cattle and poultry. For human beings there is a certain sentiment against converting waste products into alimentary delicacies, but our great chemists frankly state that we must in the future look with increasing expectancy to the laboratory for sustenance, and that into those laboratories more and more men with brains and originality will have to go. The manufacture of artificial butter and margarine, which no one would have dreamed possible a few years ago, is now rapidly becoming an important industry. And other food-supplies will have to be augmented by similar means.

Chemistry, the Prudent Housewife. Waste must be no longer waste in the old sense. We have advanced immeasurably since Lord Playfair opened our eyes to what was happening in the laboratories of the world when he said: "Chemistry, like a prudent housewife, economises every scrap. The clippings of the travelling tinker are mixed with the parings of horses' hoofs from the smithy, or the cast-off woollen garments of the poorest inhabitants of a sister isle, and soon afterwards, in the form of dyes of brightest blue, grace the dress of courtly dames. The main ingredient of the ink with which I now write was possibly once part of the broken hoop of an old beer-barrel. The bones of dead animals yield the chief constitutents of lucifer matches. The offal of the streets and the washings of the coal-gas reappear carefully preserved in the lady's smelling-bottle, or are used by her to flavour blancmanges for her friends."

All this was wonderful when Playfair was in his prime, but we have left far behind the outposts of the applied science of which he in his day was so brilliant an exponent. The student of to-day has at his disposal more knowledge of applied science than had the man who taught the subject to the present King of England.

VARIOUS BUILDING MATERIALS

Including Bricks, Tiles, and Terra-cotta, Pipes, Sand, Gravel, Lime, Cements, Plasters, Mortar and Concrete

Continued from page 535

By Professor HENRY ADAMS

Bricks : Size and Composition. Bricks are artificial blocks averaging $8\frac{7}{8}$ in. long, $4\frac{1}{4}$ in. wide, and $2\frac{5}{8}$ in. thick, moulded from a loamy clay called brick-earth, and burnt in a clamp or a kiln. Including the joints, they may be considered as 9 in. by $4\frac{1}{2}$ in, by 3 in. [**55**]. The plasticity of the clay enables the material to hold together before burning, the sand prevents the excessive hardening and shrinkage which would take place with pure clay, the lime assists in forming a flux producing semi-vitrification, and the iron, magnesia, etc., give the colour to the brick. Clay, or silicate of alumina, is a peculiar plastic material in its natural state, like a tenacious mud, which may be dried and again wetted without altering its properties, but when it is raised to a dull-red heat the chemically-combined water is driven off and the plasticity is permanently lost. This is the principle of the manufacture of *red ballast*, used for bottoming footpaths and for the aggregate in jerry-builders' concrete. It is also the essence of brickmaking, but in this case the burning is carried further, so that incipient vitrification takes place throughout the mass. Bricks may be hand or machine made. Hand-made bricks, again, may be sand moulded or slop moulded.

Brick Clamps. In the neighbourhood of London, where brick-earth abounds near the surface, and where the same site is to be utilised for building upon, it is usual to burn bricks in a clamp. What is called *coke breeze*, but is in reality sifted dustbin refuse, is thoroughly mixed with the brick-earth by passing them together through a pug-mill, and the tempered clay is then pressed into a mould to shape the brick. It is prevented from sticking to the mould by the latter being dipped in, or sprinkled with, dry sand, when the bricks are known as sand moulded; or the mould is dipped into water each time, when the bricks are known as slop moulded. The clamp is a loosely-built structure of 00,000 to 500,000 dried raw bricks, with layers of coke breeze in the lower portion, and live holes and flues formed of burnt bricks. The outside is covered with old underburnt bricks, and the windward side is plastered with clay or protected by corrugated-iron sheets. After the clamp is well alight the combustion spreads throughout the mass, as each brick contains its own fuel, which ensures thorough burning of all except those on the extreme outside. Clamp-burnt bricks are somewhat rough and discoloured in appearance, and often show traces of the coke breeze, but they are, on the whole, sound and cheap.

Brick-kilns. In a permanent brickfield' a kiln or oven is usually constructed for burning the bricks. A plain kiln, known also as a Scotch kiln [**56**], is an open topped brick building, with doorways at the ends and fireholes along the sides, in which the raw bricks are built up somewhat after the manner of clamps; but as they do not contain any breeze all the fuel has to be provided around and beneath the bricks. Kiln-burnt bricks are frequently *brindled*, or marked in light and dark stripes, due to the partial exposure of the surfaces when laid in the kiln, and the greater or less action of the fire upon them. With this exception, kiln-burnt bricks are more uniform in shape and colour than clamp bricks, and there is less waste in the manufacture. There are several varieties of continuous kilns, such as the Hoffmann [**57**], and others. These are arranged in compartments, in which the bricks are in different stages of burning at the same time, so that there is constantly one forward being cleared of the finished bricks and one behind being filled with raw bricks.

Stock Bricks. *Stock bricks* is a term used locally to denote the ordinary brick of the neighbourhood, but it applies more particularly to bricks made in the London district from a brick-earth immediately underlying the vegetable soil. It is rather a coarse brick, but hard and strong, usually of a pale-buff colour, but inclined to red when insufficiently burnt. Coke breeze is mixed with the clay, so that burning takes place throughout the mass, rendering the interior as hard as the outside. When Oxford clay is used, the interior is a dark blue-black colour with a shaly fracture, and sometimes containing lumps of free lime, which render it liable to crack after being built in a wall. A good stock should resist scoring on the surface by a penknife.

Place Bricks, or Grizzles. These are soft, reddish, underburnt bricks from the outside of a clamp, or the top of a kiln, of no use except for filling a brick-nogged partition, as they crumble and powder on exposure to the weather, or in a damp situation.

Chuffs. *Chuffs or shuffs* are bricks full of cracks, but otherwise of hard texture; if well burnt they may be broken up to form the aggregate for concrete.

Washed Bricks. These are made of clay which has been washed to remove the stones. When the stones are left in the clay, they burst in the burning and crack the bricks.

Cutters and Rubbers. These bricks are hand made, of a larger size than ordinary bricks, and with a certain amount of sand in their composition, so that they may cut and rub freely. They are used for gauged arches,

brick aprons, and where any carving of brickwork is required. They should yield to scoring by a knife, but not by the thumb-nail.

Fletton Bricks, or Flitters. This variety comes from around Peterborough, and has been largely used of late years. They vary in colour from red to a dirty grey, and are not equal to London stock bricks, although used as substitutes in common work.

Machine-pressed Bricks. These are of various colours according to the clay used, and owing to their smooth surface are suitable for town buildings, where smoke and soot abound. Being very regular in shape, they may be built with close joints.

Sand-faced Bricks. This variety is preferred by architects, from the good tone and texture and uniform colour, although they do not weather so well. Those should be selected which have a good ring when struck together.

Blue Bricks. Blue bricks are made chiefly in Staffordshire, and owe their colour to the large amount of oxide of iron contained in the clay. They are very thoroughly burnt to obtain a vitreous structure, and hence are very hard and durable. They are used for heavy foundations, plinths, inverts of sewers, and wherever moisture or hard wear have to be resisted. For door and window-jambs in warehouses the angles are generally rounded by using bull-nosed or quoin bricks, with a round corner, bonded in with rectangular bricks. True Staffordshire blue bricks are a deep blue-black colour throughout, but inferior ones have the outside the right colour while the inside is red, being formed of common clay dipped in a wash to colour them in burning.

Paving Clinkers. Paving clinkers are of two chief varieties—the *terro-metallic*, of the same colour and quality as Staffordshire blue bricks; and *adamantine clinkers*, of a pale-buff colour, from Stamford in Lincolnshire. They are machine pressed, and hence very heavy and dense in structure, resisting wear to an astonishing degree, and impervious to moisture.

Glazed Bricks. Glazed bricks are usually dipped in a "slip" of specially prepared clay, so that when burnt a china-like skin of an artificial colour is produced on the exposed surface, either white or any other colour that may be desired. Glazing is also produced by throwing salt into the furnace, hence the term "salt-glazed" which is applied to stoneware pipes similarly treated, but these are not dipped, so that they retain their natural colour.

Firebricks and Clays. Bricks in general are the best fire-resisting materials we have, but some varieties are peculiarly good in this respect, although not having the other properties required in ordinary construction. These are known as firebricks, and may be roughly divided into two classes, according to the material from which they are made—*viz.*, (*a*) the silicate of alumina class, in which the alumina is about half the silica, and the silica is chiefly in the combined form; and (*b*) the siliceous class, in which the silica predominates up to about 90 per cent., chiefly in the free state. Class *a* burn hard, are dense and smooth, and make good paving-bricks. They are only suited for moderate heats. Class *b* are rougher to the feel, are somewhat friable when burnt, have a coarse grain, but are very refractory, withstanding furnace heats up to 4,000 or 5,000 deg. Fahr. Stourbridge bricks are intermediate in character, while Dinas bricks possess the extreme degree of refractoriness. This results from their freedom from iron oxide and alkalies—in fact, a small percentage of lime has to be added in the manufacture as a combining material to hold the grains of silica together.

Terra-cotta. *Terra-cotta*, as the name implies, is burnt earth, or, rather, a mixture of clays that will burn to a dense but not too hard condition, with a smooth, semi-vitrified face. It must be capable of moulding easily—that is, must take the impression well and retain its shape while drying, and not shrink or warp excessively in burning. Terra-cotta for building purposes is moulded into hollow blocks, with shells about 2 in. thick, in order that the drying and burning shall be more uniform. The interiors are filled with fine concrete before the blocks are placed in position in the building. It is most important that the outer skin shall be left intact, as this is virtually imperishable; while the interior, if left exposed, would weather badly. The colour varies from a buff or pink to a dark red, according to the proportion of oxide of iron contained in the clay.

Roofing Tiles. *Roofing tiles* are generally made from red terra-cotta clays squirted in a thin band of the requisite section and wire-cut into the required length. *Pantiles* [**58**] are then baked, but *plain tiles* [**59**] undergo a preliminary pressing in order to consolidate them, and render them more impervious to the weather. Plain tiles are, before burning, bent over a leather saddle to make them hollow on the underside, so that they may fit closely at the tail, to prevent rain from driving in the joint. They are holed for the pegs at the same time.

Ridge Tiles. Ridge tiles [**60**] are used to span the ridge of a roof and cover the slates or tiles on each side in order to form a weather-tight joint.

Hip and Valley Tiles. These [**61** and **62**] are made of special shapes, to fit the hips and valleys of tiled roofs, and varied to fit the pitch of roof for which they are required.

Ornamental Roofing Tiles. Various outlines and sections are made similarly to plain tiles. Common forms are shown in **63**.

Hanging Tiles. These are made of the same material as roofing tiles, unless they are finished with a glazed surface, when they are more often of stoneware, and made to any required colour by a dip-glaze upon the exposed face.

Wall Tiles. These tiles when bedded direct upon the wall, are usually made of stoneware, with dovetailed grooves or holes in the back to form a key, and glazed on the face to any

66. *Mortar mill.*

required colour by a dip-glaze, in which they are inserted before burning, and they are then known as glazed tiles.

Embossed Tiles. *Embossed tiles* are pressed in a mould with a sunk die, which makes a raised figure on the surface of the tile, afterwards glazed.

Encaustic Tiles. For *encaustic tiles* the die has a raised pattern, forming on the face of the tile depressions which are filled in with a differently coloured slip. Various modifications are adopted to produce the different patterns and colouring required by architects. Inferior encaustic tiles, in which the colour is merely applied as a transfer on the surface, instead of being burnt in along with the clay, are now largely made. The best encaustic tiles consist of three layers: (*a*) a slab of very pure clay of the colour required for the ground of the pattern; (*b*) the body, which is of coarser clay; and (*c*) the back, which is formed with a thin layer of clay different from the body, to prevent warping.

Dry Tiles. These are, as their name implies, made by a dry process, and are of the same colour throughout. The clay is carefully prepared and mixed with the colouring agent, passed through muslin or silk sieves, dried, and reduced to a fine powder, which is placed in a press and reduced to about a third of its bulk as well as being thoroughly consolidated. At the same time the pattern, if any, is impressed by means of a die. The tiles are then carefully dried in a hot room, glazed and fired.

Majolica Tiles. This variety has various colours applied in the form of an enamel or glaze, and undergoes successive burnings to incorporate all the colours properly. The same process is applied to ornaments and figures, as in the majolica fountain in front of the Bethnal Green Museum.

Glass Tiles. *Glass tiles* were at first simply thick glass with an opal face, and are much cheaper than ordinary white-glazed tiles, but very liable to fracture. They are now made in a great variety of styles and colours and with raised patterns.

Paving Tiles. *Paving tiles*, paving blocks, or quarry tiles, are made of red terra-cotta clay, 6 in. or 12 in. square and 1 in. to 1½ in. thick. They are laid dry on a thin bed of sand, or bedded and jointed in mortar. They are used chiefly for outdoor side-passages of houses, where the traffic would otherwise work up the soil into mud, and for the floors of washhouses, sculleries, and farm kitchens.

Floor Tiles. The commonest are terra-cotta or stoneware tiles, 6 in. square and ½ in. thick, in buff, red or black, used in greenhouses. The better kind are made in various shapes—square, hexagonal, triangular, and rectangular, coloured throughout their substance by colouring matters mixed with the clay before pressing and burning, and used to form *tessellated pavements* or mosaic patterns for halls, passages, &c. When well burnt they are very durable and pleasing in effect. Smaller pieces of the same material are called *tesseræ*. These are made either by the dry process, above described, or out of moist clay cut into various shapes by wires. They are very true in form, and can be laid in mosaic work without any rubbing.

Mosaic Work. Mosaic work is formed by small pieces of tiles or marble bedded in cement. In one method a pattern is made upon brown paper, upon which the pieces are temporarily stuck, face downwards, and the whole is inverted for fixing. In another system they are imbedded direct upon the floor. This is known as *Roman mosaic*. Care has to be taken that the foundation is sound and rigid, and that properly air-slaked cement alone is used, as otherwise unsightly cracks appear upon the finished surface.

Mosaic paving slabs are made by arranging tesseræ to the required pattern in a rough wooden frame. Cement is then run in over the backs of the tesseræ and the whole formed into a slab, which is strengthened by two layers of tiles set in cement.

Drainpipes. It is only within the last fifty years or less that any care has been taken in the manufacture or laying of drainpipes. Soil drains for taking domestic wastes may be made of cast-iron or of stoneware. The former have the advantage of fewer joints and greater strength, but they have the disadvantage of requiring to be carefully protected from corrosion by coating, when hot, with a pitch compound known as Dr. Angus Smith's process. Stoneware pipes, when properly made and used, have the advantage of permanency without further preparation.

Stoneware Pipes. These are made from refractory clays, mixed with sand and ground pottery to prevent shrinkage, and burnt at a high temperature, so that they are vitrified throughout, and are hard, dense, and impervious to moisture. In order to present as little obstruction as possible to the flow of liquid, and to prevent any accumulation of deposit on the inside, they are salt-glazed; but the best kinds have the spigot ends and the insides of the sockets unglazed, so that the cement used for making the joint may hold firmly. They are 2 ft. long from bottom of socket end to the end of spigot, and vary from 3 in. to 15 in. inside diameter. A diameter of 4 in. is sufficient for ordinary house-drains, and 6 in. for a mansion. The larger sizes are sometimes made oval, so that a small flow may take place with the least wetted perimeter, and consequently the least friction. Traps of all kinds are made of the same material. Stoneware pipes should have a yellowish-grey fracture and be incapable of being scored with a knife.

Earthenware Pipes. Common socketed drainpipes are made from mild clays which will not stand a very high temperature in burning, and they are consequently somewhat porous and not so durable as stoneware pipes. As the salt-glaze that is used is nearly transparent earthenware pipes can be detected by their reddish colour. They have also a less metallic ring than the stoneware pipes, and the fractured surface can generally be scored with a knife.

Agricultural Pipes. These are made of similar clays, squirted in a pipe machine and cut off with a wire into short cylindrical lengths. They are made without sockets, and laid with butt joints nearly touching, but leaving sufficient space between for water to enter. They are only used for draining land, or for insertion in a retaining wall as weep-holes.

Flower-pots and **Seed-pans.** These articles are made of the same material as agricultural pipes, on a potter's wheel, and afterwards baked. When made into fancy shapes or into small figures they are called terra-cotta.

Sand. Sand may consist of small grains of any material, but what is commonly known as sand consists almost entirely of small grains of quartz, which is nearly pure silica, as sea sand. Pit sand is coloured by oxide of iron (Fe_3O_4), the colour varying from yellow to red, according to the amount contained. Pit sand is usually contaminated with a certain amount of clay, causing it to have a loamy feel, and this has to be washed out before the sand can be used for mortar or concrete, as the smallest quantity when wetted forms mud, which spreads and envelopes the lime or cement, preventing the adhesion of the mass. For this reason, the finer the lime or cement is ground, the better chance it has of resisting the presence of clay. All sand is formed by attrition of larger particles in the ordinary course of nature, so that the grains are more or less rounded. What is called *sharp sand* is merely sand that is free from clay, and not sharp in the sense of pointed, angular fragments. When examined under the microscope some varieties are more angular than others, but freedom from clay is the essential point. For plastering and for fine joints in gauged work it is necessary to screen or sift the sand to obtain small uniform grains, but for thick joints, especially for use in concrete, sand of varying size is advantageous. Sea sand may be used with Portland cement, as the slight hygroscopic properties are beneficial, but the same properties are detrimental in the case of lime, retarding the setting and causing an efflorescence on the work.

Gravel. *Gravel* is simply large sand. *Ballast* is sand and gravel mixed. *Burnt ballast* is clay burnt to a red colour, as described above. *Hard core* is the material used in the foundation of roads, consisting of brick rubbish, broken slag, furnace clinkers, and frequently dustbin refuse.

Varieties of Lime. *Lime, caustic lime, or quicklime* (CaO) is formed by burning chalk, marble, or any limestone containing a large proportion of carbonate of lime. Its great value in construction lies in the fact that when slaked and mixed with sand to form a mortar it can be used as an adhesive for joining bricks or covering walls, where it sets—in which process it absorbs carbonic acid from the air—and becomes hard again by reversion to carbonate of lime ($CaCO_3$). The calcination is effected in a *flare-kiln* [64] or a *draw-kiln* [65]. The flare-kiln is best for chalk-lime, where the colour requires to be kept pure. It consists generally of a rectangular building with dome top, having fire holes along the bottom over which rough, tunnel-like arches are turned with blocks of stone laid dry, leaving many spaces, and the chalk is piled over these arches so that only the flame passes through the chalk, while the carbonic acid and moisture escape through an opening at the top. Generally, two or more of these kilns are arranged side by side and worked alternately. A simple flare kiln is shown in **64**. The draw-kiln is a common form frequently seen on a hill-side in a chalk district. It is shaped like an inverted cone or parabola, with a draw-hole at the bottom [65]. In this kiln the stone and fuel are tipped in alternate layers, and the burnt limestone is withdrawn from the bottom.

Pure Lime. *Pure lime*, called also *rich*, or *fat lime*, is made from chalk or marble, which are practically pure carbonates of lime. The calcination drives off the carbonic acid and water, leaving pure quicklime. This possesses the property of absorbing a great amount of water with a hissing noise, the evolution of considerable heat, and a great increase of bulk, passing into the form of hydrate of lime, commonly known as slaked, or slacked, lime. It undergoes this change slowly on mere exposure to the air, reabsorbing carbonic acid at the same time. It is called rich, or fat lime, because it will bear a large proportion of sand mixed with it. Pure lime is used for lime-whiting and for plastering. It never attains great hardness, but is very free from *blowing*, because of its readiness in slaking. If any other lime is used for plastering, it is apt to blow—that is, small particles that have resisted the primary slaking, slake in the wall and blow off small patches, or cause blisters. As the setting is so prolonged pure lime is not suited for making mortar for building walls.

When the chalk or limestone is impure a *poor lime* is the result, the impurities forming so much inert matter, reducing to that extent the amount of sand that may be used with it.

The *grey lime*, or *stone lime*, used in the neighbourhood of London is in this sense a poor lime obtained from Dorking, Halling, Merstham, etc. It swells less in slaking, with less evolution of heat, but containing about 4 per cent. of alumina, it sets more rapidly than pure lime. Grey lime is so called from the colour of the stone from which it is produced, the lime itself being yellow.

When the limestone contains clay (silicate of alumina) the lime formed from it sets quicker, and is classed as *feebly hydraulic*, *moderately hydraulic*, or *eminently hydraulic*, according to the amount of clay contained. The term hydraulic means ability to set in a damp situation.

Blue Lias Lime. *Blue lias lime* is burnt from limestone from the lias formation in different districts, as Keynsham, Lyme Regis, Bath, Aberthaw, Rugby, etc. Some of it is only moderately hydraulic, but other samples are eminently so. As in the case of stone lime, the name comes from the colour of the stone and not of the lime, which is generally grey, with a shelly fracture. It slakes sluggishly, and is therefore better when ground in a mortar-mill [66]. For large engineering works the mortar

is usually delivered in the lump and ground with the sand, or often with broken brick. For builders' use the lime is generally delivered ready ground It is the only kind of lime that should be used for lime concrete, but Portland cement is now so cheap that cement concrete should always be used.

Selenitic Lime. *Selenitic lime*, or *selenitic cement*, was introduced by General Scott, and is hence also called *Scott's cement.* It is made from a hydraulic lime, such as blue lias, by adding 5 to 7½ per cent. of sulphate of lime in the form of plaster-of-Paris or other sulphate, or even sulphuric acid, and mixing and grinding them together finely. The slaking is reduced or arrested, the setting expedited, and the strength increased, or a larger proportion of sand may be used if no increase of strength be desired. It is used chiefly for mortar, but also for plastering and concrete.

Cements. *Roman cement* is a natural cement formed by the calcination of nodules found in the London clay at the Isle of Sheppey, Harwich, etc. It is a rich brown colour, very like the pozzolano or trass which it supplanted. It sets very rapidly, and is therefore useful for tide work in repairing dock and sea walls. It is used neat, and even then has little strength, the maximum being attained in about one month. It was formerly used in setting coppers, as it stands fire better than Portland cement. It has, however, practically gone out of use.

Portland Cement. This is an artificial cement of a grey colour, formed by mixing and calcining chalk and clay, or limestone and clay; the former being mixed by the wet process, and the latter by the dry process. In this country the bulk of the cement is manufactured by the wet process on the banks of the Thames and Medway. The proportion of the ingredients depends upon the pureness of the chalk; if it contains clay less having to be added. For example, 80 per cent. of grey chalk is mixed with 20 per cent of clay, but with upper chalk, which is purer, the proportions may be 66 per cent. of chalk to 33 per cent. of clay. The ingredients are mixed in water to the consistence of thick cream, called "slurry," and the fine particles in suspension are allowed to settle in tanks, or backs, for some weeks. The clear water is run off by weirs and sluices, and when the slip is sufficiently solid it is dug out and removed in barrows to the drying floor, and subsequently loaded into the kiln. Intermittent kilns were formerly used, the slurry and coke fuel being packed in alternate layers. Now continuous rotary kilns, gas fired, are being used. The calcined cement is afterwards ground to a fine powder, so fine, in fact, that a residue of only 12 per cent. is left on sifting it through a sieve of 10,000 holes per square inch.

Plaster Cements. *Plaster cements* is a general term applied to those cements used in plastering which depend principally upon plaster-of-Paris as their chief ingredient.

Plaster-of-Paris. This is produced by the gentle calcination of gypsum, which is a brownish, semi-transparent, crystalline, hydrated sulphate of lime, found in the clays round London and Paris. It consists of lime, 26¼ parts: sulphuric acid, 37⅛ parts; water, 17 parts; and when calcined the water of crystallisation is driven off, making it anhydrous. It sets rapidly by the absorption of water, which makes it again a hydrate, and expands slightly in setting. Being soluble, it is not suitable for outdoor work.

Keene's Cement. This is made by recalcining plaster-of-Paris after soaking it in a saturated solution of alum. It sets quickly and hard, and is used for screeds on external angles of inside wall plastering, skirtings, dados, and other parts liable to rough usage. It is not suited for outside work, as it will not withstand the weather. It is made in two qualities, coarse and superfine, and is usually of a pinkish colour.

Parian Cement. This, sometimes called *Keating's cement*, is produced by mixing calcined and powdered gypsum (plaster-of-Paris) with a strong solution of borax, and afterwards recalcining, and grinding. It is said to be mixed with a solution of alum after this, but there is some doubt on the point. It sets very hard, but does not give such sharp angles as Keene's or Martin's cement, although it is preferred to these for large surfaces, as it works more freely. It is not suited for external work owing to its solubility.

Martin's Cement. This cement is made in a similar manner to Parian, but carbonate of potash is used instead of borax.

Stucco. *Stucco* is the common term for all kinds of plastering to be finished with a coat of paint. It is also used for external rendering in cement to imitate stone. The composition of *common stucco* is one part of hydraulic lime or cement to three parts of sand. *Bastard stucco* has a small proportion of hair, two-thirds fine stuff to one-third fine sand, and is chiefly used for surfaces to be painted. *Trowelled stucco* for interior work has a small proportion of plaster-of-Paris. *Rough stucco* has larger sand or small gravel mixed with it. *Rough cast* is the final coat of plaster or rendering to external walls, much used in half-timbered work and on the basement walls of Queen Anne work. The first and second coats of coarse stuff (one lime, three sand) are evenly applied, and, when set, the rough cast is thrown on, consisting of sand, washed and screened gravel or grit, mixed with hot lime to a semi-fluid condition. It may be coloured immediately with lime and ochre, or left in its natural condition. From its mode of application it is sometimes known as *gravel-dash.*

Plastering. The first coat of plaster on laths is called the *pricking-up coat*, and is made of *coarse stuff*, which is a rough mortar containing 1 or 1½ parts of sand to 1 part of slaked lime by measure, thoroughly mixed, with 1 lb. of sound long ox-hair to 2 or 3 cubic ft. of stuff. After this coat is put on it is, while still soft, scored or scratched all over to form a key for the next coat. When this is quite firm, but not too dry, the second, or *floating coat*, consisting of either a repetition of the coarse stuff, or of fine stuff with a little hair, is applied. *Fine stuff* is pure lime slaked with a small quantity

of water, afterwards diluted with more water, and allowed to settle. The water is then run off, and that in the mass allowed to evaporate until the stuff is thick enough for use. Before the floating coat is too dry, it is swept over with a birchbroom, and when quite dry the third, or *setting coat*, is applied, consisting of two-thirds fine stuff and one-third very fine clean sand, with or without hair. *Rendering* is the application of plaster or cement mortar to brickwork.

Scagliola. *Scagliola* is a mixture of plaster-of-Paris with various colouring matters, dissolved in glue or isinglass, to imitate marble, and applied to flat surfaces or to columns. It has a wooden backing covered with coarse Keene's cement, the surface of which is scored in irregular or diagonal lines. To this the second coat is added, and is coloured when moist to represent the marble. When dry it is rubbed over with a hard stone, and afterwards treated with liquid Keene's cement to fill up the pores, and is again polished. The final gloss is obtained by a rag and linseed-oil.

Putty. *Plasterers' putty* consists of pure lime mixed with water, slaked to a creamy consistency and run through a hair sieve. It is then left in a putty-bin until it attains the proper consistency for use.

Gauged Stuff. This, also called *putty-and-plaster*, is made of three to four-fifths plasterers' putty and the remainder plaster-of-Paris. It must be mixed in small quantities as the plaster-of-Paris causes it to set quickly.

Masons' Putty. Masons' Putty is very similar to plasterers' putty, but has white marble dust mixed with it. Another variety is made by mixing lime, white-lead and silver sand.

Glaziers' Putty. This is made of whiting finely powdered and mixed with raw linseed-oil to a stiff paste and left for 12 hours, then kneaded up into small tenacious lumps. For outside work it has sometimes a little white-lead or turps, or boiled linseed-oil, to cause it to set harder. *Whiting* is pure white chalk ground and made up into lumps with water. When putty has got stale and hard it may be worked up again by beating it for some time with a mallet and kneading it with the hands.

Mortar. Good building mortar is composed of 1 part of freshly ground stone-lime to 2 or 2½ parts of clean, sharp pit sand. For ordinary work it is mixed by hand on a wooden platform. The lime having been first measured out, enough water is added to slake it, then covered with the sand, and when thoroughly slaked the whole is incorporated by turning over several times. If large quantities are required the mixing should be done in a mortar-mill [66]. The mortar should be used as stiff as possible, the bricks wetted before laying, and the joints well filled.

Cement Mortar. This consists of 1 part of Portland cement to 3 parts of clean sharp sand. The materials should first be mixed dry on a wooden platform, and then wetted through a rose while being turned over. It should be used within an hour of mixing and before it has begun to set, and in building brickwork the joints should be raked out as the work proceeds.

Mill Mortar. Mill mortar consists of plaster, old bricks, and builders' rubbish, with a dash of lime, ground together in a mortar-mill, and used by speculative builders.

Concrete. *Lime concrete* is composed of ground stone-lime or grey lime and ballast, say 1 to 6, but there is no purpose for which this material should now be used. Even the best has little strength, and it will not set in a damp foundation. If lime concrete must be used, it should be *lias lime concrete*, consisting of, say, 1 part lime to 6 of ballast, but Portland cement is now obtained so cheaply, and is so greatly superior to lime in the manufacture of concrete, that it alone should be used.

Portland Cement Concrete. This has finely ground and properly air-slaked Portland cement as a matrix, and is mixed with sand and larger material as the aggregate. The aggregate should be so proportioned and varied in size that when the mixture is properly made all the interstices are practically filled, and a solid mass results, each particle of the aggregate being enveloped in a coating of cement. For foundations the proportion may be 1 cement, 2 sand, and 6 larger aggregate, varying from ½ in. to 1½ in. diameter, consisting of any hard material; for large contracts a concrete mixer [67] is found economical. For fire-resisting floors great care must be taken in selecting the materials and mixing the concrete. A specification clause would be as follows. "The concrete is to be composed of one part by measure of Portland cement as described, to one part of clean sharp, coarse sand, and four parts of coke breeze, pumicestone, hard brick, clinker or slag, free from dust, broken in various sizes to pass a 1 in. ring as a maximum. The materials to be carefully mixed dry on a wood floor, not more than ½ cubic yard at one time, and again turned over twice while being watered through a rose." All concrete must be used within one hour of mixing, and not disturbed afterwards. Flint gravel or broken limestone is not to be used under any circumstances for fireproof work.

Ferro-concrete. *Ferro-concrete* consists of Portland cement concrete and steel rods used in combination, so that the concrete takes the compression, or thrust, and the steel takes the tension, the amount of each material being inversely proportional to its resistance. It is now used for all varieties of building, and is very economical, but it is essential that the concrete should be made by skilled men under rigid supervision. The cement forms a natural protection to the steel, preventing oxidation, so that it is expected to be very durable, but the system has not been long enough in use to enable any actual estimate of durability to be formed.

Reinforced Concrete. Used as a raft in foundations, this may consist of not less than one-tenth per cent. of steel rods in both directions, laid through the middle of the depth and previously painted with cement wash.

VARIATION AND EVOLUTION

Causes of Variation. Influence of Environment. Parent and Child. The Main Theories of Evolution Considered. Bathmic, Lamarckian, and Darwinian Views

By Dr. GERALD LEIGHTON

SOME, perhaps a little better acquainted with biological literature, would mean by their question "Do you believe in Darwinism, or the doctrine that living species have originated by a process of natural selection of the fittest in the struggle for existence?"

Here the word evolution is used as a synonym for one particular theory of the origin of species—Darwin's theory. This is almost as inaccurate as the former case. One may be a Darwinian or not—that does not necessarily affect our recognition of the great fact of the existence of evolution. It may be remembered that the late Lord Salisbury, in his Presidential address to the British Association, seemed to throw doubt upon the fact of organic evolution by a disbelief in Darwin's theory of natural selection. Huxley's retort showed how the term was misused. He said, "If all the conceptions promulgated in the 'Origin of Species' which are peculiarly Darwinian were swept away, the theory of the evolution of animals and plants would not be in the slightest degree shaken." Nothing could put the matter more clearly. To use the word evolution when Darwinism only is meant is like making the word Christianity synonymous with the teachings of one sect only. Evolution may include Darwinism, but Darwinism at most is only one aspect of evolution. The greater may include the less; the less can never contain all that the greater involves.

Progress is not "Evolution." One other most common abuse of the word evolution is to be found in the writings of those who restrict the meaning to that of the evolution of living things only. As we have seen, this is "organic evolution"—again only a part of the whole. This mistake is an exceedingly common one in biological literature, and is a relic of the time when "inorganic evolution" was unthought of. There is no longer any excuse for this misuse of the word.

It need hardly now be emphasised that evolution is by no means another word for "progress," though that also is an all too common idea. What we mean by progress depends entirely upon our particular ideal of what life should be. We *hope for* progress, individual and national, but evolution is *inevitable*, a universal principle proceeding in every sphere whether accompanied by what we regard as progress or the reverse.

In a word, the fact of evolution is admitted by all races and creeds; *the methods of evolution* have provided matter for dispute for ages, and still do so. It is our task in this course to learn something of those methods, but it was imperative that we should first realise the full meaning of the fact itself. Moreover, it will be now clearly understood that we are here concerned only with organic evolution, the evolution of plants and animals.

Causes of Variation. We start from the obvious fact that all plants and animals show variation amongst themselves, and change somewhat under different surroundings. That is our common basis; from that we may reasonably hope that a due consideration of evidence will lead us to something in the nature of a common conclusion, making all allowance for individual differences of temperament in the realm of thought. The only real dispute will then be that which is still a somewhat disputed question even amongst those best qualified to judge—namely, the exact method by means of which organic evolution comes about, exactly how it is that living species exhibit the changes which we observe.

Since variation lies at the foundation of all adaptive change, we must first consider what is known as to the causes of variation, concerning which it may be at once stated we are very largely in ignorance. The study of these causes is a comparatively new one, and at present all that can be done is to draw attention to the suggestions that have been made, and the lines upon which the investigation is being carried out.

We have already emphasised the fact that although all living organisms tend to beget offspring like themselves, yet every individual differs in some smaller or greater degree from every other, including its parents, and that this difference constitutes what we term variation. Very remarkable variations we term *monstrosities* or *abnormalities*. It has also been pointed out that variations are *continuous* or *discontinuous*. Looked at in the simplest way, we may say that variations are said to be continuous when they form a gradual series connecting a typical or normal form with an extreme variation. If there are big gaps in the series which have no recognised connection we speak of the departure from the type as a discontinuous variation.

The Laws of Chance. "At present our knowledge of any particular kind of variation is very meagre. . . . But in a few cases a sufficiently large number of observations have been made to enable us to deal with them in a mathematical way, and as far as they point the road to any conclusion it is that they are fortuitous and accord with the 'laws of chance.' Now, events which accord with the laws of chance are simply those which happen under conditions of which we are ignorant. If we toss a penny the chances are equal that the

tail surface of the coin will be uppermost as frequently as the head surface; and we say that in a given throw it is a chance whether the head or the tail will be uppermost. If we knew all the conditions which govern the movements of the penny we could predict of any particular throw which surface would be uppermost, and it would be no longer a matter of chance. But our ignorance of these conditions does not make the throw of the coin anything else than what it is, and our statement that it is governed by the laws of chance does not make the conditions which govern it any different from those laws which control other falling bodies, such as planets, the movements of which we can accurately predict. The laws of chance, therefore, are the same as other natural laws, but they are acting under conditions of which we know little or nothing. The student, therefore, must not be misled by the expression 'laws of chance,' and believe that they are laws independent of, or different from, other laws; they are natural laws acting under conditions of the nature of which we are ignorant." (Mudge.)

Environment and the Germ-cell. We may term such variations fortuitous, or spontaneous, or what we will, remembering all the time that in so doing we simply deny that their origin is known at present, at the same time believing that their origin is governed by some conditions which the future may reveal.

At present the facts of variation seem to be exceedingly disconnected, and no man can say with certainty exactly whither they will lead us. All we can do under such circumstances is to note the indications as far as we can observe them.

Looking for some theoretical explanations for the cause of variation in offspring, the thought naturally occurs that it may be possible that the surroundings or environment of the individual may so affect the whole body that some influence is exerted upon the germ-cells contained in that body. Though the germ-cells are in no real sense produced by the parent (in higher animals), still their vitality depends upon that of the parent being maintained until they themselves become fertilised and started upon their independent career. For a large number of years, perhaps forty or fifty, they are lodged within the parent organism, for care and protection, and for nourishment, and it is no wild suggestion that the condition of the body of the parent must exert some influence upon the germ-cell within. The effect of this may possibly be seen in the production of variations in the offspring.

How does Variation come about? This is by no means the same thing as saying that the environment must produce the same effect in the offspring as it did upon the parent. That would be an entirely different matter. It does not follow, for example, that an alcoholic environment of the parent which caused in him the production of a drunkard will necessarily cause the offspring to exhibit a variation in the direction of drunkenness. But it seems almost impossible that the germ-cell can escape being affected in some way by the abnormal nutrition supplied to it by an alcoholic parent. It may well be that the result of such an environment may be to cause the germ-cell to vary in some way from what it would have been had the parental environment been otherwise.

The variation may be in the direction of insanity or other condition. We know relatively little regarding the nature and extent of variation which may be produced by environmental influences of this kind, but it is difficult to escape the conclusion that there must be some proportion of variations which are to be accounted for by the environment of the parent. We shall have to say something concerning the objections to this view of the causation of variations when we consider the problem of heredity. At present we simply note environment of the parent as one possible explanation.

Causes Within the Germ-cell. It is perfectly plain that if the parental environment is not the cause of variation in offspring, the cause must lie within the germ-cells themselves. Now it is perfectly certain that the parental environment is not responsible for *all* the variations which occur. It is even disputed whether it can account for any of them. Nothing is easier to prove than that all variations cannot be attributed to environment [see HEREDITY later]. Some, at least, arise from causes which act from within the germ-plasm, the laws of which we do not know at present, and for this reason we term these variations *spontaneous*. Spontaneous variations in this connection may be taken to mean all variations which arise independently of any directly immediate action of the environment. "For example, the germ-cells from which a litter of puppies, kittens, or pigs arise are all exposed to practically the same environmental influences, yet the germ-plasms contained in them often differ immensely in hereditary tendencies, as is proved by the great range of variations which may occur among the different members of the same litter." (Reid.)

Sex and Variation. If parental environment were a potent cause of variation, then we should expect all the members of the same litter to vary in the same direction, which they do not. Some of the variations—indeed, some biologists think all, or nearly all—obviously arise independently of the environment—that is to say, from causes which act from the side of the germ-cell, from within. The differences lie in the germ-cells themselves. We have no option but to believe that some variations are thus spontaneous; the question to be determined is whether *any* can be traced to environment. It may be that the processes which are concerned with the maturation and fertilisation of the germ-cells are responsible for some variations, by inducing new molecular arrangements of the germ-plasm which is the basis of inheritance [see PHYSIOLOGY].

It has also been held that the mixing of two more or less dissimilar masses of germ-plasm, such as occurs in the sexual reproductive processes, is a cause of spontaneous variation in offspring. Professor Weismann, the great biologist of Freiburg, and his followers at one time

attributed to this cause all variability, except that in the lowest organisms. On the other hand, Dr. Karl Pearson, Professor of Applied Mathematics, in University College, London, who has given great attention to the mathematical study of variation, denies the influence of this factor *altogether.* "*Variability is not a product of bi-parental inheritance. . . .* Whatever be the *physiological function of sex in evolution, it is* not the production of greater variability."

Parent and Child. The probability is that the truth lies between these two opposing views, and that some variations are the result of sexual reproduction, which, however, cannot be regarded as the sole cause of variability. In what is known as *blended inheritance,* where the characters of the two parents appear to unite so as to cause the production of offspring more or less intermediate between the two, we see a variation obviously due to sexual reproduction. For example, the child of a white man and a black woman as a rule is intermediate in colour and other characters between the two parents. Some variations, then, may be ascribed to this factor, but not all. Variations are not restricted to the offspring produced by sexual means; they occur also in asexual reproduction in abundance, so that there is good reason for believing that some at least of the variations in higher animals which reproduce sexually are due to causes other than the sexual method of reproduction. It will probably be found that the variations due to sexual reproduction are not fortuitous, but in very definite directions, and that if we knew all the characters which made up the parents we could predict with some approach to certainty the kind and amount of variation which could be attributed to the union of their reproductive cells.

To sum up, then, the causes of variation are by no means yet fully understood. The fact itself is seen to be universal in living organisms, and is the basis of all organic evolution. This organic evolution is also a recognised fact; the methods by which it is brought about are to a large extent matters of dispute and opinion.

We are now in a position to turn our attention to the views which have been advanced upon these methods of organic evolution, and to endeavour to take a dispassionate survey of the evidence for and against the different theories. Our view of life itself depends upon the conclusion we reach.

Theories of Organic Evolution. We have already stated that organic evolution has been accepted as a fact by all races and creeds, and that only the methods are in dispute. At first sight this may appear a strange statement, but a moment's consideration will convince that it is true. It is still denied by some that all the species of plants and animals sprang from one common origin. But all men, even the savage races, have some kind of belief in the origin of mankind from a common stock. They may believe that in the far distant past man arose from their heathen gods. Others derive mankind from Adam and Eve or from some lower species of animal. The exact belief matters not. In any case there is admitted or implied a belief in organic evolution, because at the present day mankind is found to differ vastly in his different races—some nations being big, others small; some white, others black or red or yellow; some having straight hair, others having hair short and woolly; each being adapted to special surroundings. It is not possible for a sane human being to doubt the existence of organic evolution. "In particular, it is not possible for the orthodox Christian, who derives the human race from Adam and Eve, to doubt it. Such a one must admit also that evolution may be very rapid, since, according to him, six or seven thousand years only have sufficed to produce types so widely divergent as the Scandinavian and the African pigmy." (Reid.)

The whole problem of organic evolution is the answer to the question—*By what methods have these changes come about?* Three views at least require mention.

Evolution by Miracle: The Bathmic Theory. We need not devote much space to this view, which supposes organic evolution to occur under the direction of a Deity who works by ever-recurring miracles. Very few educated persons now hold it. It is not a question whether an all-powerful Creator *could* bring about organic evolution in this way or not; it is a question of whether this has been the method adopted.

There is, it seems to us, a far grander faith than that in evolution by miracle, using the word miracle in the sense of the supernatural. It is surely better to search for an explanation of natural phenomena in natural laws (God's laws) than in exceptions to those laws, which miracles are. "Only when a natural explanation has been proved to be impossible have we an excuse for a direct appeal to the supernatural." (Reid.)

"Of course the theory of Bathmic evolution may be enunciated in vague terms. God and miracle need not be mentioned. We may be told that species undergo evolution, and so adapt themselves to the changing conditions of existence, not by the action of natural selection, nor by the transmission of requirements, but simply through the operation of an inherent adaptive 'growth force.' Nevertheless, the appeal to miracle is still necessary. No doubt the universal existence of variations demonstrates the existence of a growth, or, rather, change force. But the difficulty which has to be surmounted by the Bathmic evolutionist arises, not from existence of specific or racial change, but from the fact that this change—*i.e.*, evolution—has led, since the beginning of life, to the close adaptation of every race of animals and plants to its own successive environments. Either the environment has acted on species, which have reacted to it, or their adaptive changes were miraculous. There is no third alternative." (Reid.)

We see around us species which under our own eyes are changing in response to surroundings, and we have absolutely no reason

to think that the operations of Nature in the past were different in principle from what they are at present. We see species and varieties connected with each other by subtle links suggesting a common origin. The idea of the special creation of all these connecting links is unthinkable in view of the facts of life. Why all the connections, if every species were created as such? "Why are animals that live a wholly terrestrial life possessed of organs of respiration and associated structures of a purely aquatic nature? Why is it that man, in the course of his embryological stages, passes through conditions that characterise stages and permanent and finished structures of the lower vertebrata? These are difficult questions, very hard to answer, and cannot to-day be answered with certainty or finality. But this much is certain—the hypothesis of special creation does not answer them." (Mudge.)

The Bathmic theory may therefore be dismissed, and we must turn our attention elsewhere for a more reasonable explanation of the facts.

Evolution by Transmission: The Lamarckian Theory. Ever since the time of Aristotle naturalists have been searching for some explanation of organic evolution other than the paralysing dogma already considered. Foremost amongst those in order of time must be placed the eminent French zoologist Lamarck, who, in the year 1801, gave utterance to the view that all existing species have descended from pre-existing species. He did not stop there, but also enunciated a theory which attempted to explain *how* this had come about. It was not until Charles Darwin and Alfred Russel Wallace propounded their views, however, that Lamarck's theory attracted general attention. The two views are contradictory, and hence the one attracted attention to the other. Buffon, another French naturalist, also gave support to the view of Lamarck, and, indeed, Darwin himself attached some importance to some of Lamarck's arguments.

The theory of Lamarck hinges upon the question of the inheritance of acquired characters. According to him, the origin of species results from the acquired characters of the parents being capable of transmission to the offspring. His theory also involves the view that the environment of an animal can directly bring about acquired characters, which are transmissible. It asserts that living creatures are, to a great extent, modified by the kind of life they lead, that these modifications are handed on to their offspring by heredity, and that the modifications accumulate and become perfected in succeeding generations. Nature is supposed to mould creatures to their surroundings.

Heredity in Evolution. The theory has been admirably summarised by Dr. Archdall Reid in "The Principles of Heredity," from which we may quote this passage:

"If we believe with Lamarck that acquirements are transmissible, we find ourselves committed at once to a theory of evolution. In the face of common experience, we need not believe that acquirements tend to be transmitted in their entirety—that a dog which has lost its tail tends to have tailless puppies, or that a man who has attained great mental acquirements tends to have children endowed at birth with *all* that he achieved with pain and toil. But we are committed to the doctrine that the dog's loss and the man's gain will be inherited to *some* extent, however slight, and that, if many successive generations of dogs and men make similar acquirements, the race of dogs will ultimately become tailless, and that of men highly endowed mentally. In brief, the Lamarckian supposes that the effects of everything that benefits or injures the individual, including the effects of all use and disuse, are, to some extent, transmitted to offspring, and that evolution or degeneration results from the accumulation of these transmitted effects during generations. It supposes, for example, that . . . the descendant of many generations of blacksmiths will be stronger physically, but weaker mentally, than the descendants of many generations of students. It supposes that the conditions which produce health and strength in a succession of parents—absence of disease agencies, sufficient exercise, abundance of suitable food and fresh air, the right degree of moisture and temperature, and so forth—will ultimately render the race strong, hardy, and vigorous, whereas contrary conditions will render it feeble."

Limits of the Lamarckian Theory. "It is necessary to note a few additional points: (*a*) Just as the doctrine of the transmission of acquirements is not adequate to explain all the facts of heredity, so, also, it is not adequate to explain all the facts of evolution; for example, while it is perhaps competent to explain man's intellectual powers or the antelope's speed, it cannot explain why man has long hair on his face, which is lacking in woman, or why the colours of one species of antelope differ from those of another. Neither man nor antelopes make acquirements with respect to hair or colour, except such as lead to the loss of them. It cannot explain the differences in the integuments of the different species of fish. It can hardly explain a single fact in the whole world of plants. In fact, however simple and fascinating the Lamarckian doctrine may appear at first sight, however well it may seem to explain certain phenomena, it is quite insufficient to explain the totality of phenomena. It may possibly be accepted as a partial explanation of evolution; it cannot be accepted as a complete explanation. (*b*) Again, it must be noted that the Lamarckian hypothesis . . . supposes that all beneficial agencies which act on a species are causes of evolution, whereas all injurious agencies are causes of degeneration. In this, as we shall see presently, it is in violent and fundamental opposition to the Darwinian view."

The above summary from a work which should be carefully studied by all students of organic evolution will serve to make clear the theory of Lamarck. It will be still more appreciated when we have considered Darwin's view.

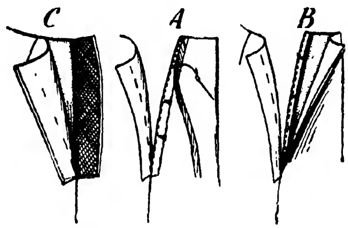
THE MAKING OF A SKIRT

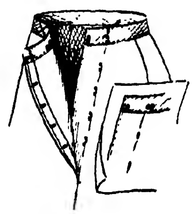
Darts. Fastenings. The Pocket. The Waistband. Finishing a Skirt. How to Evolve Fashionable Skirts from Simple Drafting

By AZELINE LEWIS

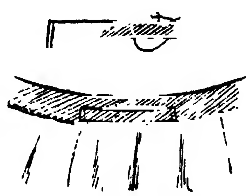
The Darts. Before stitching up the darts, it is well to put on the skirt, to see that they are in their right position, and set well at the waist. If correct, tack them from the top to *about 3½ in.* down, graduating them off to a nice point, so as to avoid any bulging out at the bottom. To do this, when the darts are machined, cut off the threads, leaving fairly long ends; thread one of these, and fasten off the tip of the dart with two or three stitches of oversewing. Now cut down the centre, press open, and fell the lining over.



59. PLACKET-HOLE

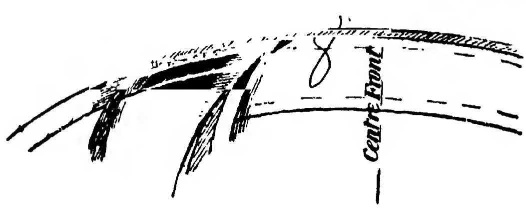


60. PLACKET-HOLE FASTENINGS



61. THE HANGERS

Preparation for Placket. For the front side gore fold a piece of tailors' linen 1 in. wide, place the fold on the white cotton outline of the placket, holding the linen rather tightly, and slightly easing the bias side to this. Turn down and tack. When this is done the edge should be in a direct line with the seam; then machine ¼ in. from the edge. Catch the raw edge down to the lining, being careful not to take the stitches through. Press before putting on the fastenings. [59*A*]



63. BRAIDING AND FACING

62. FACING FOR FOOT PART OF SKIRT

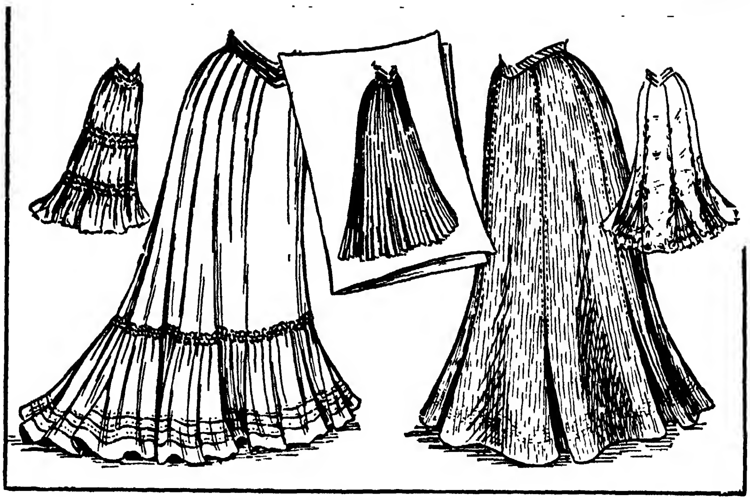
Another way of preparing the left side of front for the fastenings is shown at *B* in the same diagram. In this the fold of lining is placed to the outline of material, the edge of which is then folded over it, tacked and stitched, and the fastenings sewn on. The lining edge is then turned in and felled over them. This method is sometimes advisable in the case of fairly thick materials, and in this case the binding is not necessary; but great care should be taken not to stretch the crossway edge.

For the side gore, take a strip of tailors' linen, 2½ in. wide, and tack between the lining and material. Place one edge of the linen to the edge of the wrap, and the other about ¼ in. beyond placket outline; tack with white cotton along the outline of the placket, taking the stitches right through the linen and material, this last being a guide for putting on the fastenings. If the edges are selvedges, they can simply be stitched without turning in; if raw edges, turn in, tack, and then fell down the long edge and the bottom of the wrap. Take out the tackings and well press. [59*C*]

The Fastenings. The fastenings employed may be socket or spring fasteners, hooks and bars, hooks and loops, either small spring ones or the ordinary kind. Most people prefer the small spring hooks and silk loops, as being neater and more invisible than either of the others.

The socket, or spring fasteners are of two kinds—the one placed on a narrow band of webbing, the other being loose and sewn on singly. The former are recommended, as they are simply felled on the opening of the wrap, care being taken that the fasteners are opposite each other. If hooks and bars are used, the long edge of the bar is sewn on the placket outline of the wrap, the eyes of the bar

being placed towards the edge and buttonholed with silk, to make neat. [60] The hooks are sewn on the bias side, ½ in. in from the edge, and should be faced with galoon or Prussian binding. [59 and 60] If loops be preferred, they should be small, strong ones of silk twist.



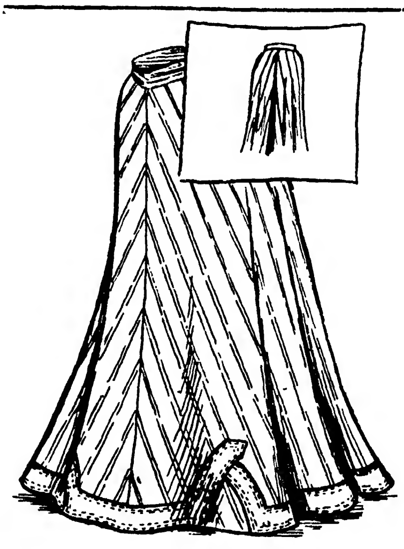
66. SOME POPULAR SKIRTS

The Pocket. The shape of the pocket is shown in diagram 49 [see page 525]. Two selvedges of material and two of lining are required for the opening side, to avoid raw edges, and also to neaten and strengthen the pocket. To draft it, mark 1 to 2, 2 in. down from the waist; 2 to 3—the opening, or mouth of pocket—is 6 in.; 3 to 4—depth of pocket—6 in.; 4 to 5, 7 in.; the line 3, 6 in., or more if required; 1 to 7, 2½ in. Curve from 7 to within 1 in. of bottom (*i.e.*, 5), and curve off from here to line 4.

Outline the opening on both sides with white cotton as a guide to putting in. If placed at a gore, or where the opening is likely to show, this will need to be faced with a strip of the material 2 in. wide, selvedges being placed to those of opening.

To make the pocket, lay the two right sides together, tack the edges, and stitch. Turn inside out, and again tack and stitch all round. Mark 2 in. from the waist; chalk 6 in. down for the pocket opening. Now cut the required opening in the wrap, insert the pocket, stitch in place, and press well.

Putting on the Waistband. The skirt should be put into the waistband before turning up the hem. In the case of a circular skirt, it is best to finish this off entirely at the band and upper part, and then let it hang on a stand for a day or two, if possible, before turning up the foot part. The reason for this is that a circular skirt, being cut mostly on the cross, is apt to "sag," or drop a good deal, especially at the sides; and if it is left to its own reflections on a stand, it will probably decide to do most of its sagging there and then, and so a good deal of the after unevenness may be avoided.



64. A TWO-PIECE SKIRT

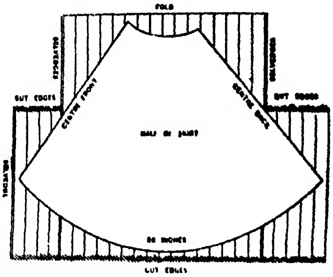
For putting on the band, straight or curved double webbing, single petersham, or satin-faced belting may be used. There is much to be said in favour of the curved double webbing, as it follows the contour of the waist more correctly than the straight; but it must be interlined with linen to give firmness and to take the strain of the hooks and eyes or bars.

Cut the webbing 3 in. longer than the actual waist measure, turn in ½ in. on the right side; run a white cotton at the size of the waist, which will leave 2½ in. for the wrap and for turning in at the other end. Mark the webbing into equal parts, quarter of half-waist measure in each—*i.e.*, 3 in. for 24 in. waist; pin the white cotton on the webbing to come in a direct line with the outline thread of the wrap, then pin the other measurements, one at each seam, and also on the darts; tack and stitch.

The first bar, or eye, is sewn on the part marked F [50] at top of wrap, the corresponding hook being sewn ⅛ in. from C [49]. Care must be taken that the hooks and eyes are exactly in the right places. Another bar or eye is sewn at the extreme end of the placket wrap. For the second hook chalk 2 in. away from the first hook, and the bill of the second must be exactly on this chalk

mark. The hooks and bars should be buttonholed over with silk to be neat. When single webbing is used, the turnings must be neatened with galoon or Prussian binding.

To put on the Hangers. Take 4 in. of Prussian binding for each "hanger," or loop, turn in the ends ¼ in., oversew the edges together, and sew one on each half of the band—inside, of course—stitching them on at the extreme end, and again ¼ in. away. [61]



65. ARRANGEMENT OF STRIPED MATERIAL

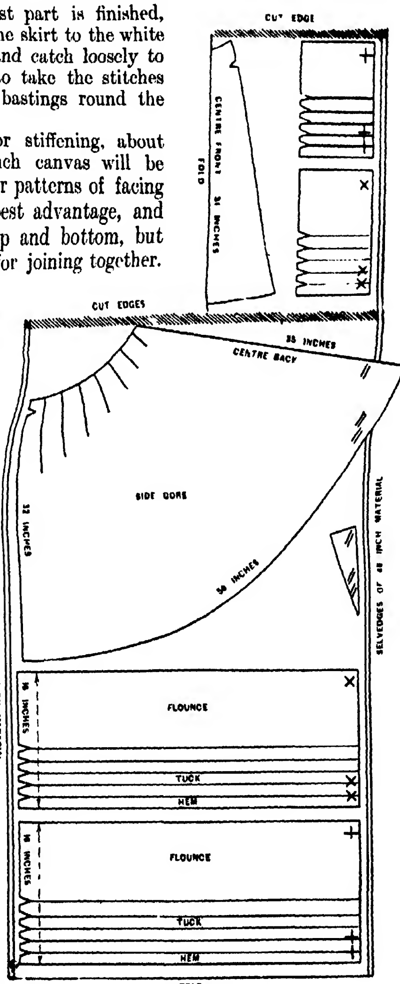
The Bottom of the Skirt. When the waist part is finished, turn up the bottom of the skirt to the white cotton on the lining, and catch loosely to this, being careful not to take the stitches through. Remove the bastings round the bottom only and press.

For the interlining or stiffening, about 1 yd. of very fine French canvas will be required. Lay the paper patterns of facing on the canvas to the best advantage, and cut without turnings top and bottom, but leave ¼ in. at each end for joining together. Trace the centre line on both canvas and lining, and number each piece of canvas the same as the pattern.

The facing must be cut with turnings all round, the fold being placed to the fold of the lining, the edge of side and back-gore portions being placed to the selvedge of the lining.

Now join the facing, open and press the seams. Tack the pieces of canvas together quite flat—*i e.*, place the ¼ in. turnings to overlap each other, to prevent a lumpy seam. Tack facing to canvas along the centre, then turn down the edges top and bottom, keeping the facing quite smooth, and tack along. Now machine top and bottom with a loose stitch ¼ in. from the edge. [62]

The Binding. The protection for the skirt edge will now be put on, which may be braid, brush binding, or one of the many varieties sold for the purpose. We have found brush binding by far the most satisfactory in wear, and also very easy to put on.



67. CUTTING OUT FLOUNCED SKIRT

If braid be used, let this be a good make, as a cheap one wears out almost directly. Before putting it on, soak it in cold water, and then hang out on a line to dry, without wringing it at all. When ready, tack the edges of the braid together, and fell on the skirt, allowing the fold to come ⅛ in. below the edge. Then tack the facing in position over the edge of the braid, placing the fold on the fold of front; pin in position on side gores, also midway between, then baste on the table top and bottom. If a deeper facing be required, it should be tacked three times. Fell the facing to the lining with a fine needle and cotton, then take out the tackings and press, placing a piece of lining on the facing to prevent marking, but on no account use water. [63]

Unlined Skirts. When pleated or full skirts are the mode, they are not always lined throughout. *In this case, however, the fronts should be lined, to prevent the ugly bulging or stretching out at the knee-part, which results when there is no lining to take the strain here.* This latter is a method indulged in by many good tailors and dressmakers. An unlined skirt is faced up at the bottom with lining cut to shape, arranged as already described, but *without* the canvas interlining.

In the case of thin materials, the foundation would be made separately, and secured or not to the waist, as preferred.

Fashion in Skirts. Fashion changes so frequently with regard to the cut of skirts that we cannot attempt to describe the many varieties introduced so frequently to our notice. Sometimes the sheath-like style may be the mode, at others the skirt may be required to fall in voluminous folds

from the waist to the feet. The width, too, may vary from $3\frac{1}{2}$ yards at the foot part (a good average for a walking skirt) to 5 and 6 yards, and even more. We hope, however, that the reader will have grasped from the foregoing examples how easy it is to add fulness at the back for an inverted pleat, and a flare to the sides of the gores of three or more inches; to narrow the front width, or to pleat this as required; to make the whole skirt wider and fuller; in short, to cope with the many variations of the prevailing mode.

So far, we have dealt with a one-piece or circular skirt, also a three, five, and seven gored affair, and shown how to obtain these; but skirts may be cut with any number of gores, up to eleven, this last, however, being better suited to a stout than to a slender figure.

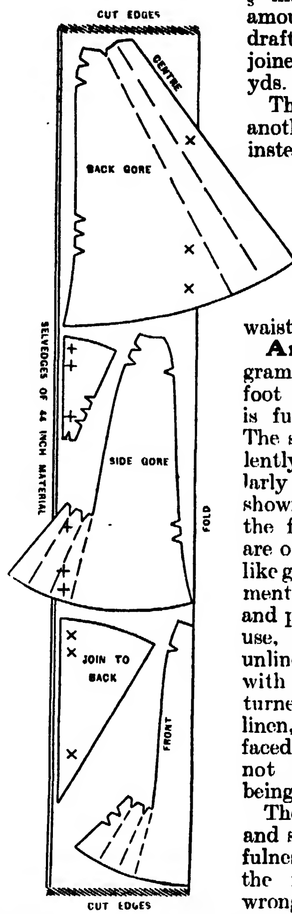
The four-gored shape is a very nice one for a walking skirt, and is practically the same as the five-gored, the difference being that the centre-back is placed to the fold, instead of having a seam here.

With respect to the gores, it may be said that, as a rule, when the number is even — from four upwards—the centre-back and front are placed to the fold.

Some other Skirts. In a two-piece skirt there is a seam at centre-back and front, as seen in diagrams **64** and **65**, which shows a very smart way of arranging this on striped material. For this, however, very great care must be paid to the matching of the stripes, and to the danger of stretching the seams when making up.

Diagram **66** introduces three more skirts. The first has a deep gathered flounce; the second inverted pleats at the foot part; whilst the centre sketch shows a sun-ray skirt.

The shape and method of cutting out the first are shown in the next diagram [67]. From this it will be seen that our drafting can be utilised, the upper part being a three-piece affair, cut, as we have already shown, to the length required to allow for the flounce, the extra width being obtained by separating the gores further at the lower edge. For the tucks in the flounce, 4 in. are allowed—*i.e.*, 1 in. for each—which will give a $\frac{1}{2}$-in. tuck. One inch is allowed for the hem, and the remainder is for the heading. This flounce is cut on the straight, as this will not stretch or drop like a crossway affair, and, of course, may be of any width desired. The upper part is tucked at the waist instead of being fitted with darts; for each tuck about $\frac{3}{8}$ in. should be allowed, and this amount can be easily added to the drafting. Pieces will have to be joined on to the foot part, and $5\frac{1}{4}$ yds. of 44-in. material are required.



68. SKIRT WITH PLEATS

The small sketch on the left shows another arrangement, by gathering instead of tucking, a style which may be recommended only to a tall, slender figure. This skirt, as well as the sun-ray one, is made up without a lining, and both are worn over a separate foundation, which may be secured to it at the waist, or not, as preferred.

An Evening Skirt. In diagram **68** we have an addition to the foot part of a five-gore skirt, which is further cut with a slight flare. The seven-gore variety is also excellently adapted to this style, particularly if used for the evening skirt shown in the smaller sketch, where the fan-like additions to the seams are of net, chiffon, lace, or any such like goods, whilst embroidery or passementerie further decorates the seams and panels. This skirt, for everyday use, may be lined or not; but if unlined, the front breadth is better with a lining, the foot part being turned up over a crossway strip of linen, or horsehair cloth, and then faced with lining cut to shape, but not interlined with canvas, before being machine stitched.

The seams are oversewn, opened and stitched on either side, the lower fulness being tacked down flat in the form of a box-pleat on the wrong side, then secured to the seam and neatened with binding, care being taken to keep the sides straight and to see that they do not drop below the level of the skirt-edge. Four yards of 44-in. material should make this skirt for a medium figure, whilst 9 yards of silk would be needed for the evening skirt, if made with a slight train, which addition is easily made.

Legal Aspect of Discount—continued. Divisions of a Business Office. Show-room and Counting-house. Salesmen and Clerks

By A. J. WINDUS

The Benefit of Prompt Payment. It comes to this, then, that not only has X received from C cheque, value £97 10s., but he has also received the benefit of prompt payment, and we know from what has gone before that he places a monetary value of £2 10s. upon such benefit. X, therefore, has received a total of £100—namely, £97 10s. by way of cash, and £2 10s., being the value he attaches to the prompt payment of C's debt. Having already, by rule (*a*), charged X with £97 10s. for cash received, we have now to charge him, under the same rule, with discount £2 10s., representing the value of what else he received—namely, prompt payment. This completes our record of the transaction in the books of C.

The incident we have been studying will also furnish food for thought to the student of Law. In our introductory chapter we made mention of the relations subsisting between Commerce and the Law, and it is most interesting to trace their connection in a given case. We cannot, in our course of study, give prominence to the legal aspect of commercial transactions, but perhaps a few remarks inspired by the foregoing illustration may help to dispel the illusion that Law is a dry subject, and may induce readers to turn their attention to the section which treats of it.

Two Parties in a Transaction. A business transaction presupposes two parties. When money is deposited in a bank, the two parties are the *depositor* and the *banker*. When a shipowner insures his ship with an insurance company, the two parties are known as the *insured*—that is, the shipowner—and the *underwriter* respectively. Similarly, the two parties to the sale of goods for £100 are X, the seller, and C, the buyer. Now, the depositor lodged money at the bank, the insurance company insured the shipowner against the loss of his ship, and X sold goods to C on certain conditions and for a named consideration. The term *consideration* is a legal one and rather difficult to define in few words. Pending our further investigation of it in the Law section [see LAW], let us content ourselves with a partial definition and call it a direct or indirect benefit conferred by one of the parties to a contract upon the other. In the first case just now cited the consideration was the interest allowed by the banker; in the second it was the premium paid by the shipowner; and in the third it was the price of the goods.

In all three cases consideration is present, and the terms on which the business is carried through are understood and assented to by the parties on both sides. Whenever these two elements, (*a*) consideration, (*b*) agreement to terms, are found in a transaction, there is said to be an *Agreement* or *Contract* between the parties. Generally, agreements are reduced to writing—or they may be partly written and partly printed—their precise form being the outcome of the combined effect of law and custom.

Commerce Abounds in Contracts. From the legal point of view, nearly all the more important documents met with in commerce may be described as contracts of one sort or another. Thus a *bill of lading*, besides serving as an acknowledgment of the receipt of goods on board ship, also constitutes a contract between shipowner and shipper for carriage of the goods on the terms named in the bill of lading. In like manner, an *invoice*—formerly called *bill of parcels*—frequently does duty as the contract between the buyer and the seller. All mercantile contracts are founded upon proposals or offers which have been accepted, but for a fuller explanation of the legal doctrine on this point consult the section on Law. [See LAW.] Applying the rule to X, we gather that his invoice for £100, dated March 31st, and giving short particulars of the goods sold, was based upon a prior offer of those goods to C and C's acceptance of such offer. In this way an agreement between X and C sprang into existence, the consideration for which was mutual. X was to supply certain goods and C was to pay £100 for them, and neither party could lawfully break the contract without the consent of the other. Suppose, however, X had promised to deliver the goods to C gratis, could C compel him to do so, the transaction being in all other respects the same as before? He could not, for the reason that X received no consideration for his promise, whereas English law requires consideration for every contract not under seal.

The Legal Aspect of Discount. Let us now apply this reasoning to the case where, X having agreed with C to supply goods for £100, C asked X to take £75 in full discharge, and X promises to do so. C thereupon sends a cheque for £75 to X, which X receives, and then sues C for £25, the balance of the original debt. Can he recover? He may do so, because his promise to take a smaller sum in payment of a larger is, in the eye of the law, a new contract for which he has received no consideration. The lawyers could doubtless explain the justice of such a decision to their own satisfaction.

It is very different, however, with the £2 10s. discount which X has allowed C to deduct. Undoubtedly, there is a second contract in this

case also, which to some extent overrides the first. C agreed to pay X £100, but now X offers, and C accepts, 2½% discount for payment within ten days from date of invoice. This constitutes a new agreement between them, and it is perfectly valid, because X receives consideration for his surrender of £2 10s.—namely, the benefit of prompt payment. Here for the pres nt we take our leave of X.

OFFICE AND STAFF

Hugh Miller, the famous geologist, was employed at one time in a bank. Concerning this experience, he afterwards affirmed that he was handicapped by his inability to trace the bearing of isolated details on the system of which they formed a part. "I could do literally nothing," he wrote, "until I had got hold of the system." The useful hint here given may be pursued to our own advantage. Let us commence with a comprehensive survey of Bevan & Kirk's business, and then, contracting our horizon by degrees, go on to examine with the necessary care all the matters that may come under our notice upon a nearer inspection. The firm of Bevan & Kirk is one but recently established. It was founded at the beginning of the present century for the purpose of carrying on the business of merchants and manufacturers' agents in the City of London—the metropolis of the world. At a later stage, and also in the sections on banking and commercial geography, reference will be made to the immense and preponderating influence which London enjoys in virtue of its position as the geographical, political, monetary, and commercial centre of the world, and then we shall perhaps learn what are the advantages which Bevan & Kirk may derive from the fact of being located in London. Meantime, we note that the firm conducts a shipping as well as a domestic trade. Their business address is 500, Wood Street, London, E.C. The letters "E.C." are an abbreviation for "East Central," showing the postal district of London in which Wood Street is situated.

Definition of a Merchant. The term was formerly restricted to those engaged in the importing and exporting of goods on their own account, but the modern interpretation gives it a far wider meaning. In general, it serves to distinguish a wholesale business of any sort—even though retail and agency transactions are mixed up with it—from a purely retail business. Thus, a firm of colliery owners who sell coal by the hundredweight might describe themselves as coal merchants, on the ground that they supply coal by the hundred thousand tons to steamship companies and others; but for a small greengrocer who obtains his daily stock of vegetables from the Borough Market to call himself a potato "merchant" is a palpable misuse of the term.

Messrs Bevan & Kirk, then, are merchants in a wholesale line of business, but they are manufacturers' agents as well. An illustration will best explain the meaning of the latter term.

The Function of a Manufacturers' Agent. The Berlin Manufacturing Company (headquarters in Berlin) are engaged in the manufacture for export of ladies' blouses and costumes. Now, it is the great ambition of all foreign exporters of manufactured goods, whether French, German, or American, or whatever their nationality, to find an entrance into the most profitable and desirable of all foreign markets—namely, Great Britain. The Berlin Company are, therefore, naturally anxious to introduce their goods into this country, but until they have thoroughly gauged the vagaries of British feminine taste in blouses and costumes they do not wish to incur the expense of a London office and manager, and possibly two or three travellers. The Company accordingly arrange for Messrs. Bevan & Kirk to act as their agents or representatives for the sale of their goods in this country. The agreement drawn up between the parties would contain provisions stating the mode of securing and executing orders, how goods sold are to be paid for, the amount due to Bevan & Kirk for their services as agents, and so on, and we shall consider these matters in their due place.

From what has been said we have an inkling of the nature of the *articles of trade* dealt in by Bevan & Kirk, and we may now add to our list the following: Silks, laces, trimmings, ostrich feathers, boas, fans, lace handkerchiefs, collarettes.

In any business such as this there are two main divisions or departments, known as the warehouse (or show-room) and the counting-house respectively. Occupying a middle position, and related in some sense to both departments, is the entering-desk.

Show-room and Counting-house. Everything that has to do with the actual buying and selling, receipt and despatch, unpacking and repacking, placing in stock and taking out of stock of the goods themselves, is regarded as belonging to the show-room, or *productive* side of the business. On the other hand, everything that has to do with the receipt and payment of money, and the bulk of the work of registering or recording business operations or transactions, is looked upon as belonging to the counting-house, or *unproductive* side of the business.

Salesmen and Clerks. Here we are brought face to face with perhaps the most "pestilent heresy" the clerk will ever be called upon to do battle with in the business arena. Shortly stated, the doctrine is this: A salesman is worth his salt, a clerk is not. Let no one underrate the malignant character of such false teaching. In too many instances the practical effect is that the clerk's salary is grudgingly paid, and is far below that of his fellow-worker, the salesman. Well-known business houses might be named in which boys who started on level terms as counting-house juniors 10, 12, 15 years ago are to-day filling positions, some as salesmen and others as clerks, still in the same establishments, but whereas the maximum scale of salaries for clerks is under £200 per annum, their quondam

companions of the counting-house are drawing hundreds yearly for their more valued services as salesmen. How to combat this undoubted evil must be a point reserved for future consideration; but should any reader have the opportunity of choosing between the position of salesman and that of clerk, he would be wise not to reject the former, except after due deliberation.

But we must hasten on to explain the duties and positions of the various members of the *staff* of Bevan & Kirk, after which we shall treat of the different books of record used both in the show-room and the counting-house. We shall then deal in a comprehensive manner with the firm's system of bookkeeping, and finally we shall exhibit a few specimens of the business forms in use by the firm, such as *invoice*, *statement*, *certificate of origin*, *receipt for goods*, *receipt for cash*, etc. Afterwards we may turn our attention to the import and export trade, and this, we trust, will be found not the least interesting portion of our subject.

The staff of Bevan & Kirk is thus arranged.

Show-room or Warehouse:

2 town travellers, who also act as indoor salesmen, and attend to the execution of orders received.

1 stockkeeper, whose business is to look after the stock, advise his principals when a "line" is running short, assist in the show-room when the travellers are out, and otherwise qualify himself to become a buyer or a salesman.

3 girls, engaged on pattern cards and samples for travellers, and in labelling goods, packing them in cardboard boxes, and so forth.

2 strong messenger boys, who do rough work and act as porters, and who, by assisting or "understudying" the stockkeeper, may learn how to fill his position when a vacancy arises in the firm or elsewhere.

—

8

Counting-house:

The accountant and the junior clerk.

The cashier's duties are performed by Mr. Kirk, the junior partner, who signs all cheques and attends to the financial side of the business.

Correspondence clerk: young lady shorthand writer and typist.

The staff accordingly comprises eleven employees in all. Everyone but the accountant and correspondent (who receive their monthly salaries by cheque) is paid weekly.

Entering-desk. The business is not of sufficient size to warrant the employment of clerks specially for the entering-desk—that is to say, for the work of entering in the *day-book* and on *invoice forms* particulars of the orders executed. This work is therefore distributed among selected members of the staff.

The common routine of the entering-desk in bigger concerns may, however, be described. One clerk takes the day-book, another a batch of invoice forms, and there is a third person who calls off the goods for entry. The caller "gives down" the customer's name, address (but this is sometimes omitted), shipping marks (if any), customer's order number, salesman's number, quantities, weights, or measurements, with the descriptions and prices of the goods and any trade discounts allowed. These particulars are "taken down" by the invoice clerk and the day-book clerk simultaneously. The extensions are made as they go along. Thus, the caller might say, "$50\frac{5}{8}$ yds. No. 48 trimming at 1s.," and this would be extended at £2 10s. $4\frac{1}{2}$d. both in the day-book and on the invoice while he was preparing to give down the next line. So expert do the clerks become in making the extensions of the various items and the castings of the different invoices that within a very few minutes after the caller has ceased calling they have finished their calculations. Of course, the clerks compare notes on the correctness of each invoice total, and when they agree on any total it is assumed that the details which go to make up that total are correct. Comparison of totals is sometimes carried on concurrently with the other work, and then differences can be easily located and adjusted which, if left over until all the calling has been done, might become a source of trouble.

A Bad School for BookKeeping. Regret that this time-honoured method of "entering" is being superseded by the introduction of labour-saving devices, such as the book-typewriter, should be tempered by the reflection that the entering-desk is not a good school of penmanship, and that the old-style entering clerk rarely developed into an ideal bookkeeper because he was too much imbued with the spirit of haste to do his work with that neatness and entire absence of erasures on which the skilful bookkeeper prides himself.

A frequent substitute for the entering-desk is found in the plan adopted by Messrs. Bevan & Kirk. The day-book entries are made throughout the day—whenever, in fact, orders are ready for despatch. The junior clerk makes out the invoices from the day-book, and they are either sent under separate cover along with the goods, or separately by hand, or by post, as the case may be. Yet another variation is to write out the invoices in copying-ink from information supplied by the persons who executed the orders and from the orders themselves. As press copies of the invoices are taken, it is not strictly necessary to repeat in the day-book all the information contained in the original invoices. Consequently the day-book shrinks to a bare record of dates, names, and amounts.

The modern universal tendency towards the subdivision of labour is quite as effective in business circles as elsewhere. As a rule, no ledger clerk would be allowed to act regularly as buyer, no salesman as cashier; nor would a factory foreman be allowed to combine the functions of a general manager. Therefore, it is imperative to arrive at an early decision—let us say, between the ages of 17 and 20—on the all-important question: "What are we going to make of our lives?"

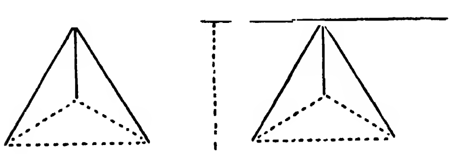
WHAT GRAVITATION MEANS

Kepler's Laws and Newton's Deductions. Universality of the Law of Gravitation. The Simplicity of the Law and its Wonderful Meaning

By DR. C. W. SALEEBY

Three Kinds of Equilibrium. Three kinds of equilibrium are usually described—*stable, unstable,* and *neutral.** A body is said to be in a state of stable equilibrium when it tends to return to its original position after the temporary application of a disturbing force—the book lying on the table or a weight hanging at the end of a string are in stable equilibrium. In the case of any given body, it is often necessary to ascertain the conditions of stability or of stable equilibrium.

Let us take, for instance, a three-legged stool. If this be slightly tilted, it will come back to its original position, and it is found that in the case of such a stool, or any other body which is supported at a series of points, the conditions of stable equilibrium are satisfied when the vertical line dropped from the centre of gravity of the body in question falls within the figure formed by joining all the points of support. If, for instance, the three-legged stool has a very wide top and we place a heavy ball upon the edge of this top, the whole thing will topple over—the centre of gravity has been shifted, and the vertical line dropped from it reaches the ground at a point outside the figure formed by joining the three points at which the stool is supported.



A body is in a state of unstable equilibrium when the temporary application of any new force causes a permanent change in its position. An egg may be balanced on its end for a moment, and during that moment there is equilibrium; but it is unstable because the very slightest displacement cannot be recovered from, as it can in the case of a weight hanging from a string.

The Case of the Billiard Ball. Midway between these two is neutral equilibrium, in which the body, when a new force is impressed upon it, undergoes a change of position without returning to its original position, but without continuing to leave it. A billiard ball, for instance, is in a state of neutral equilibrium on a billiard table. When gently pushed, it moves a few inches and then comes to rest. That its equilibrium is neutral but not stable is evident when we contrast its case with the weight hanging from the string, for when the weight is pushed, just as the billiard ball is pushed, it not only comes to rest as the billiard ball does, but it comes to rest in the original position, whereas the billiard ball comes to rest at a distance from it.

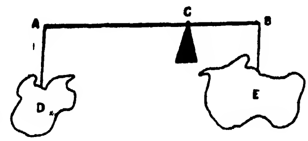
Let us turn now to the consideration of forces tending to produce rest in virtue of their interaction. Suppose that the forces be parallel, as in the case of a rod balanced upon a point by means of a weight hanging from each end of it. We must suppose also that the rod has no weight of its own, else the case becomes too complicated. Let us imagine that the two arms of the rod are of unequal length, the weight hanging from the end of the shorter arm being heavier than that hanging from the longer arm, but the proportion between the two being such that the rod is balanced. Here we have two downward forces, one acting at each end of the rod, and they are exactly counterbalanced by an upward force which acts at the point where the rod is supported, and which consists of the resistance offered by the supporting point to the forces represented by the two weights hanging from the two ends of the rod.

Principle of Moments. Now we find that the rod remains balanced—that is to say, equilibrium results—only on this condition, that the force represented by the one weight multiplied by the length of the arm to which it is attached be equal to the force exercised by the other weight multiplied by the length of its arm. This exceedingly important proposition, which is true in all cases, simple and complex, is known as the *principle of moments,* a technical term which involves the definition of the word *moment.* The language employed is really very stupid, for surely anyone is entitled to think that *moment* and *momentum* have the same meaning, the first being obviously the English of the second, which is a Latin word. But they have two totally different meanings. By momentum, as we saw, is meant the quantity of motion, but the word moment is a description of a much more complicated idea. In the case of the weights hanging from the ends of the rod, the moment of the force represented by one of the weights is the product of that force and the length of the arm of the rod from which it hangs. This must now be put into more abstract language.

We have seen that the point where the rod is supported, or the fulcrum of the lever, exercises a force vertically upwards; the arm of the rod is therefore at right angles or perpendicular to the force exercised by the fulcrum; hence we may say that the moment of the force is the product of the force into a perpendicular dropped

* See "Centre of Gravity," later in the course.

from the fulcrum upon its line of action. Even this statement may be made more abstract still, thus: The moment of a force about a point is the product of the force and the perpendicular from the point to the line of action of the force. This sounds very difficult, but it is simple enough if we read it over carefully in connection with such a diagram as this.



In the diagram, C is the "point" of the definition, D or E represents the force of the definition, and AC or BC represents the perpendicular from the point to the line of action of the force.

The Lever. Now, the principle of moments underlies the whole theory of the lever. In the simplest and most useful kind of lever we find, for instance, a man exerting a small force at one end of a rod, which results at the other end in the motion of a very heavy object which the man could not possibly have moved directly. This is the principle of the crowbar.

The fact that determines the movement desired is the adequacy of the moment on one side of the fulcrum as compared with the moment on the other side. The *force* the man applies may be small, but this is multiplied by the length of the long arm of the lever, and hence its *moment* is adequate. That is to say, it is equal, or more than equal, to the *moment* of the force acting on the other side of the lever. It might easily be shown that nutcrackers and scissors and pincers are cases of levers which act in a similar fashion.

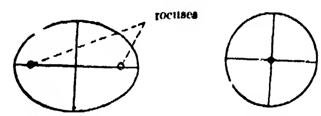
The Discoveries of John Kepler. The discussion of the third law of motion is deferred to the chapter in which we deal with the conservation of energy and the relation of this great principle to the facts of dynamics. We may conclude the present discussion of motion in general by the statement of the three laws of planetary motion discovered by the great astronomer John Kepler (1571–1630).

This illustrious genius was born at Weil in Wurtemburg. He had a miserable childhood, for not only was he born prematurely, like Newton, but his hands and his eyes were permanently injured by an attack of small-pox in his fourth year. Destined for the Church, Kepler turned to astronomy, to his great regret, in his twenty-third year. He soon became dissatisfied with the chief business of a German astronomer in those times—the making of almanacs that prophesied the future from the movements of the planets—and he attempted, but in vain, to reduce these movements to law. It was not until many years later, in the first decade of the seventeenth century, that his ceaseless labours of observation led to memorable results. He had bad health, he was not a great mathematician, he was overwhelmed with domestic cares, but he left an enormous mass of accurate and precise observations.

Three Laws of Planetary Motion. His many years of labour enabled him to arrive at the three great laws of planetary motion now to be stated.

1. *The orbit of each planet is an ellipse with the sun in one focus.*

An ellipse is a closed curve, symmetrical about two axes, which are at right angles to one another. Within this ellipse there are two points, each of which is called a focus. It is plain that if the two axes become equal the ellipse is converted into a circle, and the two focuses coincide. [See GEOMETRY in DRAWING.]



ELLIPSE CIRCLE

From this law Newton inferred that the attractive force which keeps each planet in its orbit varies inversely as the square of the planet's distance from the sun. Newton inferred the existence of this attractive force from the second of Kepler's laws, which is as follows:

2. *The radius-vector of each planet describes equal areas in equal times.*

The radius-vector is the line drawn from the sun to the planet. It follows from this law that the velocity of the planet must be greater when it is nearer the sun than when it is farther away.

3. *In the case of each planet, the square of its periodic time bears the same proportion to the cube of its mean distance from the sun.*

The periodic time is the time taken in journeying once round the sun—one year for the earth and 165 of our years for Neptune. The mean distance is usually taken as half the length of the longer axis of the ellipse which represents the planet's course.

How Newton Deduced his Theory. We have already seen what Newton inferred from the first and second laws; from the third he inferred that the attractive force which keeps the planets in their places is the same for each planet—that is to say, is the same absolutely, though we have already seen that it varies inversely as the square of each planet's distance from the sun. Hence Newton concluded that it must be one and the same force, directed to the sun, which keeps each planet in its orbit.

Before Kepler's day it was thought that each planet moved in a circle round the sun at an unchanging speed. These remarkable discoveries of Kepler were thus absolutely essential to Newton's discovery of the law of gravitation. Since Newton's time it has been proved by mathematicians that Kepler's second and third laws are necessarily deducible from the first.

The reader must clearly distinguish between Newton's laws of motion—three in number—and Kepler's laws of planetary motion, also three in number, which latter constitute the data from which Newton made the crowning inference of the law of universal gravitation. This is the great subject which we are now about to consider.

WHAT GRAVITATION MEANS

The law of universal gravitation is as follows:

Every particle of matter in the universe attracts every other particle with a force which is in the direction of a straight line joining the two, and whose magnitude is proportional to the product of the masses, and inversely proportional to the distance, between them.

This may be stated in slightly different language. Every portion of matter attracts every other portion of matter, and the stress between them is proportional to the product of their masses divided by the square of their distance.

Now, before we go any further, we must distinguish once and for all between a law and a cause—what, in fact, is this statement of the law of gravitation? It is what is called in philosophical language a *generalisation.* Indeed, all the laws of which we speak in science are generalisations—that is to say, general ways of stating the common character of a large number, perhaps infinitely large, of particular facts. Now, it is plain that there can be no final generalisation as to such a matter as gravitation, since it is plain that we cannot possibly examine all the particular instances concerning which the general statement is made. All we can say is that in every case we have examined we find that this attraction exists, and that its magnitude is determined according to the conditions stated in the law. We find further, as the case of the discovery of Neptune proved, and as is also proved by innumerable experiences of astronomers, that the law may be trusted as a means of prediction and discovery. We may take it, then, that though we have not examined every case in the universe throughout all past, present, and future time, yet a general statement which is true of all the facts we have observed, and which actually informs us in detail as to innumerable facts which we have never observed, is as much entitled to be regarded as true as is any proposition which the human mind is capable of framing. In other words, we will admit ourselves to be very dogmatic, and, if you like, arrogant, and to say that the law of gravitation is positively true; that we have here the truth, the whole truth, and nothing but the truth—in short, that concerning this law we have nothing more to learn.

Distinction Between Law and Cause. But when we come to consider the totally distinct question, which is nevertheless constantly confused with the previous question, we find that our dogmatism is silent; whereas, concerning the *law* of gravitation we dare to assert that we know all there is to be known; concerning the *cause* of gravitation, we know nothing whatever.

We have laid much emphasis on this point, in the first place because it will lend clearness to our subsequent discussion; but, in the second place, because the distinction between a law and a cause is of cardinal importance in scientific thinking, and because, to our mind, the fundamental distinction between the two finds no illustration so cogent and convincing as the present one.

For we have here a universal principle concerning the details of the operation of which we know everything, but concerning the cause of which we know absolutely nothing at all. Surely we may hope that no reader of this chapter will ever again make the disastrous mistake of confounding law with cause, a mistake which has led to more controversy and confusion in science and, notably, in the conflict between science and dogmatic theology, than any other that can be named.

Universal Gravitation. First, then, as to the facts of universal gravitation, which will occupy us at much length, before we spend a few paragraphs in a discussion of the attempts that have been made to explain them. At present we are concerned merely with description, with the fact of the law of gravitation; later we shall be concerned with explanation, the cause of the facts which we have described.

Newton was led, as we may remember, to this supreme discovery by the contemplation of a falling apple; and gravitation is in the first place a terrestrial or earthly matter. It does not need a Newton to know that unsupported objects fall to the earth; and if they fall, it must be that some force has been impressed upon them; our study of the first law of motion has taught us that. It is plainly a great step from the assertion that the earth exerts an attractive force upon an apple to the assertion that the sun exerts an attractive force upon the earth, and to the further assertion that the apple attracts the earth, and the earth the sun.

For very many years the truth of the law of gravitation could not be asserted save of the earth, objects upon the earth, and the planets in their relation to the sun—that is to say, gravitation was a truth of the solar system, but we could positively say no more. The French philosopher, Auguste Comte, declared that we should never be able to assert whether or not gravitation acts amongst the stars. He was wrong, for less than fifty years after his death we are able to say that the facts recorded in an enormous and constantly increasing number of observations do demonstrate the action of gravitation amongst the stars. We are, therefore, now justified in believing that it is an omnipresent force.

If Gravitation were Abolished. Some of the more immediate indications of gravitation have already been indicated. We saw in a previous chapter that we must carefully distinguish between the two words "mass" and "weight"; we saw that the mass of a body is the stuff it contains, but that the weight of a body is merely the outward indication of the force of gravitation between the earth and the body in question. If gravitation were abolished it would require no effort whatever to lift by one finger a weight of a million pounds, but there would be as much stuff in the object lifted as before; its mass would be unaltered. Hence in the case of the planets and the stars, astronomers never think of talking of their weight; the term has no meaning, for gravitation is acting upon them in all directions. We can only conveniently

talk of weight where, as in the case of a stone held in one's hand, gravitation is for practical purposes acting only in one direction—*viz.*, downwards. Thus by weight we mean the downward force of gravitation, but downwards means nothing when applied to Sirius or Jupiter. Astronomers may, therefore, talk of the mass of the heavenly bodies and of their density, which is the relation of their mass to their size or volume, but never of their weight.

As we have seen, then, if gravitation were abolished we should all be strong men, and if its force were altered, as it would be by our transference to a smaller or a larger planet, such as Mars or Jupiter, the possibilities of our lives would be very much modified; but it has nowhere been clearly enough stated that, according to the prevailing theory, we owe our very existence to gravitation!

Energy and Shrinkage of the Sun. Everyone knows that the earth owes its energy to the sun, the source of all our light and heat, without which life could never have been evolved upon the earth, and with the extinction of which it must necessarily cease. Now, according to the theory of the great German physicist, Hermann von Helmholtz, the sun obtains energy from its constant shrinkage, and this shrinkage is due to the mutual action of gravitation between the innumerable atoms of which the sun is composed. Quite recent research has shown that, in all probability, gravitation is not the sole source of the solar energy, but it is at the very least an important contributing source of the power in virtue of which human life is possible.

Gravitation having given us life, and ever binding us to the sun—from the company of which the earth would soon separate herself in virtue of Newton's first law of motion but for the constraining power of gravitation—this great principle proceeds to supply man's mind with the most striking proof of what is perhaps its most lofty conception. This conception is that this great and various world of ours—flowers and stars, educators and elephants, men and meteors—is what we rightly but uncomprehendingly call a universe—that is to say, all are in reality one. It is Newton's law of gravitation that furnishes us with the most powerful support for this belief. The poet is actually right who says:

"Thou canst not stir a flower
Without troubling of a star."

A Wonderful Thought. If the law of gravitation be true, you cannot stir a flower, you cannot even cause movements of matter in your brain in the mere intention to stir a flower, without thereby altering the position, in accordance with universal gravitation, of all the matter in the universe. As the present writer has ventured to say elsewhere, every breath we draw affects the path of Sirius and the Pleiades.

Another point which we consider to be inadequately emphasised is the extreme simplicity of this universal law. This simplicity becomes more striking when we realise that a similar statement to that of Newton holds good of certain important facts of magnetism and electricity.

The Marble and the Star. The simplicity of the law of gravitation is so striking that it leads to a very interesting speculation as to the cause of gravitation. The cause underlying a law so simple must itself be very simple. The law states that not only every atom in the universe attracts every other, but that the force with which they do so bears the simplest possible relation to their mass and the distance between them. If the mass be added to, the force is added to in proportion. If the distance be doubled, the force is reduced to a fourth of what it was before. The law holds to a hair, however you alter the conditions as to distance, or mass, or disparity of size between the two bodies we consider. It holds whether you deal with a couple of marbles on the table before you, or with the mighty star Sirius and that invisible dark companion of his which the law of gravitation has discovered for us, or with one of the marbles and Sirius. Plainly, therefore, the cause of phenomena so constant, so invariable, yet capable of such very simple expression, must itself be constant, invariable, and simple.

Three Facts. Let us note one or two facts corroborative of the law of gravitation and of the assertion that it is universally applicable. We find, for instance, that the weight of a body is equal to the sum of the weights of its parts; that a spherical shell exercises no attraction upon a particle in the centre—that is to say, appears not to exercise such attraction, because the attraction, in accordance with the law of gravitation, is equal in all directions. Thirdly, we find that a spherical shell acts on a particle outside it with a force the direction of which is through the centre of the sphere, and is exactly equivalent to the force which would act on the particle if the whole mass of the sphere were condensed at its centre.

Since we know that at any one place the weights of all bodies are proportionate to their masses, we know that the force of gravitation varies in proportion to the masses of the mutually attracted bodies. The last statement in the law, the "law of inverse squares," is a necessary deduction from Kepler's laws of planetary motion, which, as we have seen, are simply general statements of facts.

Continued from page 502

Hebrew Race. The Mosaic Law. Jericho Destroyed. Solomon's Reign. The Babylonian Captivity. The Rise of the Greek Race

By JUSTIN McCARTHY

THE earliest appearance of the Hebrew race, that race which has performed in the world's progress so important a part, belongs to the dawn of history. We learn much of its story from the narrative bequeathed to humanity in the Old Testament, sustained as it is by many monuments and human records. The Hebrews trace the opening of their historic progress back to Abraham, who came from Chaldea and settled in the region of Canaan 2,000 years at least before the Christian era. In the region between the Nile and the Red Sea, a land most fertile and ready for cultivation, the Hebrews rapidly increased and multiplied, although the Egyptian occupants of the soil treated them for a long time as underlings, or, indeed, as if they were mere captives of the bow and spear.

The Hebrew Race. The Hebrews were from the outset a conquering race, though not in that merely physical sense which is usually associated with ideas of conquest. From the dawn of history down to the present day the Hebrew—or the Jew, as we now call him—has always made himself an influential and even a ruling figure, in fact at least, if not in title, among every race in whose movements he has come to take any part. The narrative of the Old Testament tells how Joseph, sold as a slave in Egypt, rose by his intellectual and practical capacity to become one of the Ministers of the Pharaoh Sovereigns, and this early record fitly illustrates the story of the race. Throughout the history of the world, since its earliest records, the Hebrew has been persecuted in every country, ancient or modern, where he endeavoured to establish himself as a citizen. It must be owned, too, that the Hebrew when he had the opportunity has shown himself as ready and as capable of instituting religious and caste persecutions as ever his enemies have been; but in the power of maintaining himself against all such oppression, however resolute and steady in its continuance, he is almost without a rival in man's history.

Birth of Moses. In the region where the Hebrews settled they soon began to multiply greatly, but they made no intermarriage with the Egyptian population. The story of the finding of Moses serves to illustrate most effectively the traditions which tell us how the government of the Pharaohs endeavoured, by the ruthless exercise of tyranny, to check the growth of the hated Hebrew race. An Israelite woman gave birth to a male child at a period when the ruling sovereign of the Pharaohs had issued an order that all male infants of Hebrew women should be killed at birth. The Hebrew woman, after having concealed her child for three months, began to fear that she could not much longer prevent its existence from being discovered by the enemies of her people. She put the child in a basket of bullrushes on the Nile, where the daughter of the reigning Pharaoh was accustomed to bathe every day. The wailing of the child drew the attention of the princess, who had a woman's heart, and was moved to genuine compassion by the infant. She brought him up in her own palace, and had him instructed by the best teaching which the Egyptian priests could give him.

The Pharaohs. The child was named Moses, meaning "drawn out," because he had been literally drawn from the waters of the river. Later on the mother of Moses found access to him, made known to him the secret of his birth, and revealed to him the whole story of the persecutions inflicted on his race by Egyptian rule. Moses, now growing up, saw one day an Egyptian beating and ill-treating one of the Hebrews, and he killed the Egyptian aggressor.

Knowing what the consequences of this act must be, Moses escaped from that region and made his way to Jethro in the southern extreme of Arabia Petræa, where he found the ancient faith of his forefathers prevailing. He thereupon resolved to devote himself to the task of delivering those of his race whom he could influence from the tyranny of the Pharaohs, and to lead them "out of the house of bondage." He asked Pharaoh to allow him and his people to go "three days' journey into the desert and sacrifice unto the Lord our God." The recent discoveries made by Dr. Flinders Petrie, in Sinai, have brought to light some evidences in stone that there was near Sinai in the days of Moses a Semitic temple, a central place of worship to which the Jews and their kindred peoples were accustomed to resort, and that this was the temple which Moses proposed to reach by the three days' journey into the wilderness.

The Law of Moses. The world is familiar with the story of Moses. He and Aaron the Levite led the Hebrews and their herds into the desert, where they wandered for long in the Arabian plains. There he spread the doctrine of the one Divine Being, and enforced his teaching by the promulgation of ordinances and laws which showed, and show, an entire superiority over every other system of legislation known to the world at that time. He abolished the distinction of castes, and declared the equality of all citizens before the one Divine Spirit, and before the existing law; emancipated slaves, and ordered the restoration of alienated property to its real owner. The laws of Moses

always protected the poor, forbade usurious practices, proclaimed the virtues of charity and almsgiving, enjoined kindness to strangers, and insisted on kindly dealing even with the lower animals. The Mosaic system was a complete reversal of the principles then prevailing in the world outside. The stranger was to be treated as a friend and not as a natural enemy; the slave was restored to the position of a free man, and the wife was allowed to take a place of equality beside her husband. The Decalogue—the interpretation of the whole moral code by ten commandments—is the outcome of that time of marvellous and inspired legislation.

Destruction of Jericho. It was the desire of Moses that his people should return to the ancient land which had been chosen by Abraham for a settlement. Joshua, who succeeded him, traversed the Jordan with the object of settling there, destroyed the city of Jericho, and partitioned the soil of Canaan among the twelve tribes of Israel. But when Joshua died the government of the ruling elders was not strong enough either to ensure the Israelites the occupation of the land or to resist the invading impulses of foreign rulers. Sometimes the Hebrews were reduced for a while to complete servitude, and then were rescued again by heroic and patriotic men of their own race, who made for themselves an era of sovereignty—in fact, although not in name, and the Hebrews before long accepted the dominion of an actual king.

This was Saul, of the tribe of Benjamin. Saul was selected for this office by Samuel, who had been practically the ruler of the people and who was induced, or compelled, by the demands of his people to set a Sovereign over them. The administration of Saul at first seemed to promise great success, because of his capacity for the resisting of encroaching enemies and the moderation and the wisdom of his rule.

The Rule of Saul. But Saul seems to have gradually changed his nature because of the temptations offered to him by his position, and to have endeavoured to make himself an absolute dictator without any regard for the sacred traditions and long established habits of his people. Then came the era of David, the son of Jesse, a Hebrew shepherd, whom Samuel had already anointed as King. He was introduced into the Royal household with a hope that he might one day become the actual ruler in the place of Saul, who was growing to be more and more distrusted and disliked among his people. David had won for himself the admiration of the Hebrews by killing the Philistine giant, Goliath, but by this feat he aroused the jealousy and hatred of Saul, who made many attempts to get rid of him, and even attempted more than once to kill him.

Saul was afterwards killed in battle. And then the tribes of Judah and Benjamin, and finally the other ten Israelite tribes, accepted David, who had married Saul's daughter, Michal, as their Sovereign. David proved himself a powerful leader. He captured Jerusalem, completely defeated the Philistines and the Moabites, and spread the Hebrew kingdom to the Euphrates on the north, and to the Red Sea on the south. His rule was for a long time a complete success. He established effective laws for the maintenance of religious worship, for the administration of justice, for the support of a sufficient army: and he initiated and organised the arrangements for the building of the great Temple. David lived in Jerusalem, which was then called the City of David. His later days were troubled and darkened by the revolt of his sons Absalom and Adonijah. He died somewhere about 1,000 years before the Christian era. He has well been styled "The sweet singer of Israel," for he must ever be regarded as the original inspirer of the marvellous religious lyric poetry of the Hebrew race, and his name must live for ever in all human history.

A Time of Prosperity. Solomon, the son of David, succeeded to the rule of the Hebrew race. By this time the remaining populations who had belonged originally to the soil of Canaan—among them the Philistines, Edomites, Amalekites, Moabites, and others—had been brought under the rule of the Hebrew kingdom, and Jerusalem was made the capital of the ruling race. Solomon's was in every sense a splendid reign in its earlier days. The cultivation of arts, and especially of architecture, made itself manifest everywhere. Poetry and music held a leading place in the intellectual glories of the period, and indeed suffused the minds and feelings of the population to a degree never known before in any part of the world, and hardly excelled even in the most palmy days of Greek and Roman culture—hardly surpassed, perhaps, at any later period of human history.

Commerce also began to thrive in a manner new to the world, and the trade of the kingdom was carried on with Egypt, India, and Ceylon, and with regions and islands still farther off. Solomon was indeed one of the most brilliant and picturesque figures of whom history gives us any record. He was unquestionably a man of superb intellect. His mind was endowed with a marvellous combination of practical wisdom and of imaginative power. It is more than probable that oracular sayings, imperial projects, and intellectual triumphs have come to be ascribed to him which were not actually the offspring of his own intellect; but even this is only another evidence of the immense influence which he must have exercised over his contemporaries and over their descendants through many successive generations.

End of Solomon's Reign. A great man is always thus invested by tradition with some intellectual triumphs to which he himself might have laid no claim, and the tendency of posterity thus to exaggerate the greatness of any ruler of the past is but another and a very impressive tribute to the position which he must have acquired among those over whom he came to rule. There can be no doubt that the artistic genius of Solomon became to some degree a great trial to the people. He was a voluptuary of the most lavish and uncompromising order, and even some of his noblest artistic and architectural achievements began to create heavy burdens for his over-taxed

subjects. He spent money in the most prodigal fashion, and his enormous resources of money did not enable him to gratify to the full his genius for artistic splendour. He had to lay heavy taxes on his people, who grew poorer and poorer under his rule; and towards the close of his life the burden which he thus imposed upon those who were compelled to yield to his demands made his reign increasingly oppressive to a large proportion of those whom he governed. His renown had spread everywhere over all surrounding regions, and the Queen of Sheba was induced to visit the ruler of the Hebrew race.

As the close of his life drew on he appears to have accepted the ordinary position of a despotic Eastern Sovereign, and he was charged with having decided according to his own arbitrary will many questions of judgment which ought to have been settled according to the recognised and traditional principles of religion and established law. He was charged with having departed so far from the faith of his fathers as to encourage, and even to patronise, idolatrous practices, and to make the authority of the priesthood depend entirely upon his own caprice. His reign continued to degenerate steadily in its later periods from the magnificent opening of his career; some of the outer populations rose in revolt against his ordinances, and even his own people often turned against him.

Israel and Judah. After Solomon's death the dissatisfaction which had been growing up among his subjects broke into actual dissension. For it seemed impossible at the time to obtain any common agreement among all parties and sections as to the proper means of restoring general content and prosperity. The monarchy soon divided itself into two separate sections: one the kingdom of Judah under Rehoboam, Solomon's son, and the other the kingdom of Israel, under Jeroboam, the Ephraimite. The kingdom of Judah was made up for the most part of the tribes of Benjamin and Judah with also, it would seem, the inhabitants of some outlying cities and provinces. The kingdom of Israel included the remaining ten Hebrew tribes.

Nineteen kings succeeded each other in Israel, but these kings did not come to their ruling places as regular successors in the same dynasty. Most of them became rulers by actual conquest, by seizing the throne, and in some instances by putting to death their predecessors. Then the region over which they ruled was invaded and conquered by Shalmanezer, Sovereign of Assyria. Hosea, the King of Israel, was immured in prison, many of the Hebrew people were sent as captives into the far eastern regions and the mountainous districts of Media, and their lands were occupied by Assyrian settlers. These new colonists mixed themselves with the Israelite population still left in the land, and by their inter-marriages were formed the race described as the Samaritans.

Nearly 600 years before the Christian era Nebuchadnezzar, King of Babylon, captured Jerusalem, burned the Temple, and carried off some of the most distinguished and wealthy of Jerusalem's inhabitants as prisoners to Babylon. Then followed that period in the history of the Hebrews which is known as the Babylonian Captivity. The Israelites who had been forced into exile before the exile of the race of Judah occupy no distinct place in history after this period. Those of the Hebrew race who formed the kingdom of Judah seem to have been treated with comparative mildness by the rulers of Babylon, and came to exercise a strong and general influence over the people of that kingdom. The region of Babylon became the "second land of Israel," and remained so for many centuries.

A New Chapter in Man's Development. We must pass away now for the present—but only for the present—from the story of the Jewish race. The most important event in the history of that race—the most important event, indeed, in the history of the world—was yet to come, but it belongs to a period when great peoples and great realms had arisen in Europe on whose influence over the progress of human civilisation the historian has yet to tell the marvellous tale. Europe was about to open an entirely new chapter in the history of man's development, and in that development the Hebrews came to perform a most important part. Europe, Asia, and Africa now begin to be blended in the world's movements, and the Hebrews cease to be, and Asia herself ceases to be, separate and isolated influences over the working out of man's earthly destiny.

Meanwhile, the influence of the Holy Scriptures was beginning to diffuse itself in the Eastern world. The name of the Bible is taken from the Greek word "biblos," which means a book, but is adopted in special and exclusive reverence to the consecrated writings. The teachings which are embodied in the book of Genesis are believed to have been already making their way into the world's knowledge some 4,000 years before the birth of Christ.

The prophets were teaching down to some 400 years before the Christian era. The Scripture history of the Jews ends, according to Latin writers, about that time, and from thenceforth we take what we know of Jewish history from the accounts given to us chiefly by Roman authors.

The Rise of the Greek Race. Greece opens the next momentous era in the civilisation of the world. In war and in peace, in all departments of literature and art, Greece won for herself a fame in her early days which no succeeding age has been able to outrival. Greece, with her islands, was happily situated for the work which she had to do. In the extreme south-east of Europe she had the western shores of Asia almost within speaking distance, and the Mediterranean Sea spread itself around her southern shores. Her history goes back to blend with that of the Hebrews and the Persians, and the name of her great poet, Homer, carries us far into antiquity. The Greeks were navigators from the very beginning, and loved to make their way into far foreign regions and study there the movements of a life which was

new to them, and, in many of its characteristics, widely different from their own. Greece is a small country, and yet there is no part of the world in which from the opening of her civilisation she has not made her influence felt. The modern world—if we include in that phrase the whole Christian world—has never produced greater narrative poems than those of Homer, greater dramas than those of Æschylus, Sophocles, and Euripides; greater works of philosophic thought and critical disquisition than the writings of Socrates, Plato and Aristotle; more vigorous and vivid satirical comedy than that of Aristophanes. The sculpture and the architecture of classic Greece are the world's wonder, and the traveller, from whatever land he comes, must feel that he is looking on one of the noblest works of man's making as he stands upon the Acropolis and gazes on the Parthenon.

Early Days of Greece. Greece is but a small country, even if we include the islands which belong to it; one of which, Crete, much exceeds in its size any of the other islands. Yet, in the days of her greatness Greece was famous as a conquering warrior state no less than as the home of literature and the arts. The earliest inhabitants of Greece, so far as we can trace back the history of the country, appear to have been the Pelasgi, who belonged to the immemorial Aryan race. *The coast of Greece is, when considered relatively to the size of the country itself, the longest coastline of any country in Europe, and* this fact enabled the Greeks to become incessant voyagers to other shores, and at the same time induced and permitted the inhabitants of foreign but neighbouring regions to make incursions into Greek territory.

Greece is much intersected by mountain ranges, and these became barriers dividing the Greeks into small and separate petty states, and thus prevented them, in some instances, from making a prompt and general resistance to foreign invasion. The earliest known religion of Greece appears to have inculcated the worship of many gods, each representing some attribute of the human mind, and even in certain instances the worst passions of man. The Greek deities thus created bore, for the most part, the forms of human beings. Their supreme divinity was Zeus, or, as the Romans called him, Jupiter; Apollo typified imagination and poetry, and there was a strong belief in a future life, when virtue was to be finally rewarded and vice punished. There seems to have been in their religious faith no distinct idea as to any relevation, and their creed came rather from within than from without.

The Founders of European Civilisation. The Greeks were undoubtedly the founders of European civilisation. We need not here pause to retrace the merely poetical and mythological history of Early Greece as told in the great poems of Homer and of other illustrious poets and dramatists in the classic days of Greek literature. We have the books themselves to consult, and many of them are well known to most readers at the present day. We need not tell of the capture of Helen and the siege of Troy which followed it; of the wrath of Achilles and of the troubles it brought upon the conquering Greeks; of the fall of Troy and the fate of Hector. Indeed, the supposed history of the author himself is almost as mythological as that of the gods and goddesses who move about in his pages bearing the forms of men and women, who seem to be animated by many of the most selfish ambitions, the meanest prejudices, and the most unreasonable passions which belong to humanity itself.

The Dorian Invasion. There are many English translations of Homer's works, Pope's being far the most popular; Chapman's earlier rendering was hardly known. Pope's is fluent, and even fascinating; but its style and metre are essentially not Hellenic. The eminent parliamentary leader, Lord Derby, has given to the world an admirable version of the Iliad in English blank verse, and the American poet, William Cullen Bryant, began, but did not quite complete, a blank verse translation which promised to be the finest of the kind in English.

We must come, however, to the earliest records we have of the actual growth of the great nation which had for its principal states Athens, Sparta, Corinth, Thebes, Arcadia, and Macedonia. The most distant record we have of the more or less mythical history of the land tells of the Dorian invasion, which is described by some more or less mythological records as the return of the Heraclitæ, the descendants of Heracles, or, as we now call him, Hercules, who were described as coming back to the land which was originally their own.

First Greek Settlers. The Pelasgi appear to have been the earliest of the Greek race actually settled in the country, and were long afterwards known as the Thessalians. The state afterwards known by the name of Sparta became a great and vigorous rival of the Athenian state. The Spartans were, above everything else, a people of soldiers. One result of the Dorian invasion was the establishment of slavery in most parts of Greece. The Helots of Sparta were slaves whose forefathers had been conquered by the invaders, and were the property of the whole state or camp, rather than of individual masters. Attica was the most highly cultured part of Greece. There were almost incessant invasions of Greece by foreign peoples. These invasions were made the more easy of temporary success by the fact that Greece was divided by its mountain ranges into separate settlements. Cyrus, the Persian monarch, was one of those invaders who attempted to absorb the whole of Greece, but Greece rallied successfully to resist this project.

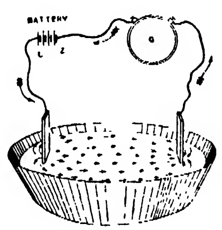
THEORY OF THE ELECTRIC CIRCUIT

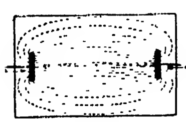
Circuits through Water and Earth. Return Circuits. Swirling Current Paths. Resistances. Insulation and Insulators

By Professor SILVANUS P. THOMPSON

The Necessity of a Circuit. In order that an electric current may flow at all, there must be a circuit in which it can flow. Electricity will not flow from a battery or a dynamo unless there is a path along which it can return back to the source. When there is provided a system of wires of metal or conductors to lead the current from the battery to the place where it is wanted to do some work and to conduct it back again, we describe this closed path as *a circuit.* If there be in it any gap occupied by air or any other non-conductive substance, even though the battery and the going and returning lines are all in proper order, no current will flow. A circuit which is thus incomplete by reason of the interposition of some non-conductive obstacle, or of a gap, is called an *open circuit.* As soon as the obstacle or gap is bridged over by a conductor, the flow of current begins, and we describe this completed path of the current as a *closed circuit.* Some of the practical experiments suggested on page 463, were for the specific purpose of making clear this necessity for a closed circuit if the current is to flow at all.

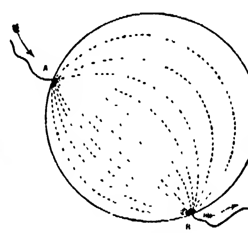


29



30

SWIRLING CURRENT PATHS



31

Circuits through Water or Earth. It must not be supposed, however, that a current cannot flow in other paths than metallic wires. It is true that for electric bells, electric telephones and electric light, metallic conductors are used both for the outgoing lines and for the return lines. But there are other cases in which a current may flow without being confined to a wire circuit. Water (unless chemically pure) is a conductor, though by no means so good a conductor as any of the metals. This we may easily demonstrate by a simple experiment. Provide a battery of three or four cells, and a simple detector or cheap galvanometer [marked G in **29**], and let them be joined in series between two wires to which two copper plates have been fastened. If these two plates be allowed to touch one another their contact will complete the circuit, and at once the galvanometer will show that a current is flowing. Separate them, by even one-hundredth of an inch, and the current at once stops. Even a gap of one-thousandth of an inch in width, filled with air, or with oil, or dry paper, or any non-conducting substance, stops the current. Now procure a tub or basin filled with water. Dip the plates into this water, keeping them wide apart. You will see, on observing the galvanometer, that the water conducts the current from one plate to the other, but hardly so well as a good metal wire would do. Now bring the plates nearer together, so that the current in flowing from one plate to the other will have a shorter length of water to traverse; on thus bettering the path, it will be seen that more current flows, for the galvanometer will indicate a larger deflection.

Such an experiment might be tried on a much larger scale. Suppose a metal plate to be immersed in a stream or river at some place, and the wire attached to it carried on supports (like a telegraph line) along the bank, and connected, as illustrated in **29**, to one pole of a battery, the other pole of which is joined to a galvanometer, and from the galvanometer let the wire continue along the bank for some distance and then terminate in another metal plate immersed in the stream. It will be found that the stream or river conducts the current and provides a path for the electricity from one metal plate to the other. If the plates are buried in moist earth the effect will be the same, because moist earth conducts. Because water conducts, our electric light mains and wires must be insulated with non-conducting coatings that are waterproof, otherwise some of the current would escape.

Earth as a Return Circuit. When it was found that the earth would serve as a portion of a circuit, it was at once proposed to use the soil as a return conductor in telegraph work (each circuit consisting of one line and an earth return), instead of there being two metal lines, one for the outgoing conductor and one for the return conductor. But in such an arrangement great care must be taken to ensure that the circuit is provided with good metal *earth plates* of sufficient surface, and that these plates are sunk in really wet earth. They will not be effective if too small, or if buried in dry sand or dry rocky ground. Telegraph

engineers habitually talk of an outgoing conductor as the *line*, and the return conductor of a circuit as *earth*, even if it be made of a metal wire. Earth returns are not permissible for electric lighting or for telephonic lines. In a town, a good way of *earthing* a conductor is to connect it by a wire to the water pipes that are buried in the soil instead of using special earth plates.

It is worthy of note that water makes a better *earth*, in the telegraphic sense, than the earth does. It is also worthy of note that when earth is used in any straight circuit as a substitute for one of the conductors, it makes no difference whether the earth be used as the outgoing or the returning line. Also, it should be observed that for many purposes—as, for example, in the use of electric bells, telegraphs, and ocean cables—the earth may serve as return, or, for that matter, as outgoing conductor, if separate metallic returns be used, for more than one circuit at one time. Why many circuits may thus share a common conductor without appreciable interference with one another will be better understood after study of the law that governs electric circuits.

Swirling Current Paths. When a current is flowing through a portion of a large wide conductor, such as a pond of water, a tract of earth, or a large sheet or mass of metal, and is not confined to a linear path along a wire, it spreads out into sheets or swirling paths, occupying the largest cross-section of path available. If a current, for example, be introduced into a rectangular tank of water by means of two small metal electrodes entering the water at one and leaving it at the other, it flows round in curving paths from one electrode to the other, as indicated by the dotted lines in **30**. If a *circular piece of tinfoil* be cut out and laid down on a dry board, and current be caused to enter at the point A at one edge [**31**], and leave it at point B at another place on the edge, the current does not take the shortest route from A to B ; or, rather, though some of it takes the shortest route, a large proportion of it will flow by other and longer routes, as shown by the curved dotted lines. If this circle represented a shallow pond into which water ran in at A and ran out by a drain at B, it would not all run straight across, but would similarly follow swirling curves. In fact, the statement often made that "electricity always takes the line of least resistance" is grossly untrue. In any wide conductor it always takes all the other available paths at the same time. This is true of the flow of electricity through the earth from one earth plate to another.

The Law of the Circuit. Dr. G. S. Ohm discovered in 1827 the law that governs the steady flow of currents in circuits. We have already seen [page 291], that to make any current flow there must be some generator, such as a battery or a dynamo, capable of exerting an electric effort, or *electromotive force*. It was there explained that electromotive forces are expressed in terms of the unit called the *volt*. A volt is not a current ; it is only the tendency to produce a flow. A battery, for example, of 10 Daniell's cells will exert an electromotive force of about 11 volts, whether any current is being drawn from it or not. It was also explained that the strength of an electric current is expressed in terms of the unit of current called the *ampere*. We cannot have amperes unless there be a circuit by which they may flow from the battery (or dynamo) back to the battery (or dynamo). The volts drive the amperes. You can have the volts without the amperes, for the battery or dynamo that is exerting the electromotive force can exist without there being any circuit connected to it. But you cannot have the amperes in the circuit without the volts to drive them. The electromotive force (volts) is the cause ; the current (amperes) the effect. As volts and amperes then stand to one another as cause and effect, we should expect them to show, under given circumstances, a certain proportionality one to the other. And in practice it is found to be so.

Proof by Experiment. Suppose, for example, we had 100 ft. of german-silver wire, of No. 23 S.W.G. (about $\frac{1}{42}$ in. thick), to serve as our circuit, either stretched out as a large loop, or coiled up (properly insulated by being overspun with cotton) on a bobbin. Suppose we applied to this wire an electromotive force of 100 volts, we should find that such is the resistance offered by this long thin wire that even with this electric pressure applied to it only two amperes would flow through it. Now, if without altering the wire in any way we were to vary the electromotive force which we apply to it, we should find the current in the wire, which we should measure with an *amperemeter* [see p. 291], would vary in exact correspondence If we altered the electromotive force from 100 to 200 volts, we should find that the current would of itself alter from 2 to 4 amperes. If we lowered the electromotive force to 50 volts, the current would reduce itself to 1 ampere. The effect would be exactly proportional to the cause.

Had we taken a longer wire, it would have offered more resistance, and then on applying over 100 volts we should have got less than 2 amperes. For example, if we had taken twice the length, it would have offered twice as much resistance, and, in that case, on applying our 100 volts we should have found that the resulting current would be only 1 ampere.

It becomes clear on thinking this over that the resistance offered by the conducting wire to the flow of electricity through it is a measure of the proportionality between the cause and the effect. This is what Dr Ohm expressed in the rule that the current is directly proportional to the electromotive force and inversely proportional to the resistance. To express this in mathematical form, let us write the symbol E for the number of volts of electromotive force, and C for the number of amperes of current. But we shall need a third symbol to express the amount of resistance offered by a conductor, and we shall need a name for the unit of resistance. Clearly,

to fit the other units we must have, as the unit of resistance, a resistance so great that if we apply one volt to it there will be 1 ampere produced in it. A resistance of this magnitude has been called *one ohm*. We will adopt the symbol R to express the number of ohms of resistance that any circuit or conductor offers to the flow of electricity through it. We may now write *Ohm's law* as:

$$\frac{E}{R} = C;$$

or, in words:

$$\frac{\textit{volts}}{\textit{ohms}} = \textit{amperes}.$$

In the case of our German silver wire, it has evidently a resistance of 50 ohms—for if we take $E = 100$, and $R = 50$, we get $C = 2$, as follows:

$$\frac{100}{50} = 2.$$

And if it offers 50 ohms, the effect when we raise the voltage to $E = 200$ will be:

$$\frac{200 \text{ volts}}{50 \text{ ohms}} = 4 \text{ amperes}.$$

So, to use Ohm's law, we may put into words the rule: *To find how many amperes will flow in a circuit, divide the number of volts by the number of ohms.*

Example: How many amperes will flow through a conductor that has 25 ohms resistance when we apply to it an electromotive force of 200 volts? Here $E = 200$, $R = 25$; therefore, dividing 200 by 25 we get as the answer 8 amperes.

Calculations by Ohm's Law. We can change Ohm's law into another form for use in some other problems; for, by transposition it becomes:

$$\frac{E}{C} = R; \quad \text{or,} \quad \frac{\textit{volts}}{\textit{amperes}} = \textit{ohms}.$$

Or we may put this into words as follows: *To find the number of ohms of resistance offered by any conductor, divide the number of volts applied to it by the number of amperes that result as current in it.*

Example: How many ohms of resistance has a wire, if it is such that on applying to it 40 volts we find that the current through it is 12 amperes? Here $E = 40$, and $C = 12$. Therefore, dividing 40 by 12, we find the answer to be $3\frac{1}{3}$ ohms.

There is another useful transformation of Ohm's law, as follows:

$$C \times R = E;$$

or,

$$\textit{amperes} \times \textit{ohms} = \textit{volts};$$

which we may put into words, thus: *To find the number of volts needed to drive a prescribed amount of current through a conductor of known resistance multiply the number of amperes by the number of ohms through which they are to be driven.*

Example: How many volts of electromotive force are needed to drive 40 amperes through a resistance of $2\frac{1}{4}$ ohms? Here $C = 40$, and $R = 2\frac{1}{4}$. Multiplying 40 by $2\frac{1}{4}$, we find as the answer 90 volts as the needed electromotive force.

Further Examples. The following examples, with their answers, are given for practice in working:

1. A glow-lamp of resistance 240 ohms is placed across live electric mains, having a voltage of 100 volts between them. How much current will it take from the mains? *Answer*: 0·42 ampere.

2. It was observed that when wires from a battery of accumulators whose voltage was 80 volts were applied to excite a certain electromagnet, the current which flowed (as measured by amperemeter) was 16 amperes. What was the resistance of the coil of that electromagnet? *Answer*: 5 ohms.

3. The armature of a certain dynamo is known to have a resistance of 0·025 ohm. How many volts will be needed to drive 300 amperes through that resistance? *Answer*: 7·5 volts.

4. A certain line for electric transmission of power was constituted by two conductors, each 110 miles long, each offering 75 ohms resistance. How many volts will be required to drive 20 amperes through these conductors, if the current go through one line and return through the other? *Answer*: 3,000 volts.

Resistance of a Conductor. It is obvious that a wire of given material and thickness will offer a resistance that depends on its length. The longer the wire the more it resists. A little thought will show that if we have wires of the same length and same material, but of different thicknesses, the one that is thicker will be a better conductor, as it has a larger cross-section to carry the amperes; just as a larger pipe will carry a larger flow of water. In fact, the resistance of a conductor is inversely proportional to its area of cross-section, other things being equal. As most conductors in electrical engineering are made of copper, it will be convenient to remember this fact—that a bar of copper 1 ft. long and 1 sq. in. in cross section offers a resistance (at ordinary temperatures) of eight one-millionths of one ohm—*i.e.*, 0·000008 ohm. Hence, if we know the length (in feet) and the cross-section (in square inches) of any copper conductor we can calculate its resistance. As an example, let us take 1,000 ft. of a No. 19 S.W.G. copper wire, which has a diameter of 0·040 in. We must first find its cross-section by the rules of mensuration, by squaring the diameter and multiplying by 0·7854. So we have: $0{\cdot}040 \times 0{\cdot}040 \times 0{\cdot}7854 = 0{\cdot}001256$. Then a piece 1 ft. long will have a resistance of $0{\cdot}000008 \div 0{\cdot}001256 = 0{\cdot}00637$. We divide because the resistance varies *inversely* as the cross-section; and therefore, this wire, which has a section of about $\frac{1}{800}$ of a square inch, will, for equal length, resist about 800 times as much as a conductor that has a section of 1 sq. in. Then, if this be the resistance of 1 ft., multiply by 1000 to find the resistance of 1000 feet; giving the answer 6·37 ohms.

The resistivity of copper—and, indeed, that of all pure metals—increases if they become warm. If ice-cold, the copper rod 1 ft. long and 1 sq. in. in section would have a resistance of

HOW FOOD BECOMES LIFE

Continued from page 580

Process of Digestion. Nature's Device for Sustaining the Human Frame. "The Mission of a Sandwich." Strengthening and Preserving Elements

By Dr. A. T. SCHOFIELD

LET us make a careful review of the actual process of digestion. We shall try to remove the mystery from this function, and give a clear and intelligible picture of what digestion really is. It may facilitate progress and make the picture more graphic if, instead of speaking in the abstract, we take some actual article of food and follow it in its mission of sustaining the human frame. Perhaps we cannot do better than select that peculiar and prehistoric fossil food that so fascinated Dickens at Mugby Junction, as it stood in its glass case for inspection—the ancient British sandwich.

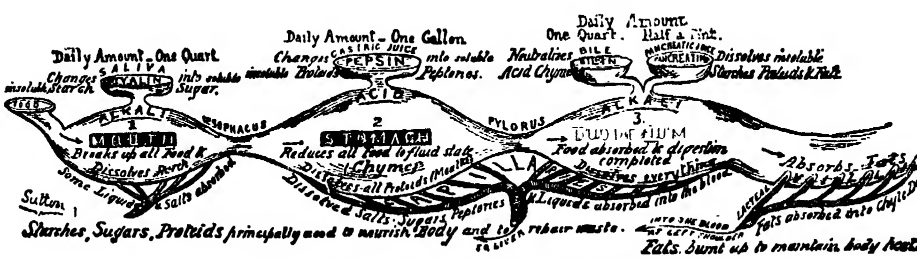
Every Variety of Human Food. It is a painful thought, but none the less true, that this weird article actually contains within its own arid compass every variety of human food. These varieties are four—*proteids, carbohydrates, hydrocarbons,* and *mineral food.* We get the proteids in the meat, however dubious its origin; the carbohydrates in the bread, however sawdusty; the hydrocarbons in the certain fat and very uncertain butter; and the mineral food in the liberal salt, which creates a thirst that is almost unquenchable.

Nothing more than this is wanted for human sustenance; and it is quite conceivable that a man, with unlimited drink, could sustain Nature for an indefinite time on sandwiches alone. It is not recorded that anyone has actually done so in practice.

At the present day we have advanced so rapidly that travellers may search in vain for the interesting fossil that Dickens described, for it is often replaced with appetising and dainty modern substitutes. It still lingers in the glass case, however, at certain country junctions, where it helps lovers of the antique to refresh their memories of the "good old times."

We shall now consider how this sandwich is prepared to be turned into flesh and blood by the tissues. The process is called digestion, and *consists essentially in dissolving all articles of food* so that they can be introduced into the blood, and thus circulated through the body No substance can be considered as food unless it is capable of solution by the digestive fluid, so as to reach the blood. Such substances as cork, stones, fruit-skins, etc., pass through the body unchanged. The one fact essential to remember is that *digestion means dissolving.*

As the digestive tube has no direct communication in any part with the body, all food placed within it is still practically outside the body—just as a train in the Thames Tunnel is not in the river—and the whole purpose of the digestive process is to dissolve the food inside this tube so that it can pass across the walls and into the vessels outside. We will see how this is effected. We have already seen that, setting aside minerals and liquid food that require no digestion, being already soluble, we have carbohydrates, proteids, and fats. Observe, then, that the mouth digestion, or *oral digestion,* is for carbohydrates; the stomach, or *gastric digestion,* for proteids; and the *intestinal digestion* for fats.



36. STAGES OF THE DIGESTIVE PROCESS

In other words, the salt in our sandwich, being soluble, requires no digestive process, but passes straight into the blood, leaving the bread, meat, and fat to be dealt with. How the process is effected in each case we shall consider in detail, and the diagram [36] will help us.

The Importance of Cooking. The food, whether liquid or solid, enters the body by the mouth at the rate of about 2 lb. of solid and 2 quarts of liquid per day. The first important aid to digestion is *cooking,* which acts by rendering the fibres more brittle in meat, and in starchy food by swelling up and bursting the covering of the starch grain. We can see the importance of this. The starch grains are packed in hexagonal capsules—as they always are in grain—which are formed of a tough fibrous material called cellulose. As long as the grains are in these capsules the digestive fluids cannot reach them easily. Cooking, however, softens, swells, and bursts the cellulose walls, and sets the grains free, when they are readily changed into sugar.

In the mouth two changes are effected in the solid food. In the first place, it is ground and cut up into small pieces by the teeth, so as to afford ready access to the digestive fluid ; and, secondly, it is mixed throughout with saliva, which has the power of changing starch into sugar. Saliva is produced at the rate of about a quart a day, one-third being secreted during and *by* mastication, and two-thirds at other times. It dissolves any soluble portion of the food, moistens the rest, and by means of the mucin mechanically lubricates it and renders it easy of deglutition. Its chief action, however, is chemical, and is due to the minute amount of *ptyalin* it contains.

A Vital Factor. Ptyalin, discovered in 1831, is one of a large number of bodies known as ferments, which, by their presence alone, and without undergoing any change themselves, enable changes to take place in the substance acted upon, generally in the form of the addition or subtraction of a molecule of water. Although, therefore, only a trace of ptyalin is found in saliva, it never gets used up or loses its power, but is capable of acting upon any amount of material. It is an unorganised ferment (like the diastase in barley), and the action is, therefore, chemical. Yeast is an organised ferment, and is certainly vital in action. The process of fermentation is retarded or prevented by cold ; and while heat above 140° F. generally destroys the ferment, 212° is certain to do so.

Starch grains, as we have seen, consist of two parts—a covering of cellulose upon which ptyalin cannot act, and which does not colour with iodine, and particles of granulose, or true starch, which colour blue with iodine. Saliva cannot, therefore, digest unboiled starch; hence the necessity of boiling all starchy food long enough to burst the covering and set the granulose free.

The action of saliva is assisted by moderate heat, by a neutral, or slightly alkaline medium, and by the removal of the digested product—sugar. It is retarded by cold, acids, or strong alkalies, and the presence of much sugar. It is destroyed by high temperature.

Observe here that the mouth digestion is *neutral*, the stomach digestion *acid*, and the intestinal digestion (pancreatic) *alkaline*.

Saliva has no action on proteids or fats, or on sugar, gum, etc. The saliva has no digestive power before the sixth month, hence flour foods cannot be digested by infants under that age.

The Transformation of Food. About half of starch food is digested in the mouth, if properly masticated. We see that the oral, or mouth digestion, really concerns only the bread of our sandwich, leaving the meat and fat unchanged; and the result of this oral digestion properly carried out is to change the bread into sugar. Anyone who doubts this has only to chew an old crust until it gets intolerably sweet. Here we get a glimpse of the resources of Nature and the way (to use a golfing term) she gets round "bunkers" she cannot get over. Starch is insoluble in water. We may keep a crust immersed in water indefinitely, and it will never dissolve. Ptyalin is therefore placed in the mouth to change starch into a soluble substance—sugar. It may also be noted that sugar itself requires no digestion, being a soluble substance ; but articles that require no digestion, through being soluble, may yet, from other reasons, cause violent indigestion. To be soluble is not always to be wholesome. Alcohol is an example.

Our sandwich, cooked and carved, is taken into the mouth, and, if properly chewed, the bread is partly turned into sugar, the dry and arid substance is broken up and moistened throughout, formed into a mass, or bolus, coated as it passes into the throat with a sort of glycerine, and propelled down the gullet into the stomach.

Gastric digestion, or digestion in the stomach, consists of two processes—the solution of the proteid, or meat food, by the digestive fluids, and the constant movement of the food, which corresponds partly to mastication. Let those who are inclined to bolt their food remember that the stomach has no teeth, nor have human beings any gizzards, which are a substitute in some animals for teeth.

Digestive Fluid. The *gastric juice* is the digestive fluid of the stomach, and is produced, at the rate of about one gallon daily, by the glands we have already considered. It is a clear, colourless fluid, of sour taste and odour, with a specific gravity of 1001. The chief function of the gastric juice is first to coagulate and convert insoluble proteids into soluble peptones that can pass easily across the wall of the digestive canal. It is essentially an acid digestive, and cannot work in a neutral or alkaline medium. It acts like saliva, by means of a ferment called *pepsin*. The action on proteids is in at least two steps.

Before the food comes into the stomach, from its presence in the mouth, and sometimes even from its mere smell, or the anticipation of it, the empty stomach, pale and nearly dry, is affected by the reflex action of the *sympathetic* and *pneumogastric* nerves, and begins to blush a rosy red as the capillaries become distended with blood. Very soon drops of digestive fluid begin to ooze out from the pits, or glands, all over the surface, and before long a little pool of clear gastric juice is collected. The softened food, thoroughly mixed throughout with saliva, the action of which still continues until neutralised in the stomach, enters from the gullet at the cardiac end of the stomach, and immediately the movement of the stomach begins, while more gastric juice is poured forth. The cardiac entrance from the oesophagus is tightly closed, as well as the pyloric valve at the outlet of the stomach, the muscular walls contract on the contents, and a peristaltic, or spiral wave of motion begins, getting more rapid as digestion goes on. The effect of this is to propel the food rapidly from left to right along the sides, while it returns in another current along the middle.

Every bit of the food is thus thoroughly exposed to the action of the gastric juice. The

value of this part of the digestive process is seen by experiment. A piece of boiled salt beef took *ten* hours to digest artificially with gastric juice; part of the same piece took only two hours inside the stomach, where this violent movement was combined with the chemical action. The length of the digestive process varies with the food taken. It averages four hours. Easily digested articles, such as tripe, take one hour. Pork takes five or six hours.

Dissolution of Food. The semi-fluid contents of the stomach during digestion become more and more acid, and it is believed that this relaxes the pyloric valve, hitherto tightly closed, so that at first the liquid, then the non-liquid parts, pass through into the duodenum, and the second great section of the digestive process is completed.

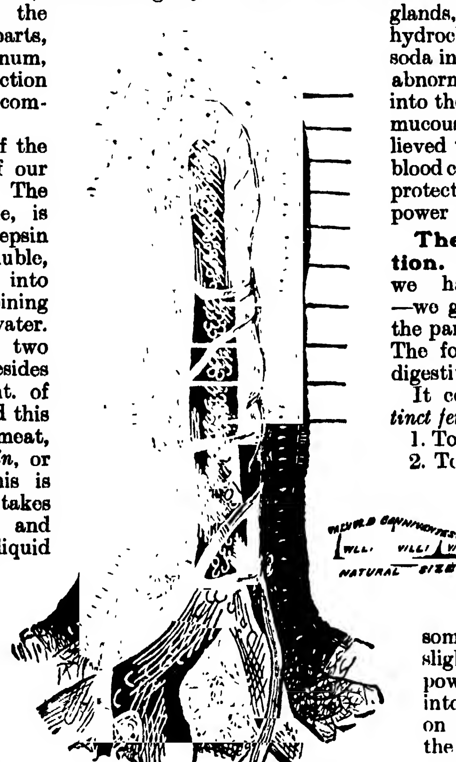
Here, then, the second of the three great constituents of our sandwich is dissolved. The meat, which is insoluble, is formed by the ferment pepsin into peptones, which are soluble, exactly as starch is made into sugar, by chemically combining it with one molecule of water. The actual process is in two steps. Gastric juice, besides pepsin, contains 2 per cent. of free hydrochloric acid, and this acting on the proteids, or meat, makes it first into *syntonin*, or acid albumen. Then this is acted on by the pepsin, takes up a molecule of water, and becomes peptone, or liquid meat—a very different article, by the way, from beef-tea.

This action is aided by heat, acid, sub-division of the food, and its removal as soon as dissolved into the bowel, or duodenum. It is retarded by cold, alkalies, great masses of food, and over-repletion of the stomach.

After use, the gastric juice is reabsorbed. By this time our sandwich has decreased in size. We have supposed it to have been taken into the mouth all at once, as is often done by hurried passengers at railway stations.

The salt, all dissolved in the mouth, and half the bread, changed into sugar, has soaked through into the blood. The meat, changed into peptones, has followed. Only half of the bread and the fat passes on if the process is completed so far. Often, however, it is only partially carried out, and so more goes forward into the duodenum. The "soaking through" is by two methods—*filtration* and *osmosis*. Filtration is fluid passing across the membranous wall under pressure. Osmosis is where two fluids interchange that can mix (not oil and water). Crystalline substances—sugar, salt, etc., filter out readily. Colloid or gummy substances, such as starch and meat, do not. The osmosis is in two parts. The positive osmosis is the flow at first of digestive fluids into the cavities—mouth, stomach, etc.—and the second is the negative osmosis, or the flow out into the blood-vessels of the digestive products.

One question of interest is why the stomach does not digest itself, seeing its walls are formed of proteids. The best answer that has been given is based on the circulation of the blood in its walls. The blood first of all supplies the digestive glands, that take from it the hydrochloric acid, leaving the soda in the blood, which is thus abnormally alkaline, as it passes into the surface capillaries of the mucous membrane. It is believed that this alkalinity of the blood circulation acts as a special protection against the digestive power of the acid gastric juice.



37. A VILLUS

Magnified elevation of mucous membrane projecting into the intestine

The Intestinal Digestion. In the duodenum—which we have already considered—we get two digestive fluids—the pancreatic juice and the bile. The former is the most potent digestive in the body.

It contains at least *four distinct ferments*:

1. To act on starch—*amylopsin.*
2. To act on proteids—*trypsin.*
3. To act on fat—*steapsin.*
4. A milk-curdling ferment—*rennin.*

The *bile*, from the liver, has several actions on the food. In some animals, and very slightly in man, it has the power of changing starch into sugar. It has no action on proteids, but it renders the gastric juice neutral, and precipitates the peptones. It slightly emulsifies fat—*i.e.*, breaks it up into globules—but does not saponify it—*i.e.*, coat it with soap—and acts more powerfully when mixed with the pancreatic juice. By bathing the intestinal walls, it greatly assists the passage of the fat globules across them. It is an antiseptic and a natural laxative, assisting contraction of the intestines. Not more than one-sixteenth of the bile secreted is excreted, and this contains very little of the bile salts.

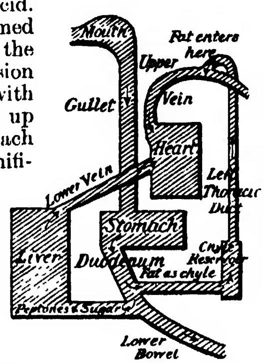
The *succus entericus*, or intestinal juice, may be called a third digestive fluid, and is principally the product of the glands of Lieberkühn. It is a yellow alkaline fluid of specific gravity 1011, containing 2·5 per cent. of solids, largely sodium carbonate. It has a slight power of changing starch into sugar. Otherwise it has no active properties.

We shall now follow our sandwich, which, in the form of acid chyme, has entered the duodenum through the pyloric valve in the third section of the digestive process.

The passage of the chyme over the common orifice of the bile and pancreatic juice at once produces a copious flow, and the acidity of the fluid begins to be neutralised. It does not, however, become alkaline till about the middle of the small intestine, and it gradually becomes acid again after this, especially in the colon.

Complete the Work of Digestion. Any cane sugar in the chyme is almost instantly changed into a more soluble form ; any undigested and even uncooked starch is made into sugar, proteids into peptones, and the fats into a fine emulsion of a soapy nature by the combined action of the bile and pancreatic juice. In short, in the duodenum the work of digestion is completed, and any food left unchanged by the imperfect action of mouth or stomach is changed here, mainly by the pancreatic juice, the meat by the *trypsin* ferment, the starch by the *amylopsin*, the digestion here being strongly alkaline, in contrast to the stomach, which is acid.

We have noticed that the fat is formed into an emulsion by the action of the ferment *steapsin* and bile. An emulsion is a fluid formed by shaking oil up with an alkali. This causes it to break up into tiny, microscopic globules, each coated with a soapy covering (saponification) derived from the alkali, and these, reflecting the light, make it white and opaque, instead of yellow and transparent. Milk is an emulsion, and butter is an oil. Cod-liver oil is a yellow fluid ; shaken up with an alkali (soda) it becomes an emulsion, and is opaque and white, and much more digestible. This fine sub-division is a first step in that incredibly difficult process, the digestion of fat, and is equivalent to the fine sub-division of the food by the knife and the teeth.



38. COURSE OF FOOD FROM MOUTH TO HEART

The difficulty of fat is that it is oily, and no process of filtration or osmosis can pass it through a watery membrane into the blood. Mechanically and chemically it is impossible. Here, then, vital action has to be invoked, and the digestion of the fat of our sandwich differs in principle from that of the bread or meat, in that while these were mechanical and chemical, this alone is truly vital, as we shall see.

Four Million Tubes. While, therefore, all the sugar and peptones, being of a watery nature, can now freely pass into the network of capillaries through the mucous membrane of the intestine, the globules of fat, small as they now are, cannot possibly, owing to their nature, diffuse in this manner. A very special apparatus exists for their absorption.

We have already noticed the rounded elevations of the mucous membrane that project like fingers into the intestine [37]. They average about a line ($\frac{1}{12}$th of an inch) in length, and about 80 or 90 to a square line (or 11,000 to a square inch) in the duodenum, and about 50 in the rest of the small intestines. There are about 4,000,000 in all. They vary in form according as they are full or empty.

Each is composed of a central tube [37], communicating below with the lacteal and lymph vessels in the intestinal walls, and ending above in a blind extremity. This tube is surrounded by a thin layer of longitudinal muscle fibre, which in turn is surrounded by blood capillaries, in loose connective tissue, then a fine basement membrane on which, at the surface of the villus, is a single layer of columnar cells. The free surface of these cells has a fine striated border. These striæ have been supposed to be really processes like the sea anemone's tentacles. They grasp the globules of fat and pass them into their interior. The fat is then supposed to be conveyed across to the lacteal in the centre. This, however, has never been fully confirmed, and more recent observation favours the idea, supported by the behaviour of leucocytes elsewhere, that leucocytes emerge between the epithelial cells, swallow the fat globules, and then convey them across by their own amœboid motion into the lacteal. There may be truth in both views. Anyhow, the fact remains that the fat globules are rapidly conveyed by positive vital action, and not by filtration or osmosis, after being still further sub-divided, into the central tube, which, when full, is pulled down and squeezed empty by the muscles surrounding it, and then springs up empty, to be refilled, the fat passing away into the lymph as a white fluid known as *chyle*.

Inexhaustible Resources of Nature. We may pause a moment to take in this marvellous process, showing the inexhaustible resources of Nature. The fat is first melted to oil by the body heat, then sub-divided into a perfect emulsion, in which state it is brought to these four million elevations, the tiny cells of which greedily seize the globules and pass them into an empty central tube. Immediately it is full this tube, wonderful to say, automatically contracts, and forces the chyle, or emulsified fat, not into the blood, but into another system of vessels altogether—the lymphatics—to be eventually delivered by a further marvellous process into the blood. We thus see that the digestion of the bread and meat is by *chemical* action in each case, one molecule of water being added to the food to make it soluble, but in fat action is *vital*.

As the contents of the small intestine are forced on by the slow peristaltic action of the bowel, all the digested part of the food gets absorbed—the sugar and peptones into the blood, to be carried to the liver, the fat into the lymphatics, and the undigested residue passes on into the colon. The food remains from 3 to 12 hours in the small intestines, and from

12 to 24 hours in the large intestines. Here the principal function is to draw off the remaining water, and the solid residue is excreted at the rate of about half a pound a day. This completes the third, or intestinal digestion, and the whole process.

Four Great Divisions of Food. We must now follow the sandwich, which has at length left the alimentary canal and entered the vessels outside, where it is further prepared for use before it enters the general blood current. Of the four great divisions of human food *three*—the carbohydrates, or sugar, the proteids, or peptones, and the salts and water, or minerals—enter the blood capillaries.

All the capillaries of the digestive system from the stomach, and the whole of the intestines down to the rectum, are collected into one large vein, called the *portal vein*, which runs to the liver, thus conveying three-fourths of the digested food.

The fat alone has a different destination. It does not enter the blood-vessels directly, but finds its way by means of the villi into the *lacteals*, which empty themselves into the general lymphatic stream.

These are so called because the lymph here, being mixed with finely-divided fat, closely resembles milk (*Lac* = milk).

To make the difference clear, we may say, speaking of our own bodies, that when the four articles of food leave the digestive system three of them, the sugar, meat, and salts, turn to the right into the liver; while the fourth, the fat, turns to the left in the lymphatic system.

We propose now to follow the foods through the liver, and then the fat through the lymphatics [38].

The meat, in the first place, enters the liver in the form of unpurified peptones—*i.e.*, liquid digested meat, laden, however, with albumoses and other deleterious products, which are formed in the process of the acid digestion in the stomach, and the alkaline digestion of the duodenum.

The Liver. The business of the liver is to purify the peptones from these bodies, so as to render them fit to nourish the body. When it fails to do this, the body gets poisoned, and we have a bilious attack.

In the next place the sugar has to be dealt with in a remarkable manner. Sugar is such a vital and important food that it must be supplied to the hungry tissues with great regularity in a certain proportion every moment, day and night. How is this to be effected when it is only eaten in any shape two or three times a day? The peculiar glycogenic function of the liver is the answer.

Glycogen is an animal starch, formed in quantities in the liver from the sugar received into the blood by removing from it the molecule of water that was added to it in the starch digestion to make it soluble, thereby rendering it again insoluble. This is stored up in the liver, to be dealt out by re-dissolving it as required.

Glycogen is formed slowly from proteids as well, probably by splitting them up into glycogen and urea. It is found that only half as much glycogen is found in the liver on a pure meat as on a mixed diet.

The object of the formation of glycogen, which is not diffusible, is clearly to store up the soluble sugar in the liver, thence to be re-made as required into glucose.

During digestion more sugar enters the liver than leaves it, but in the intervals twice as much leaves it again as enters it.

Glycogen has been found in small quantities in other tissues of the body. The sugar is finally consumed by the action of the muscle cells, and passes away as water (H_2O) and carbon dioxide (CO_2).

Another function of the liver is the formation of bile. The first function, when more fully understood, will probably be seen to be of great importance in connection with the general question of *autosepsis*, or self-poisoning, which is believed to be more common than is generally supposed.

The blood that leaves the liver by the inferior vena cava (the hollow vein), and thus enters the heart, is laden with the purified peptones into which the meat of our sandwich has been converted, and with the requisite proportion of sugar derived from dissolved glycogen, into which the bread of the sandwich has been changed. We will consider its further destination later on.

How the Food Reaches the Heart. It remains for us now only to trace the dissolved fat, or chyle, to its end. When it enters the lacteals, or "milky" vessels, they pour it with other fluid into the lymphatics, which join together and make their way to the left side of the body, till they enter a reservoir some 2 in. long in vertical height and nearly ½ in. broad, called the *receptaculum chyli*, or the receptacle for the chyle. From the top of this ascends a fine tube 15 in long, called the *left thoracic duct*, which opens into the left arm vein, just behind the collar-bone. This vein carries the blood into the superior vena cava (hollow vein), and so into the heart.

The chyle in the reservoir is pumped upwards along the thoracic duct by the action of respiration, and by movement, and so the fat is poured into the blood, and at length, when it reaches the heart regions, the rest of the digested sandwich, that has been brought there by the other vein from the liver.

Such are the wonderful steps by which all food is carried from the mouth to the heart; and when the difficulties and complicated nature of the process is fairly grasped, it may lead to some increased care in eating, so as not to embarass unnecessarily the natural process by unsuitable food, taken in an improper manner, or in excessive quantities

POETRY OF THE ELIZABETHAN AGE

2. The Dramatic Poets. A Review of the Origin and Rise of the Drama, with an Outline of Shakespeare Study

By J. A. HAMMERTON

IT is worthy of note that the Drama in England, so often and long condemned by the puritanical, is not only one of the world's oldest and noblest arts, but had its origin in religious worship. The art which produced in Shakespeare the greatest genius of all time was in ancient Greece an evolution of pagan ceremonial and in its modern revival it might be described as a graft on the priestly propaganda of mediæval times. We cannot, of course, attempt any study of the Greek drama, which, to be made thoroughly intelligible, would require well-nigh as much detail of treatment as our scheme permits our giving to the whole body of English poetry. We can allow ourselves only such incidental references as may be necessary in discussing English drama. But let us be clear on this point: the art of the dramatist, both in the ancient and the modern world, has attracted the mightiest intellects ever devoted to creative literature, and, in proportion to the whole body of the drama, the works of absolute genius which it contains outnumber those in any other division of literature.

The Place of Drama in Literature. It is necessary to state this in the most emphatic manner, because there still exists to a surprising extent a considerable measure of prejudice against everything associated with the theatre; the legacy, on one side, of puritanism, and the outcome, on the other, of the present debased condition of the English drama, which has long ceased to be literary and does not give to the playgoers of our time any inkling of a glorious art. Broadly speaking, our drama is to-day in much the same condition as English poetry during the barren age that separates Spenser from Chaucer, and it is to the written page alone, and not to the theatre—excepting Shakespearian revivals—that we must turn to study the drama. It may be said that this is as it should be, since the dramatist, not less than any other poet, is for the study. But the fact remains that what is called "a drama for the closet" is no drama at all; the play which cannot be acted is for that reason no play, and equally the play which is only tolerable when acted is not literature. Of these two, the former class is of more interest to us as students of literature than the latter, to which we need give no attention whatever. If we bear these points in mind there will be no need to enter into any minute explanations of the varying qualities of dramatic literature as we proceed with our study.

The Rise of the Drama. We turn now to what is our chief inheritance from the Elizabethan age—its dramatic poetry. Our drama might almost be said to have begun and ended in one great burst of glory; for if all that has been written since the last of the Elizabethans, with two or three exceptions, were to be wiped away, our dramatic literature would not be greatly impoverished. The evolution of the English drama is sometimes ascribed to the old "mysteries" invented by the mediæval clergy for the purpose of teaching the ignorant mob some smattering of Biblical knowledge, which crude representations of sacred history gave place gradually to the "morality" play, wherein the teachers of the people endeavoured to visualise before their dim intelligences the Christian virtues. From this it was but a step to the stage representation of the common life, and, as we have seen, that step had been taken before the reign of Elizabeth, Heywood's interludes forming a link between the morality play and the drama proper.

Early Dramatists. GEORGE GASCOIGNE (b. 1537; d. 1577) was one of the earliest dramatists and a poet of no mean place among the Elizabethans, his spirited satire, "The Steel Glass," being the longest and one of the most virile compositions in blank verse before Milton. But it is evident in his dramatic work that he was influenced not so much by the disappearing morality play as by the ancient classical drama, his "Jocasta" being an adaptation from the "Phœnissæ" of Euripides, while his "Comedy of Supposes," whence Shakespeare borrowed for his "Taming of the Shrew," was a prose translation of Ariosto's comedy, "Gli Suppositi." Indeed, it is hardly correct to speak of any "link" between the modern drama and the morality play, as in all countries the rise of the drama was the outcome of a revival of learning which led the writers to look back across the ages and to find their models in the ancient classical drama, the machinery of the stage, however, being ready to their hand as it existed for the purpose of the "moralities." The first regular comedy in our language, "Ralph Roister Doister," by NICHOLAS UDALL (b. 1506; d. 1556), Master of Eton, was modelled on the comedies of Plautus and Terence, while Sackville and Norton's "Gorboduc," our first regular tragedy, produced on 18th January, 1562, was modelled on the tragedies of Seneca.

Scholarship and Character. Comedy shaped itself into true dramatic form earlier than tragedy, and the art owed well-nigh as much to such writers as Greene and Peele as tragedy did to Marlowe. Most of the early dramatists were poet-scholars, men who had been educated at Oxford and Cambridge, and who, to their knowledge of classical models

added a racy intimacy with the life of the day, which enabled them, while observing the ancient ideas of dramatic construction, to appeal to the common people with subjects of living interest. In fact, these men of rare wit and scholarship were sadly too familiar with the life of their times, and their biographies, so far as we can ascertain them, are for the most part melancholy records of lives untimely sacrificed to debauchery; sometimes, as in the case of Greene, utterly at variance with the ethical standards of their writings. It is noteworthy that Shakespeare, the great king of them all, was almost the only one who had no university training, and, in the then accepted definition of scholar, could rank with few of his contemporaries. He, too, was among the lesser group who showed a better balanced character, and in his own life observed a standard of conduct which to-day would have made him a person of almost suburban manners.

Lyly, Peele, and Greene. We shall not endeavour to enter in any detail into a chronicle of the early drama, and shall deal with the artists rather than the art, and even so, with only a few of the more notable of the dramatists. Among these some mention must be made of JOHN LYLY (b. 1553 ; d. 1606), as his name is, for other reasons than his talent, conspicuous in the early Elizabethan period. He was not a dramatist of any great ability, his comedies in prose and verse being unworthy of attention to-day except from the close student of the Elizabethan drama. He had a lyrical rather than a dramatic gift, some of his songs in his plays being wholly delightful. We shall have occasion to consider his work in more detail when we come to deal with the origin of modern prose. GEORGE PEELE (b. about 1558 ; d. 1598) made more valuable contributions to comedy, though his plays are stronger in poetic fancy and form than they are in dramatic construction. His comedies, such as "The Arraignment of Paris," and "The Old Wives' Tale," are as pretty and engaging as his tragedies, such as "The Battle of Alcazar," are bombastic and preposterous. ROBERT GREENE (b. 1560 ; d. 1592) was a poet of very similar gifts to his boon companion Peele. A follower of Lyly as a novelist, the best of his genius is to be seen in the beautiful lyrics which are introduced in his prose romances and his plays. Perhaps the most noteworthy of his dramatic pieces is "Friar Bacon and Friar Bungay." While both Peele and Greene have no great interest for the general reader, any student desiring to familiarise himself with this period of our drama must neglect neither of these writers. Although not strictly in place, we cannot refrain from quoting some lines from Greene's "Farewell to Folly," as illustrative of his lyrical poetry:

"Sweete are the thoughts that savour of content,
The quiet mind is richer than a crowne:
Sweete are the nights in careless slumber spent,
The poore estate scornes Fortune's angry frowne:
Such sweete content, such mindes, such sleepe, such bliss,
Beggars enjoy, when princes oft doe miss."

Christopher Marlowe. The first great name, however, the real herald of the English drama, was CHRISTOPHER MARLOWE (b. 1564 ; d. 1593), one of the most melancholy figures in our literary history. Had not he fallen a victim to a vicious and irregular life at the early age of twenty-nine, he might, his splendid powers ripened and exercised with the restraint of maturer judgment, have stood no more than a step behind Shakespeare himself. Indeed, when Marlowe was killed in a wretched tavern brawl Shakespeare's dramatic genius was still in the bud, though both poets had been born in the same year. Marlowe was the son of a poor Canterbury shoemaker, and may have owed his education at Cambridge University to some wealthy relative. He graduated M.A. in his twenty-fourth year, but two or three years earlier he is supposed to have been in London intent on becoming a dramatist. Records of the production of his works are somewhat confused, none of the plays being printed in his lifetime. "Tamburlaine the Great," supposed to have been his first, though disfigured by much bombast and fustian, is alive with real drama, and its style is instinct with poetic feeling. His other chief works are "Doctor Faustus," "Edward II.," "The Jew of Malta," and "The Massacre at Paris." It is generally agreed that "Edward II." is the best historical play in our language after Shakespeare, and Charles Lamb is not unduly enthusiastic when he says, "the reluctant pangs of abdicating Royalty in Edward furnished hints which Shakespeare scarcely improved in his 'Richard II.,' and the death scene of Marlowe's king moves pity and terror beyond any scene, ancient or modern, with which I am acquainted."

Marlowe's "Doctor Faustus." His greatest work is "Doctor Faustus," founded on the legend of the German magician who, for twenty-four years of unrestrained life, sold himself to the devil both body and soul, which is also the theme of the greatest poem of modern times, Goethe's "Faust." "There is," says Hallam, "an awful melancholy about Marlowe's Mephistopheles, perhaps more impressive than the malignant mirth of that fiend in the renowned work of Goethe. But the fair form of Margaret is wanting; and Marlowe has hardly earned the credit of having breathed a few casual inspirations into a greater mind than his own." Neither of the other two productions we have named is worthy of the poet's undoubted genius, and perhaps the opinion of Thomas Warton, the erudite historian of English poetry, gives the best critical summary of Marlowe's work: "His tragedies manifest traces of a just dramatic conception; but they abound with tedious and uninteresting scenes, or with such extravagances as proceeds from a want of judgment, and those barbarous ideas of the times over which it was the peculiar gift of Shakespeare's genius alone

to triumph and to predominate." Marlowe's plays are now little read, but every reader with any pretension to literary culture should at least be conversant with his "*Doctor Faustus*" and "The Jew of Malta." His beautiful lyric, "The Passionate Shepherd to his Love," will be familiar to most readers.

William Shakespeare. If we were to shear away every name in English dramatic poetry but that of Shakespeare, we could still claim for it such pre-eminence, especially in tragedy—the highest form of drama—that not even the glorious art of Greece could be said to transcend it. Indeed, tragedy, which sprang from the worship of the god Dionysus, or Bacchus—the altar and the chorus of the pagan temple having their counterparts in the Greek theatre—and rose into supreme poetic form in the tragedies of Æschylus, Sophocles, and Euripides, may be said to have culminated in the works of Shakespeare: the four greatest tragedies in the world are "Hamlet," "Othello," "Macbeth," and "King Lear." But it is the unmatched glory of WILLIAM SHAKESPEARE (b. 1564; d. 1616) that he achieved the highest in both tragedy and comedy. As Coleridge points out very aptly, Plato, in his "Dialogue of the Banquet," had two thousand years before framed "a justification of our Shakespeare" when he argued that "it was the business of one and the same genius to excel in tragic and comic poetry, or that the tragic poet ought, at the same time, to contain within himself the powers of comedy." This in Plato was little short of prophetic, as it laid down a canon utterly opposed by all the ancient critics, and quite unsupported by any example from the Greek dramatists, to whom tragedy and comedy were incompatible elements, having but one quality in common—ideality. "Both were alike ideal," says Coleridge; "that is, the comedy of Aristophanes rose to as great a distance above the ludicrous of real life as the tragedy of Sophocles above its tragic events and passions; and it is in this one point of absolute ideality that the comedy of Shakespeare and the old comedy of Athens coincide. In this also alone did the Greek tragedy and comedy unite; in everything else they were exactly opposed to each other. Tragedy is poetry in its deepest earnest; comedy is poetry in unlimited jest." Thus we see at a glance why Shakespeare is in all the world of genius the most commanding figure; his the one intellect which, while comprehending all human passions and emotions, could equally express all.

Shakespeare's Characters. Of course, no one will expect of us anything so audacious as an effort to condense within a page or two a study of Shakespeare. Betterton, the first really great tragedian, at the end of his career, when performing Hamlet for the last time, said that he had seldom in fifty years, and with all his continuous study, discharged that role without finding in the character some new beauty to express which previously he had not noticed, and this not less in his last performance of it. If this be true of only one of the multitude of characters created by Shakespeare, one might devote a lifetime of study to his works, and leave them unexhausted at the end. Nay, many men of great and original talent have done so, and many more will follow in their steps. For Shakespeare and his writings are not to be regarded as a great author and a department of study, but as a life and a literature. So limitless is the literature which has grown around the name of Shakespeare in all the languages of European culture, that only a man of the ripest scholarship and linguistic attainments can hope ever to obtain more than a partial knowledge of this mighty genius. But that is in no way to deter the ordinary reader from entering upon the study and enjoyment of a series of works which, if one read no others, would furnish the mind with the very essence of intellectual joy, and make its owner a person of culture. It is not the least of Shakespeare's distinctions that he commands the devotion and lifelong service of the best scholars while he entertains the most ordinary reader and the common playgoer.

"The True Enchanter." Remembering our point of view, perhaps we cannot do better than commend Shakespeare in the memorable words of Washington Irving, written on his visit to Stratford-on-Avon:

"On returning to my inn, I could not but reflect on the singular gift of the poet; to be able thus to spread the magic of his mind over the very face of Nature; to give to things and places a charm and character not their own, and to turn this working-day world into a perfect fairyland. He is indeed the true enchanter, whose spell operates, not upon the senses, but upon the imagination and the heart. Under the wizard influence of Shakespeare I had been walking all day in a complete delusion. I had surveyed the landscape through a prism of poetry which tinged every object with the hues of the rainbow. I had been surrounded by fancied beings; with mere airy nothings, conjured up by poetic power, yet which, to me, had all the charm of reality. I had heard Jacques soliloquise beneath his oak; had beheld the fair Rosalind and her companion adventuring through the woodlands; and, above all, had been once more present in spirit with fat Jack Falstaff and his contemporaries, from the august Justice Shallow, down to the gentle Master Slender and the sweet Anne Page. Ten thousand honours and blessings on the bard who has thus gilded the dull realities of life with innocent illusions; who has spread exquisite and unbought pleasures in my chequered path, and beguiled my spirit in many a lonely hour with all the cordial and cheerful sympathies of social life!"

The Life of Shakespeare. Only in the most summary fashion can we hope to outline Shakespeare's work; nor is there need that we should do more, as the reader must familiarise himself with *every* poem and play from the master's pen, as well as with those in which his share of authorship is a matter of speculation, and with various works of biography and criticism relating to Shakespeare. Although it is often said that some half-dozen facts are all

that we possess with certainty of the poet's life, the untiring industry of biographers and critics, especially during last century, not only in England but in Germany and in France, has supplemented the few historical facts with so much inferential knowledge, that there is no difficulty in realising for ourselves an adequate conception of the man, and in understanding, to the best of our individual capacities, the poet.

Shakespeare's Education. We have mentioned that almost alone among the Elizabethan dramatists—if we discredit the theory of Jonson's training—Shakespeare was not a university scholar; but it is fair to suppose that he received his education at the free school of Stratford, being under fourteen years of age when his father, who had hitherto been prosperous and prominent in the public life of the town, fell upon evil times, and had to withdraw his son in order to put him to a trade. It has been thought that he was apprenticed to a butcher, though some critics, on the strength of the legal knowledge displayed in his works, have supposed him to have been for a time an attorney's clerk. But on similar grounds it might be argued that he had meant to be a gardener, or had thoughts of the ministry. He was not eighteen when he married Anne Hathaway, a yeoman's daughter, eight years older than himself; and three or four years later, now the father of three children, and a social failure in his native town, he came to London, where in 1592 we find him an actor and a rising playwright. It is in this year that Greene, in his "Groatsworth of Wit," jibes at him as a "rude groome," who "supposes he is as well able to bumbast out a blanke verse as the best of you"—the sneer of a practised dramatist at a younger and more promising member of his craft.

Chronology of the Plays. Shakespeare attained to no great distinction as an actor, but his connection with the stage brought him in the way of literary work in the shape of altering old plays, retouching the writings of other dramatists when the manager employing him desired to revive their plays. Playwrights were then in the habit of selling to the theatrical managers for a few pounds the entire copyright of their plays, and as actors thought it prejudicial to their interests that the plays should be published, only a few plays of the period, and these chiefly in unauthorised versions, were printed during the lifetime of their authors. None of those which Shakespeare revised could be "old," in the sense that now attaches to old plays, as the theatre itself was only in its infancy when Shakespeare was a young man, the first tragedy, "Gorboduc," as we have heard, having been written but three years before his birth. The chronology of his earlier dramatic works has undergone many changes at the hands of different critics, from Malone, in 1778, to Mr. Sidney Lee, in 1898, but there is no great difficulty in deciding upon the approximate order of the 37 plays attributed to him, or in distinguishing those of which he was only part author. As Mr. Lee observes, "the subject matter and metre both afford rough clues to the period in his career to which each play may be referred. In his early plays the spirit of comedy or tragedy appears in its simplicity; as his powers gradually matured he depicted life in its most complex involutions, and portrayed with masterly insight the subtle graduations of human sentiment and the mysterious workings of human passion. Comedy and tragedy are gradually blended, and his work finally developed a pathos such as could only come of ripe experience. Similarly, the metre undergoes emancipation from the hampering restraints of fixed rule, and becomes flexible enough to respond to every phase of human feeling." For this reason the works of Shakespeare are best read in something like chronological order.

Shakespeare's Early Poetry. It is well, therefore, not to begin with the plays, but with the two long narrative poems, "Venus and Adonis" and "The Rape of Lucrece," as the former, published in 1593, was almost certainly the first effort of Shakespeare's muse, and the latter, appearing in the succeeding year, did much to establish the fame of the young play-actor, whose name was becoming familiar to patrons of the theatre as an adapter of plays. These were the works which first won him renown among his contemporaries, and, apart from their great poetic beauty, they are interesting to us for that reason. They are elaborately classical both in matter and in manner, typical of what we know as the Pagan Renaissance, because the influence on the Elizabethans was, as we have noted, that of ancient Greece and Rome.

"Venus and Adonis" is almost lascivious in the warmth of its passion, the ardour with which the amorous goddess woos the young hunter being in perfect harmony with the Greek ideal, and it has been thought that in this Shakespeare was not above the desire to win the regard of the patron to whom he dedicated his work, the young Earl of Southampton, who was reputed of a somewhat amorous disposition. But the exuberant fancy of the poem, the sensuous beauty of its imagery, its rhythmic sweetness, all give it such distinction that the licence of its tone cannot be held to preclude it from anyone's reading.

"The Rape of Lucrece," which deals with the tragic story of the lawless passion of Tarquin's son for the wife of Collatinus, whose nāme was fragrant of all wifely devotion, was dedicated to the same patron, and was truly that "graver labour" which the poet promised in his dedication of the first work. It gives evidence of such maturity in its reflective passages, and so great an increase of art in its whole conception and construction, that there may be good reason for supposing "Venus and Adonis" to have been an effort of the poet's youth, and considerably earlier in execution than even the first of his attempts at play revising. At all events, these two poems, if read before we undertake the study of the plays, will help us the better to understand

the unfolding and blossoming of Shakespeare's genius.

The Order of Shakespearian Study. We may now set forth the names of the plays in their order, following Mr. Sidney Lee's arrangement, and marking with an asterisk (*) those of which Shakespeare was only part author :

1. EARLY DRAMATIC WORK.	
Love's Labour's Lost	1591
Two Gentlemen of Verona	1591
The Comedy of Errors	1592
Romeo and Juliet	1592
*Henry VI. (First Part)	1592
*Henry VI. (Second Part)	1592
*Henry VI. (Third Part)	1592
Richard III.	1593
Richard II.	1593
*Titus Andronicus	1593
The Merchant of Venice	1594
King John	1594
2. THE DEVELOPMENT OF DRAMATIC POWER.	
A Midsummer Night's Dream	1594-5
All's Well that Ends Well	1595
The Taming of the Shrew	1595
Henry IV. (First Part)	1597
Henry IV. (Second Part)	1597
The Merry Wives of Windsor	1597
Henry V.	1598
3. MATURITY OF GENIUS.	
Much Ado About Nothing	1599
As You Like It	1599
Twelfth Night	1600
Julius Cæsar	1601
Hamlet	1602
Troilus and Cressida	1603
4. THE HIGHEST THEMES OF TRAGEDY.	
Othello	1604
Measure for Measure	1604
Macbeth	1606
King Lear	1607
*Timon of Athens	1608
*Pericles	1608
Antony and Cleopatra	1608
Coriolanus	1609
5. THE LATEST PLAYS.	
Cymbeline	1610
A Winter's Tale	1611
The Tempest	1611
*Henry VIII.	——

In the Study and on the Stage. Now, we do not suggest that the student of Shakespeare is to procure himself a good edition of the plays and poems and read them through precisely in the order given above. But we are persuaded that it is well, so far as it may be practicable, to read Shakespeare with more regard to the chronological order of the plays than to their grouping as comedies, histories, and tragedies, which is so frequently followed in the popular editions of the poet. Many influences will condition the reading of the plays; especially theatrical representation, for we are strongly of opinion that no student of Shakespeare should miss any opportunity of seeing his plays performed on the stage by good companies, and there are few towns of any considerable size where such opportunities do not occur frequently. Shakespeare is a poet for the stage *and* the study, and those who tell us they can enjoy him in the study but not on the stage do him an injustice and themselves no credit, as they should be able to enjoy him equally in both places. It will sometimes happen that the reader may have an opportunity of seeing a Shakespearian play which he has not read, and which, if he were following the above order of reading, he would not be likely to read for some time. The opportunity must not be lost, more especially if it be to witness one of the plays, such as "Cymbeline" or "Coriolanus," less frequently staged than others. The play should be read *before* seeing the theatrical representation of it, and again immediately afterwards. We feel sure that anyone following this course will be struck by the revelation of the subtler passages which results from witnessing a play, already familiar by reading, in its natural atmosphere of the stage. It was said of a great tragedian that to see him act was like reading Shakespeare by flashes of lightning. The phrase was not quite happy, as it is not well to read anything by lightning flashes. But what the critic meant was true: that the actor often interprets passages of the poet, which thus become illumined as by a flash of bright light, to the student, who may have missed their significance when reading the play.

How to Study one of Shakespeare's Plays. In most of the innumerable popular editions of Shakespeare's plays no hint whatever is given as to the sources whence the poet derived his subjects—sometimes, indeed, his very thoughts and words. But no thorough understanding of Shakespeare can be arrived at without this data, and the student is strongly recommended to study Shakespeare in some of those editions which give each play in a separate volume, with an introduction and notes by a competent scholar, and in some cases the full text of the original stories from which the poet has drawn the foundations of his work. There are so many of these editions to be had at low prices that we need not specify any particular one.

It is only in this way that a true critical estimate of the dramatist may be formed ; but at the same time we are not to place ourselves unreservedly in the hands of the critics and commentators, as it is always better, no matter how we may blunder in the first instance, to come by our own opinions in our reading, through the exercise of our own intelligence. What we have found out for ourselves is of far more value to us and the development of our mind than what we have received without question from a teacher. Obviously, in the case of Shakespearian study, we must accept a vast amount from the expositors of his text, but in doing so we can at the same time cultivate our own critical faculty by pursuing a course which will bring that into action ; and to this end we cannot do better than read a play for the first time in an edition which is not annotated. In

this way we are forced to form some independent judgment, and it is not of the slightest importance to the end in view whether that judgment be sound or ridiculous; the effort has been made, and only thus shall we ever attain to critical aptitude. After we have received our own personal impressions of the poet's appeal to our understanding, and formed our own blundering opinions of his work, we can, with far more profit to ourselves, place ourselves in the hands of a scholarly editor, whose notes, elucidations, and parallel quotations, will enable us to shape in our own mind an adequate conception of the poet's work, from which will be eliminated the mistaken notions formed in our first unguided reading, but in which will be retained the tested results of independent judgment. We need hardly observe that this method of reading is not limited in its application to the study of Shakespeare, though it is better adapted to the study of the dramatists and the poets generally than to the writers of prose.

"Shakespeare's Sonnets." Shakespeare's mind, and therethrough his life, can best be understood by following the sequence of his works. His "Sonnets" should be read with the plays of his second period, as most of them were written in the year 1594, though the collection was not published until 1609. Extraordinary interest has centred in this, the only other important work of Shakespeare's pen, and a whole library of books has been devoted to the discussion of the "mystery of the sonnets." We are unable to touch at any length on the subject, nor do we deem it at all essential, as we are persuaded that Mr. Sidney Lee, by the rare intelligence and precision of his critical method, has disposed of all the popular and fantastic theories of these poems. His conclusions go rather to support the late Professor Minto's theory as to their being written to show Shakespeare's contempt for the extravagant vogue of the sonnet among his contemporaries, than to further any of the other popularly accepted notions of their origin. If not written as a *tour de force*, then they were no more than an experiment in the fashion of the hour, and the profound autobiographical value many have supposed them to possess is largely imaginary. Some of them were indited to the poet's patron, the Earl of Southampton; many have no relationship whatever to any others in the collection, and the common idea that sonnets 1 to 126 are "addressed to a beautiful young man of high station," and 127 to 154 "either addressed to or referring to a married woman of dark complexion, highly accomplished, fascinating, but of irregular conduct," is no longer tenable in the light of Mr. Lee's researches.

Biographical Value of the Sonnets. In summing up his conclusions as to the biographical value of Shakespeare's sonnets, Mr. Lee writes: "A personal note may have escaped him involuntarily in the sonnets in which he gives voice to a sense of melancholy and self-remorse, but his dramatic instinct never slept, and there is no proof that he is doing more in those sonnets than producing dramatically the illusion of a personal confession. Only in one scattered series of six sonnets, where he introduced a topic, unknown to other sonneteers, of a lover's supersession by his friend in a mistress's graces, does he seem to show independence of his comrades and draw directly on an incident in his own life, but even there the emotion is wanting in seriousness. The sole biographical inference deducible from the 'Sonnets' is that at one time in his career Shakespeare disdained no weapon of flattery in an endeavour to monopolise the bountiful patronage of a young man of rank. External evidence agrees with internal evidence in identifying the belauded patron with the Earl of Southampton, and the real value to a biographer of Shakespeare's 'Sonnets' is the corroboration they give of the ancient tradition that the Earl of Southampton, to whom his two narrative poems were openly dedicated, gave Shakespeare, at an early period of his literary career, help and encouragement."

Books on Shakespeare. As we have already hinted, we are making no effort in our treatment of Shakespeare to do more than throw out a few practical hints which, having proved of value in our own case, cannot fail to be useful to others. Anything approaching an adequate survey of his work is so far beyond the scope of this course that even to attempt it briefly would be as unwise as it would be unnecessary, since it is imperative that the reader must familiarise himself with every line which Shakespeare has written, together with the best that has been written about him, and at the end of this section we give a list of such works recommended for study. Here we would make special mention of two. For the beginner we do not know a better little handbook than Professor Dowden's "Introduction to Shakespeare" (Blackie, 2s. 6d.). This, however, is only for the beginner; as the student progresses he will require a work of a more comprehensive kind, and nothing in modern criticism of Shakespeare excels "A Life of William Shakespeare" (Smith, Elder, 7s. 6d.), by Mr. Sidney Lee.

It only remains to add, in pursuance of our biographical method, that the tale of Shakespeare's work from 1592 until his final retirement to Stratford, in 1611, supplies most that we know of his life. He had become part-owner of the Globe Theatre, the leading London playhouse, in 1599. His income, which in his later years must have been about £600 per annum in the money of the time, was derived chiefly from his share in this theatre. Two years earlier he had purchased New Place, the largest house in Stratford-upon-Avon, where he died, on April 23rd, 1616.

ELEMENTS OF MACHINES

Being a Study of the Principles of Several Types of Levers: Wheels and Axles, Pulleys, Inclined Planes, Wedges and Screws

By JOSEPH G. HORNER

A MACHINE, no matter of what nature or how complicated it may be, is an instrument by which force applied at one point is transferred to another point, being at the same time intensified or changed in direction. This modified force has always to overcome some resistance, as that of gravity, friction, or the cohesion of particles of matter. This resistance in mechanics is denoted by the term *weight* (W), and the force applied to overcome it is termed *power* (P). In statics, the problem is to find the magnitude of P acting at one point necessary to balance W at another point; it is generally supposed, however, that P is sufficient to set a machine in motion. When the weight (W) is greater than the power (P), the machine is said to work at a *mechanical advantage*, the ratio being shown by the fraction $\frac{W}{P}$. But if this fraction is not greater than unity—that is, if W is less than P in magnitude—the machine works at a *mechanical disadvantage.*

The elements of the most complex machine are reducible to what are called the *six mechanical powers:* (1) the lever; (2) the wheel and axle; (3) the pulley; (4) the inclined plane; (5) the wedge; (6) the screw.

A *lever* is a rigid rod free to turn about a fixed point called the *fulcrum.* Levers are divided into three classes according to the relative positions of the power, fulcrum, and weight. Thus they may be placed in the order PFW, PWF, or WPF [58-60]. The condition for equilibrium in a lever of any of these three classes is that the movement [Fig. 30, page 413] of the power round the fulcrum be equal and opposite to that of the weight. Therefore P, multiplied by its arm (AC) = W, multiplied by its arm (BC). That is, $\frac{W}{P} = \frac{AC}{BC}$.

Levers of the First Class [58]. Remembering what has been said above concerning mechanical advantage, it is clear that levers of this first group will be only mechanically advantageous when AC is greater than BC, so that the fraction shall be greater than unity. If the arm BC is longer than AC, the lever will be mechanically disadvantageous, the effort being greater than the weight required to be raised. The effort will be equal to the weight when AC = BC, and the fraction equals unity. Common examples of the first class of lever are the poker, the handle of a pump, see-saw, crowbar (when it rests on a block in front of the weight being raised), and a canal lock-gate Scissors form a double lever of the first class.

Levers of the Second Class [59]. Here AC is always greater than BC, and there is, therefore, always a mechanical advantage. The crowbar—when one end rests on the ground—and the wheelbarrow are everyday examples of levers of the second class. Nutcrackers are a double lever of this type.

Levers of the Third Class [60]. In this class, AC is always less than BC, which means that $\frac{AC}{BC}$, or $\frac{W}{P}$ is less than unity, and so levers of the third class are always disadvantageous as regards power. Nevertheless, they are useful where speed and range of movement are required. For example, if ACW [61] represent a man's arm bent at the elbow, the hand holding a weight (W), it is evident that the contraction of the muscle through the small arc at P will cause the weight to move through the relatively much greater arc shown by the dotted line from W. A fishing-rod, the treadle of a turning-lathe, a whip, and the fore-arm as mentioned above, are all levers of the third class, tongs being a double lever of the same kind.

Wheel and Axle. The second mechanical power, *the wheel and axle*, is merely a modification of the lever. It consists [62] of two cylinders turning on a common axis. The larger cylinder is conventionally called the wheel, the smaller one the axle. Ropes are coiled round both wheel and axle, but in opposite directions, so that as the rope round one unwinds, that round the other winds up. Looking at the end section in the illustration, the principle of the lever will be immediately observed. The power and the weight act at the points A and B, where for the moment the two ropes are tangents to the two circles, and the conditions for equilibrium for the ordinary lever hold good in the wheel and axle—namely, $P \times AC = W \times BC$; or $\frac{W}{P} = \frac{AC}{BC}$; *i.e.,* $\frac{W}{P} = \frac{\text{Radius of wheel}}{\text{Radius of axle}}$, and since the circumference of a circle is proportional to its radius, the conditions of equilibrium are reduced to $\frac{W}{P} = \frac{\text{Circum. of wheel}}{\text{Circum. of axle}}$. From which it follows that a big wheel and a small axle will give greater mechanical advantage than when the diameters more nearly approach each other. The capstan, windlass, rack and pinion, and toothed wheels in general, are common examples of the principle of the lever, or wheel and axle.

Pulleys. The *pulley* is a wheel whose circumference is grooved to prevent the rope —called the tackle—which passes round it from slipping off the wheel turns freely on an axis through its centre, and is fixed in a framework called the pulley-block, or sheave. Sometimes this pulley-block is fixed to a

beam, or rafter for example; sometimes it is movable, as on a crane, and sometimes a series of pulleys are arranged in a particular combination.

The *fixed pulley* [63] gives no mechanical advantage, the weight on one string requiring to be balanced by an equal weight on the other. It is useful, however, in changing the direction of a force, so that by pulling down, or horizontally, a weight may be raised vertically.

Movable Pulleys. The single *movable pulley* is shown in 64. The weight (W) being supported by two cords, the tension on each is evidently $\frac{1}{2}$ W, but as one cord is attached at A to the beam, the force or weight P has only to support $\frac{1}{2}$ W, or $\frac{W}{2}$. Thus $P = \frac{W}{2}$: *i.e.*, $\frac{W}{P} = 2$, or the mechanical advantage in a single movable pulley $= 2$. In other words, the weight is twice the power—1 lb. being able to support 2 lb. To obtain this advantage, however, the strings must be parallel.

A still greater advantage is gained when several movable pulleys are combined to raise a weight. The three methods of combining movable pulleys are spoken of as the first, second, and third systems.

Separate-string System. In the first, or separate-string system [65] each pulley hangs by a separate cord; one end is fastened to a beam or other support, and after passing round a pulley the cord is attached to the block of the one above it; the last cord, however, passes round the fixed pulley and supports the counterpoise (P), the weight (W) being attached to the lowest pulley.

It is necessary to suppose in all theoretical questions concerning pulleys that the ropes or cords are perfectly flexible and that friction is absent. Then it follows that *the tension of the rope is the same in every part* irrespective of the number of pulleys in the combination. As a matter of fact, however, these two theoretical conditions are very far from being present in practical work, and though in theory the greater the number of pulleys in any system the greater would be the mechanical advantage, the enormous amount of friction and the lack of flexibility of cord render a multiplication of pulleys impossible.

In 65 it is clear that the tensions on the strings marked 1 are equal, as in the case of the single movable pulley, so that P supports a weight equal to 2P on the first pulley-block (A). Hence the tension on the string below A equals 2P, and so the pulley B supports a weight 4P (2^2P). In the same way C supports a weight 8P (2^3P), and so on, each successive block doubling the mechanical advantage. With three pulleys, therefore, $W = 2^3P$; with four pulleys, $W = 2^4P$; with any number of pulleys conveniently represented by the letter *n*, $W = 2^nP$, *i.e.*, $\frac{W}{P} = 2^n$. Thus the mechanical advantage in the first system $= 2^n$.

Single-string System. In the second, or *single-string system* [66] the pulleys are contained in two blocks, the upper one fixed, the lower one movable, the weight being attached to the latter. The same string passes round all the pulleys as shown in the diagram. Here the tension throughout the string equals P, and as there are four (practically) vertical strings supporting the lower block, the weight W is supported by four upward forces, each equal to P. Therefore $W = 4P$. If there are *n* pulleys, then $W = nP$; *i.e.*, $\frac{W}{P} = n$. Thus the mechanical advantage in the second system $= n$.

The Third System. The third system is really the first system turned upside down, as in 67, the end of each string being attached to a bar carrying the weight. The tensions supporting the weight here are $P + 2P + 4P$. Thus $W = 7P$, or $W = (2^3 - 1)P$, the index of the figure 2 representing the number of pulleys. With four pulleys $W = (2^4 - 1)P = (16 - 1)P = 15P$. With *n* pulleys, $W = (2^n - 1)P$: *i.e.*, $\frac{W}{P} = 2^n - 1$. Thus the mechanical advantage in the third system $= 2^n - 1$. It must be noted, however, that in this system the weights of the pulleys assist the power instead of acting against it, as in the other two systems.

The Inclined Plane. The inclined plane permits of the raising of a body to a particular height by exerting a smaller force through a greater distance. The directions in which a force may be applied to a body on an inclined plane are: (1) *horizontally*; (2) *parallel to the plane*.

In 68, which represents a section of an inclined plane, the force acts parallel to the plane. Three forces combine to keep the body in equilibrium: (1) the weight (W) acting vertically downwards; (2) the reaction or resistance (R) of the plane acting perpendicularly to the plane; (3) the pull or power (P) acting up the plane. (The surface of an inclined plane is theoretically perfectly smooth and free from friction, and by the reaction (R) is meant the resistance of the plane to bending, breaking, or penetration. Hence the force R acts perpendicularly to the surface.) It can then be shown by the Triangle of Forces that $\frac{P}{BC} = \frac{R}{AC} = \frac{W}{AB}$. That is, $\frac{P}{\text{Height of plane}} = \frac{R}{\text{Base of plane}} = \frac{W}{\text{Length of plane}}$. Therefore the pull required may be found from the equation $P = W \times \frac{\text{Height of plane}}{\text{Length of plane}}$, and the resistance $R = W \times \frac{\text{Base of plane}}{\text{Length of plane}}$. The mechanical advantage of the inclined plane $= \frac{W}{P} = \frac{\text{Length}}{\text{Height}}$; in other words, the greater the incline in a road or railway the greater is the pull required.

Pulls and Gradients. On a gradient of 3 in 10 a weight of 160 lb. could be pulled by a force slightly greater than 48 lb. If, however, the gradient were but 3 in 16 the force necessary

would be scarcely more than 30 lb. The weight would therefore be raised to the same height with a less force; but it must be remembered that as this force acts through a greater distance no work is saved. Whatever be the gradient, the work done by P acting along the plane is always equal to the work which would be done in raising the load W vertically from C to B. That is, $P \times AB = W \times BC$, or, as we have just seen,

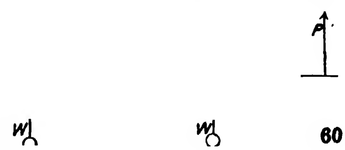
$$\frac{W}{P} = \frac{AB}{BC} = \frac{\text{Length}}{\text{Height}}.$$

When the force is applied horizontally, as in **69**, then the ratio between the forces keeping the body in equilibrium is $\frac{P}{\text{Height of plane}} = \frac{R}{\text{Length of plane}} = \frac{W}{\text{Base of plane}}$. Then $P = W \times \frac{\text{Height of plane}}{\text{Base of plane}}$, and the resistance,

penetrating instruments. A wedge whose section is an isosceles triangle is the commonest and most advantageous form. The force is applied at the back of the wedge (AB), and the resistance on each side may be considered to act at right angles to the slant edges of the wedge.

Owing to the fact that the power applied to AB is not a continued pressure but a series of impulsive forces, the theory of the wedge is less exact than that of the other mechanical powers. Considering the power and the resistance on each side, however, as three forces in equilibrium, it may be demonstrated that the resistance $R = P \times \frac{\text{Length of equal side}}{\text{Back of wedge}}$.

Then the mechanical advantage will be $\frac{R}{P} = \frac{\text{Length of equal side}}{\text{Back of wedge}}$. So that by diminishing the size of the back and increasing the length of



58

63

APPLICATIONS OF MECHANICAL POWER

$R = W \times \frac{\text{Length of plane}}{\text{Base of plane}}$. Also $\frac{W}{P} = \frac{\text{Base}}{\text{Height}}$. Considering this second case from the point of view of work done, since P acts in the direction AC, then $P \times AC$ = work done by P. Also the work done by raising the load W vertically through $CB = W \times BC$. And $P \times AC = W \times BC$; *i.e.*, $\frac{W}{P} = \frac{AC}{BC} = \frac{\text{Base}}{\text{Height}}$. Again, in **68**, since each force is proportional to the side to which it is perpendicular—*i.e.*, P, R, W are proportional to the height, base, and length respectively—and since $AB^2 = AC^2 + BC^2$ (Euc. I. 47), therefore $W^2 = P^2 + R^2$. In the case where the force applied is horizontal, $AC^2 = AB^2 - BC^2$; that is, $W^2 = R^2 - P^2$.

The Wedge. The *wedge* [**70**] is a block tapering to a thin edge, a double inclined plane as it were. It is used for splitting wood or other material, and for raising heavy bodies, as in the raising of a ship in a dry dock by inserting wedges under the keel. Common examples of wedges are knives, chisels, swords, axes, plugs, planes, needles and pins, nails, and all cutting and

the side—that is, diminishing the angle of penetration—the mechanical power of the wedge is increased.

The Screw. The *screw* is the last of the mechanical powers, and, like the wedge, is derived from the inclined plane. It consists of a cylinder, on whose surface is a spiral ridge called the *thread*. The relation between the thread and the inclined plane is easily seen by cutting out a right-angled triangle of paper, corresponding to the section of an inclined plane. If this be wrapped round a rod—say, a round ruler—the hypotenuse of the triangle forms the screw thread, or *helix*, the base of the triangle (or plane) corresponds with the circumference of the cylinder, and the height will be the distance between the threads, or the *step* of the screw, technically known as the *pitch*. The threads are sometimes square in section (square screws), sometimes acute (sharp or vee screws). The screw works in a fixed *collar* or *nut*, which is a hollow cylinder, whose internal surface carries a groove, or internal thread, in which the screw thread fits.

The ordinary copying-press illustrates the method of using the screw. Power is applied by means of a lever (the arm or handle of the press) attached to the end of the screw. The screw then moves forward in the direction of its axis, overcoming resistance. Or, as in the case of the screw-jack, it may be used to raise a weight.

In finding the relation between the force applied and the resistance which is overcome, it is important to note that every time the screw performs a complete revolution it moves forward through a distance equal to the space between one thread and the next. If, in **71**, power (P) be applied so that the arm *b* makes a complete revolution, the work done will be equal to P multiplied by the circumference of the circle of which *b* is the radius—that is, $P \times 2\pi b$. At the same time, the work (W) done by the screw in moving through the distance P (the space between two threads) equals $W \times P$. Then $P \times 2\pi b = W \times P$. And the mechanical advantage is:

$$\frac{W}{P} = \frac{2\pi b}{P} = \frac{\text{Circum. of circle described by lever}}{\text{Pitch, or step, of the screw}}.$$

Thus the mechanical advantage is increased by diminishing the pitch, or by increasing the length of the arm or lever to which the power is applied.

We recognise in the levers examples of the turning pairs of Reuleaux; in the inclined plane and wedge, sliding pairs; and in the screw, twisting pairs, or a movement of translation in a helical plane around an axis. The lever and the inclined plane, therefore, include all essential mechanical motions, no matter how they are disguised in a thousand-and-one mechanisms. Only when first principles are thus grasped is it possible to analyse machines and avoid error in classification. There have been thousands of useless patents taken out that never would have been applied for if the patentees had possessed an elementary knowledge of mechanics.

Constraint. If we now look further into these examples, we find that the feature of constraint is an essential one. The elements are all paired together in such a way that they can only move in certain relations, and each pair of elements is paired with others adjacent, so that the movements of each are under constraint. The elements themselves Reuleaux termed *links*, or *kinematic links*, and the whole series of adjacent elements, *closed kinematic chains*. As no element in a mechanism can move without reference to all the others, that is a fundamental conception of a machine, and the workability of a mechanism can always be tested by this simple proposition. In the preceding figures it is easy to see that the introduction of some one element into the chain of moving elements would interfere with their proper operation.

In the levers the fulcrum must be fixed and incapable of movement, and the arms must be free to turn around the fulcrum as a centre. In the wheel-and-pulley systems the centres of certain pulleys are fixed, others are movable. The movement of the "cord" is constrained to one direction. The sliding movements of the load on an inclined plane; that of the wedge, and that of a nut in its screw, are also constrained. In fact, it would be impossible to conceive of a mechanism from which the condition should be absent.

But in speaking of kinematic links and chains we must not be understood to use the term in its literal sense. Links are often non-rigid. A cord, a belt, a spring, or even a pressure fluid, as water, gas, steam, is as truly a link as a bar of steel is. All depends on its application and its relation to other rigid parts. Tension and compression elements are alike links. By the use of springs, for example, a mechanism is often prevented from knocking itself to pieces. Yet the movements of the mechanism are as surely accomplished under the constraint of the elastic spring as though it were a non-elastic bar. So with the cords, ropes, chains, or pulley systems. Flexibility is essential, yet the connections and the relative movements are assured.

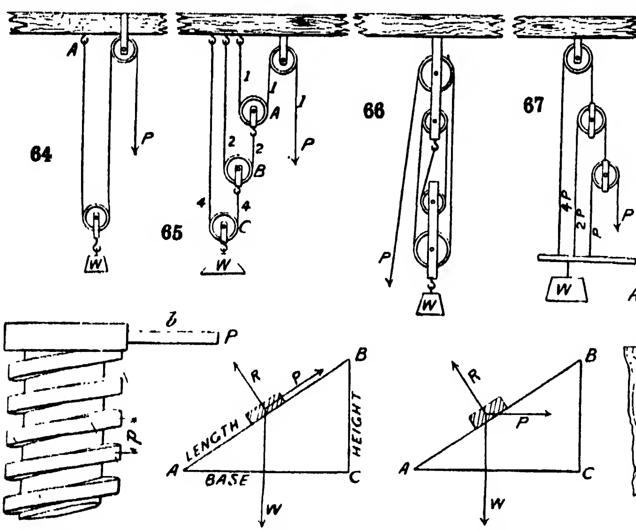
Applications of Power in Practice. Going a stage further, the engineer sees in these diagrams only the skeleton outlines which denote principles. Looking beyond them he recognises a hundred mechanisms which clothe the bare anatomy with living forms. The fulcrum in the lever group does actually occur in the triangular form shown, in the knife edges of weighbridges and balances. But most often it is the cylindrical pivot of a beam or a rocking lever, or of a derricking crane-jib, or the crank-pin of an engine, or the shafts of wheels. The gaunt lines become disguised in the strong arms and ribs of pulleys, of toothed wheels, of engine-beams. The crude wheel and axle appear in some pulley-block designs, but the "axle" much more often occurs in the disguised form of the chain-drums of cranes; while the "wheel" is recognisable in the winch-handle, or the large driving wheel on the drum-shaft. The fixed pulley is found at the head of all crane-jibs, and elsewhere. Movable pulleys occur in pulley-blocks of divers forms, arranged in more workable designs than those used for diagram purposes, while the friction which is so excessive in these is turned to account in the self-sustaining or differential type. The inclined plane is utilised in keel-blocks for ships, in inclined tracks for mines, and for heaving up slips for vessels. The wedge appears in various forms of friction clutches for the driving and release of shafting, in cottars and keys for uniting lengths of rod, and fastening wheels to shafts, and generally for making metal connections that can be rapidly made and broken.

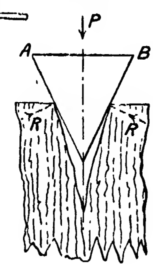
The inclined plane in the form of the screw is perhaps used to a larger extent than any other single element of mechanism. It becomes a means of connection and union, temporary or permanent, a device for producing end-long movement, a mechanism in combination with the lever for gaining almost unlimited power, a device for imparting linear movement to

materials, as in conveyors, a method of measurement, the agent for the propulsion of the biggest liners and battleships.

Over and over again mechanisms are so changed that their essential elements are disguised. The relation between the two-bladed propeller and the carpenter's wood screw is fairly obvious. But everyone would not identify the herringbone form of tooth gear with a screw, nor either with the worm-wheel Yet the relations are readily demonstrable.

The Test of Practicability. The enormous loss of power and of time in some mechanisms explains why these are not used to any great extent. Neither of the pulley arrangements shown, excepting the first two, are used much in hoisting machinery, because the speed is far too slow, and the height of lift too limited. Hence the lever, in the disguise of trains of toothed gears, is employed by preference for the gain of power, so separating the mechanism for mechanical advantage from that for mere lifting. Almost the only variety employed is that shown in **64**, where the common snatch block will be recognised. The differential block is based on **66**, though not in that form.





APPLICATIONS OF MECHANICAL POWER

If the screw is combined with a lever the power gained is enormous, but the movement is too slow for common mechanisms unless a high initial rate of movement is imparted to the lever (in such cases a shaft, or pulley, or motor) driving it.

Often the speed is of no consequence, but the screw is utilised as a precision mechanism, as in dividing-gears, and in the lead screws of lathes, in which the pitch of the threads is the first factor in effecting divisions mechanically.

Fundamental Distinction between Screws. A volume might be written on this single aspect of the screw, that of an instrument for dividing and measuring. It is used for these functions in every engineer's shop in the world, and also in the finest dividing instruments made for astronomical and scientific purposes. From the time of Maudslay to the present moment mechanicians have been constantly striving to get as nearly as practicable to a perfect screw. Recently, a Standard Leading Screw Adjusting Machine has been fitted at the National Physical Laboratory, in which the average limit of error in the screw does not exceed 0·00018 in. per foot of length. To obtain such remarkable accuracy common workshop methods fail, since the effects of change of temperature have to be guarded against; the means of support, of measurement, of cutting and correcting, have all to be devised, and applied to the one task of securing accuracy regardless of cost.

There is a great and fundamental distinction between screws. One kind, the lead-screw, is used as a master for cutting other screws by, traversing a heavy tool carriage as part of their work, as in screw-cutting lathes, and is, therefore, constantly wearing; the other is employed for division only, and is subject to practically no wear and friction, as in the dividing engines and micrometer instruments. In the latter, of which the famous Whitworth measuring machine was the prototype, the pitch of the screw itself is subdivided by a large disc (constituting a nut), and finely graduated around its periphery. One complete rotation of the disc moves the screw a distance equal to the pitch, half a turn half the pitch, and all smaller movements accordingly, these being indicated by the arc divisions on the circular periphery. In commercial machines of this kind dimensions of $\frac{1}{100000}$ part of an inch can be detected.

A number of practical applications of the foregoing will be reserved for the next article—a small selection only. The farther the student strays into the realm of mechanics the farther do its vistas seem to extend.

Applications of first principles appear in unexpected forms; analogies and problems arise to exercise the mind. There is never any slackening of interest in these things. Life is too brief and time too precious to the student to be wasted in trivialities.

SHORTHAND

Fifth Instalment of the Special Course of Shorthand Taught by Messrs. Pitman & Sons on their Twentieth Century Plan

Continued from page 588

By SIR ISAAC PITMAN & SONS

IN this lesson we deal with the hooks placed at the end of consonants, and hence termed final hooks; these are easily mastered, and complete the hooking system of Pitman's Shorthand.

Final N and F Hooks. A small final hook, struck by the RIGHT or forward motion adds *n* to straight consonants; thus

Ben, tone, coin, rain.

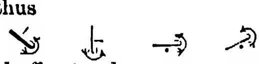
It will be noticed that the hook which represents *r* at the beginning of a straight consonant, and that which represents *n* at the end are both struck towards the RIGHT, thus

brain, train.

A small final hook, written inside the curves, adds *n* to all curved consonants; thus

fain, thin, assign, moon.

A small final hook, struck by the LEFT or backward motion, adds *f* or *v* to straight consonants; thus



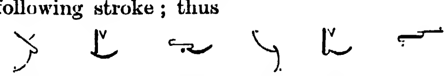
buff, tough, cave, rave.

There is no *f* or *v* hook to curves.

The hook which represents *l* at the beginning of a straight consonant represents *f* or *v* at the end, and both hooks are struck towards the LEFT; thus

bluff, cliff.

The *n* and *f* hooks may be employed medially when they join easily and clearly with the following stroke; thus

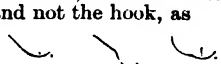


punish, dining, cleaning, fancy, diving, graphic.

A hook at the end of a word is always read LAST; as

pen, puff, fun;

therefore, when a word ends with *n*, or *f* or *v*, followed by a vowel, the stroke consonant must be written and not the hook, as



penny, puffy, funny.

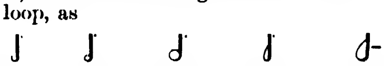
The forms *shl*, *shn*, when written upward, and *ln*, when written downward, must never stand ALONE, because it might be supposed that they had been written downward, and upward. These forms are distinct when joined to others; as

official, valuation, fallen.

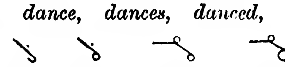
EXERCISE.

1 Ten, John, bun, ozone, Dane, then, plain, drain.
2 Doff, Jeff, pave, chough, Duff, hoof, brave, proof.
3 Wean, weave, wine, woof, run, roof, turn, turf.
4 Fen, fenny, Avon, venue, mine, Minnie, nun, ninny.
5 Banish, plenty, ORganic, mechanic, paving, cuff, coffee.
6 David, gun, agony, martial, traveL, chiefLy, aniLine.

Circles and Loops added to Final Hooks. A circle or loop is added to the hook *n* attached to a straight consonant by writing the circle or loop *on the same side* as the hook, and thus turning the hook into a circle or loop, as

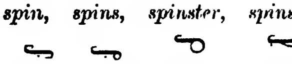


Dan, dance, dances, danced, Dunster;



pen, pens, expense, expenses;

spin, spins, spinster, spinsters;



glen, glens, glances, glanced.

The circle represents *s* only between two consonants, thus is not *pms-m* but *p-s-m*, as in the word *opossum*. Therefore, when *ns* occurs medially both letters must be shown, as

ransom, density.

The circle *s* is added to the hook *n* attached to curved consonants and to the hook *f* attached to straight consonants by writing the circle inside the hook; thus

fine, fines, frowns: puffs, drives, grieves, weaves.

In order to distinguish between *nz* and *ns*, etc., after a *curved* consonant, as in *vans(z)* and *Vance(s)*, the stroke *n* must be used for *anse, ense, inse,* or *ance, ence, ince,* thus
but but
vans Vance; men's(z) mince(s).

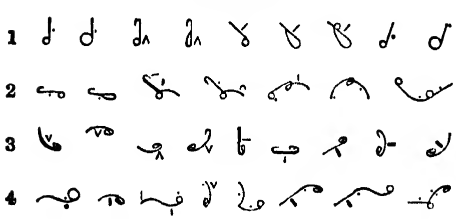
This distinction does not apply to *l* when coming *after another consonant*, and the hook is used in such outlines for *ns;* thus

balance.

The large circle *ses* and the loop *st* and *str* cannot be written inside the small *n* and *f* hooks; therefore, *nsez, nst,* and *nster*, following a *curved* consonant, must be expressed by the stroke *n* with the large circle or loop attached; thus

fences, fenced.

EXERCISE.



1 Pins, spoons, bounced, brains, tuns, trains, grains.

2 Jones, dunce, dunces, pounce, pounces, winsome.

3 Fens, offence, lens, lance, nines, ninnies, derives, Buffs.

4 Prudence, opulence, summons, science, lines, violence.

Final -*TION* Hook. The termination *-tion*, also variously written *-cion, -cian, -tian, -sian*, etc., is expressed by a large final hook; thus

edition, fashion, mission, caution, Persian.

The circle *s* is added thus

nations, additions.

When *-tion* hook follows a curved consonant it is written inside the curve, like the final *n* hook, thus

fusion, vision, session, motion, notion.

When *-tion* follows a simple straight consonant, the hook is written on the side opposite to the LAST vowel; thus

passion, option, occasion, auction,

diction, education, aberration, duration.

When *-tion* follows a straight letter which begins with a hook, circle, or loop, or springs from the curves [up] the *-tion* hook is written on the opposite side, to preserve the straightness of the letter; thus

abrasion, repletion, attrition, citation,

Grecian, section, affection, location.

After *t, d,* or *j*, not beginning with a hook, circle, or loop, the *-tion* hook is written on the RIGHT side, irrespective of the vowel; thus

dictation, rotation, degradation, magician.

The *-tion* hook is used medially, as

additional, dictionary, auctioneer,

cautionary, devotional, national.

When *-tion* follows the circle *s* or *ns*, it is expressed by continuing the circle on the other side of the consonant so as to form a small hook; thus Second-place dot vowels between the circle and *-tion* are written OUTSIDE the hook; third-place vowels are written INSIDE the hook; thus

possession, position, musician, accession, sensation,

incision, authorization, dispensation, transition.

First-place vowels do not occur between *s* and the syllable *-tion*.

The circle *s* may be added to this hook; thus

positions, *suppositions*, *musicians*;

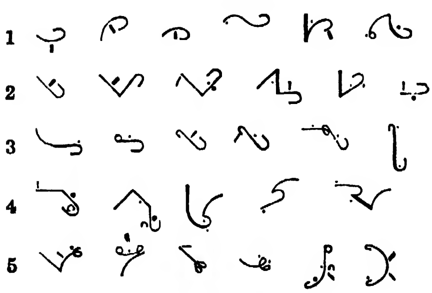
and the hook may be used medially; thus

positional, *transitional*.

When two distinct vowel signs occur immediately before *-tion*, write *sh* and the hook *n*, in order to accommodate the vowel signs; thus

valuation, *extenuation*, *tuition*.

EXERCISE.



EXERCISE.

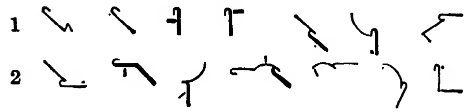
1 Ovation, omission, illusion; lotions, orations, sessions.
2 Potion, cushion, ration, apparition, elocution.
3 Expression, fiction, navigation; Prussians, accretions.
4 Tactician, adaptation, cogitation; notions, imitations.
5 Cremation, salvation, remission; donations, collisions.
6 Exceptional, occasional, sessional, missionary.
7 Cessation, precision, vexation; annexations, pulsations.
8 Accessional, recessional; superannuation (*shn* up).

Grammalogues. At this stage the following additional grammalogues should be memorized.

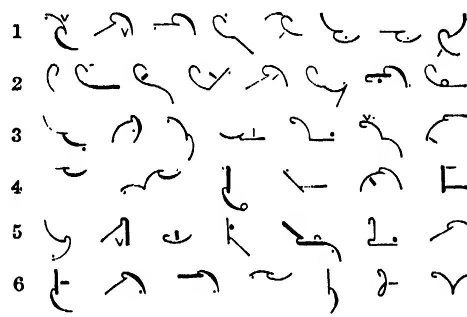
call (¹)	*more*, or *re-mark-ed* (¹)	*their*, or *there*
care	*Mr*, or *mere*	*thing*
dear	*near*	*think*
for	*nor*	*use*, (verb) *whose* (³)
from	*see*, *use* (³) (noun)	*very*
Lord	*so*, *us*	*which*

KEY TO EXERCISES IN LAST LESSON.

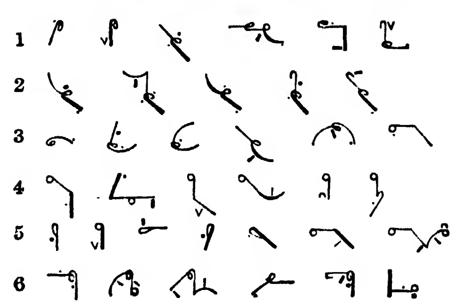
1 Play, bray, addle, adder, ogre, grow, glow, try, cry, brew.
2 Bible, breath, breakers, library, teacher, tipple, fiddle, sugar, problem.



1 Flaw, flag, fledge, flame, flung, rifle, revel, inflammable.
2 Channel, tunnel, final, partial, roguishly, Ethelred, venal, eternal.
3 Other, through, cover, frame, thrush, fresh, afresh, gather, thrice.
4 Fraud, coffer, lever, leisure, tanner, banner, Homer, thinker.
5 Differ, Fred, rubber, rubble, shiver, shovel, France, Fleming.
6 Frugal, keeper, initial, Michael, fever, trifle, brutal, joyful.



1 Supple, subtle, sable, splice, suckle, splash, saddle, saddler, sublime.
2 Display, possible, classical, exclaim, disclaim, disable, cycle, bicycle.
3 Signer, designer, soother, dishonour, suffer, blissful, sooner, savoury, deceiver.
4 Sprig, super, supreme, spruce, spring, sprawl, straw, cedar.
5 Stitcher, switcher, stagger, swagger, stutter, sweater, sucker, sabre, stopper, sober.
6 Descry, disclose, describe, disclosure, mistress, expressly, expositor, outsider, outstrip.



Continued

WHAT WE KNOW OF THE ATOM

Mixtures and Compounds. Atoms and Molecules. Atomic and Molecular Weight. Fixed and Multiple Proportions. Chemical Equivalents

By Dr. C. W. SALEEBY

The Atomic Theory. In order to understand the real meaning of the table on p. 517, we must consider at length the *atomic theory*, which we have described as the logical basis of modern chemistry. The atomic theory regards matter as being built up of minute particles, which are called atoms, a name which literally means "uncut" or indivisible; and it assumes that the difference between one element and another — the difference, say, between gold and oxygen—is due to a difference in the nature of the atoms in each case. Further, we assume that every atom of gold is exactly the same as all other atoms of gold, every atom of carbon exactly the same as all other atoms of carbon, and that this holds true whether the carbon be situated in the sun or in the human body, or in a comet or anywhere else. An *element* or elementary substance is one which consists of an indefinite number of atoms of the same kind. A *compound* consists of atoms of at least two kinds.

Are we to say, then, that a compound is simply a mixture? This is very far from being the case. Let us take familiar instances, air and water. The air is a mixture of gases—that is to say, a mixture of gaseous elements. These elements retain their own characteristic properties. The atoms of any one of these elements may go about in each other's company, but not in the company of the atoms of any other element of the mixture. Now the essential character of a compound is that the atoms of one element go about in the company of the atoms of one or more *other* elements. Amongst the elements in the air, for instance, are oxygen and nitrogen. These are mixed, but not combined. But the substance we call water also consists of two gases—oxygen and hydrogen, yet it displays none of the properties that we attribute to either of those elements, nor does it display a sort of average or blend between them. It is totally different.

Compounds Distinguished from Mixtures. Indeed, this case furnishes us with a particularly good instance of the difference between a compound and a mixture. It is quite an easy thing to measure out a certain quantity of hydrogen and a certain quantity of oxygen, and to mix them together in a tube. The result is simply a mixture of two transparent gases. It is not in the least like water, has none of the properties of water, and, in short, is not water; yet water consists of these two elements in exactly the same proportions as those in which they are present in the tube in question. This can be readily proved by simply passing an electric spark through the tube. The result is that the gases disappear, and there is found in their place a drop or two of water. This drop of water consists of the very gases that were present in the mixture, and can, if necessary, be decomposed, with the reproduction of the mixture as before. What, then, constitutes the essential difference—a difference which, in point of fact, is very great—between a mixture of oxygen and hydrogen on the one hand and a compound of oxygen and hydrogen on the other hand?

Molecules. In order to answer this question, we must consider a new conception which is represented by the word *molecule*—literally, a little mass. This word used often to be employed when atoms were meant. It was, for instance, the word used by Clerk-Maxwell in his famous address delivered to the British Association and referred to in the section on Physics. [See PHYSICS.] But Maxwell was referring to what we now call atoms. We must sharply distinguish between the modern uses of these two terms.

Let us take, for instance, the gas hydrogen, which we believe to be composed of a number of atoms, all exactly similar. We find reason to believe that these atoms do not go about singly, but that they pair with one another, and each pair of hydrogen atoms constitutes a little system of its own, which we now call a molecule. In the case of the mixture of hydrogen and oxygen, we should find, if our eyes were keen enough, simply a collection of molecules, consisting either of two hydrogen atoms linked together or of two oxygen atoms linked together. But if we made a similar inspection of the water which is formed when a spark is passed through this mixture, we should find the essential difference between a mixture and a compound. The mixture was simply a mixture of molecules of hydrogen and molecules of oxygen—each molecule, as we have said, consisting of two similar atoms; but in the compound, just because it is a compound and not a mixture, there is no such mixture of molecules.

The Molecule of Water. All the molecules of a compound are of the same kind, just as all the molecules of an element are of the same kind; but whereas the molecules of an element are composed of similar atoms, the molecules of a compound are formed of dissimilar atoms. Whereas the mixture of hydrogen and oxygen consisted of a number of molecules containing two atoms of hydrogen and a number of molecules containing two atoms of oxygen, the compound called water

formed from that mixture contains only one kind of molecule, compounded of atoms of oxygen and atoms of hydrogen, whilst no molecules consisting only of hydrogen atoms or only of oxygen atoms would be found in it.

Now these facts may be very simply expressed by the judicious use of the symbols which we have noted in our table of the elements. We may say that the mixture consisted of a number of H_2 molecules and a number of O_2 molecules —the two standing for the number of atoms in each molecule ; but in the compound there are no H_2 or O_2 molecules. The molecules are all of one kind, and each consists of two atoms of hydrogen and one atom of oxygen. We express this construction of the molecule of water by the formula H_2O. That is the formula of water ; and it expresses the fact that each molecule of water consists of two atoms of hydrogen and one atom of oxygen. Perhaps the formula would be more intelligible if it was written H_2O_1, but the $_1$ is never printed. It is understood that when the symbol of an element occurs without any figure after it, *one* atom of that element is indicated.

An Unstable Compound. The reader will very probably ask why it is that one atom of oxygen should combine with two of hydrogen. Why not one with one or two with two ? That question raises many important considerations, which will later be discussed ; but we may here point out in passing that the combination of two atoms of oxygen with two atoms of hydrogen is known and yields a compound called Peroxide of Hydrogen. This is a very unstable compound, since it contains, so to speak, one atom of oxygen in each molecule more than is comfortable, and hence it is very apt to lose this superfluous oxygen, which, when it goes, leaves H_2O, or water, behind. This property of giving off oxygen endows peroxide of hydrogen with useful properties.

Amongst other purposes, it is often applied to the hair for the purpose of lightening its colour. It produces a characteristic yellow colour—" peroxide hair "—which is due to the fact that the oxygen given off from the H_2O_2 enters into combination with the dark pigment of the hair and produces a pigment of a lighter colour now fashionable.

Atoms in Pairs. Let us return now to the consideration of the molecules of an element —molecules consisting of similar atoms, as distinguished from the molecules of a compound, which consist of dissimilar atoms. There are some elements the atoms of which go about singly. Mercury and zinc are examples. In the great majority of elements the atoms go about in pairs. We have seen that this is so in the case of oxygen and hydrogen But the precise number of atoms in the molecules of elements varies with circumstances. Let us consider, for instance, the peroxide of hydrogen, H_2O_2, of which we have spoken. We have said that it owes its use in bleaching an actress's hair to the fact that it gives off oxygen, which combines with and alters the hair pigment ; but the reader will object that the hair is always in contact with the oxygen of the air. Why does not that bleach the pigment ? A very satisfactory answer to this question can be obtained.

Let us consider the case of the atoms of oxygen in the air. Each of them is in combination with one of its fellows, thus forming a molecule of oxygen, and is, so to speak, satisfied. It has no desire to seek other partnerships (of course the reader will understand that we are using symbolical ways of talking ; these desires and satisfactions are now being explained in terms of electrical forces). The atoms of oxygen forming the molecules that surround the hair do not attack the hair pigment, because they are satisfied with each other.

The Birth of an Element. But let us imagine that we can watch what happens to a molecule of peroxide of hydrogen, H_2O_2. As we have seen, this molecule contains one atom of oxygen too many for comfort, or, to use a less symbolical term, too many for *stability ;* and the odd atom of oxygen constantly tends to escape from the molecule, leaving behind a molecule of water—a molecule so stable that men studied chemistry for centuries before they discovered that it could be broken up—that water is not an element Now, it is one atom of oxygen that leaves the molecule of H_2O_2, but it is the peculiarity of an atom of oxygen, like nearly all atoms, that it must have a partner. As a rule, we may imagine the atoms of oxygen that leave two adjacent molecules of peroxide of hydrogen to unite with each other, and thus form a molecule of oxygen O_2 ; but if, just at the moment of their escape, there are any other substances present with whose atoms the atoms of oxygen can combine, instead of merely combining with each other, they are apt to do so, and this is why the peroxide of hydrogen can bleach the hair by giving oxygen to it, whilst the oxygen of the air is quite unable to do so.

When the atoms of any element are caught, so to speak, in the act of combining with each other—that is to say, in the act of seeking companions—the element is said to be in the *nascent* state, which literally means the state of being born. It is at these moments that the chemical properties of the element are most strikingly manifest. In the language of chemistry, then, we say that peroxide of hydrogen, H_2O_2, bleaches the hair in virtue of the fact that it liberates *nascent oxygen ;* and the reader now understands why nascent oxygen should be more chemically active than oxygen that is not nascent—that is to say, than oxygen the atoms of which have already settled down to a humdrum existence in stable pairs.

The Properties of Ozone. We have seen, then, that the atoms of oxygen may sometimes be caught *single*. The formula for oxygen at such a moment would be O (the $_1$ being understood) ; and we have seen that, as a rule, the atoms go about in *pairs*, indicated by the formula O_2 ; but we further discover that, under certain conditions, the atoms go

about in *trios*, in which case the formula of the oxygen must be O_3, indicating that each molecule consists of three atoms. A special name has been given to this modification of oxygen, which is called *ozone.*

Now, just as peroxide of hydrogen, H_2O_2, is an unstable substance, always eager to get rid of its superfluous oxygen and relapse into the more familiar substance water, so, similarly, ozone, O_3, is an unstable substance, always anxious to get rid of its superfluous atom of oxygen, and settle down into the commoner kind of oxygen O_2. Whenever there is any opportunity for getting rid of the superfluous atom of oxygen to anything that will have it, the ozone seizes the chance. Indeed, two molecules of ozone left by themselves will very soon turn into three molecules of ordinary oxygen.

A Chemical Equation. Such a change may be expressed in the first chemical equation to which we shall introduce the reader:

$$2O_3 = 3O_2$$

This simply expresses the idea that two atoms liberated from two adjacent molecules of ozone have united with each other to form a third atom of oxygen, which is added to the two atoms of oxygen which were left by their departure. The equation is a true equation, as the reader will see when he applies the test of ascertaining whether all the atoms named on the one side of the equation, and no more, are accounted for on the other side of the equation. It is a true equation, because it represents six atoms on each side. Of course, the reader will understand that we have been talking in very metaphorical language, since no one can possibly see, or experiment with, two molecules of ozone or any other substance; but there is no doubt that our metaphor corresponds with the actual fact.

Now, we do not know of any form of oxygen in which the molecules consist of more than three atoms; but there are certain substances which possess four atoms to the molecule. Of these, phosphorus and arsenic are examples. Thus the formula for phosphorus must not be written P or P_2, but P_4. When we come to examine the behaviour of atoms of sulphur, we find that, at certain temperatures, they go about in pairs, and the formula for sulphur at such temperatures must be S_2; but at other temperatures they seem to go about in sixes, and the formula for sulphur at these temperatures must be S_6. We can now readily understand the relation of what is called *molecular weight* to *atomic weight.*

Molecular and Atomic Weight. The *molecular weight* of any body containing, say, four atoms to the molecule will plainly be four times the atomic weight; but, surely, before discussing molecular weight, we must understand what we really mean by atomic weight.

Perhaps the most fundamental character of matter is its mass. [See PHYSICS.] We have seen, of course, that we have no absolute measurement for mass, but can merely estimate the mass of one substance as compared with that of another. We have already seen that the mass of the hydrogen atom, being the lightest known, used to be taken as the standard of measurement, but that now there is a tendency to prefer oxygen as the standard, and to represent the weight of the oxygen atom as 16. Plainly, in such case, the molecular weight of oxygen must be 32; the molecular weight of ozone must be 48; the molecular weight of hydrogen must be 2; and the molecular weight of water, H_2O, must be $18 = 1 + 1 + 16$.

The Law of Fixed Proportions. What, then, are the chemical facts that may be explained on this atomic theory, which asserts that matter consists of atoms of different kinds, the atoms of each element being of a constant and definite weight—weight being the means by which we express the amount of matter in, or the mass of, the atom which we weigh? The first law which may be explained on the atomic theory, and on no other which has been suggested, is the law of *fixity of proportions*, or *fixed proportions.*

This law asserts that every chemical compound —assuming, of course, that it is pure—always possesses the same constitution—that is to say, is always composed of the same fixed proportions of the elements that go to compose it. Let us take, for instance, the case of the simple compound called water. From whatever source we obtain a specimen of water, and under whatever conditions we examine it, it is invariably found that, when the water is decomposed, eight-ninths of its weight is composed of oxygen and one-ninth of hydrogen. What is true of water is true of every other compound. If the compound is what it professes to be, it is invariably found to contain absolutely fixed proportions by weight of the different elements that go to compose it.

An Experimental Fact. Observe here the difference between a mixture and a compound. Oxygen and hydrogen may be mixed in any proportion; but in the combination of them called water the proportion is absolutely constant — one-ninth hydrogen, eight-ninths oxygen.

Now, this experimental fact as to the fixed proportions (by weight) of the elements in water tallies precisely with the facts we have observed as to the relative weight of oxygen and hydrogen, for we found that oxygen is approximately sixteen times as heavy as hydrogen; and, on the atomic theory, we asserted that water consists of a number of molecules, each of which contains two atoms of hydrogen and one of oxygen. If that theory were true, every molecule of water would consist of hydrogen to the extent of one-ninth part of its weight, whilst oxygen would supply the other eight-ninths, since the one atom of oxygen weighs sixteen and the two atoms of hydrogen taken together weigh two. If, then, water is made up of a number of such molecules, any quantity of water that we examine at any time should similarly prove to consist of one-ninth of

hydrogen and eight-ninths of oxygen; and that is what is found.

The Law of Multiple Proportions. The second law which can be explained by the atomic theory, and by no other that has been suggested, is the law of *multiple proportions.* This may be simply illustrated by taking two familiar substances, such as nitrogen and oxygen. There are five known compounds of nitrogen and oxygen. When we come to weigh the proportions of nitrogen and oxygen in these five compounds, we find that they may be arranged in a series of a very significant character. If we represent the weight of nitrogen on the top line and the weight of oxygen on the bottom line, we find that the ratios in the five compounds are as follows:

$$\frac{14}{8} \quad \frac{14}{16} \quad \frac{14}{24} \quad \frac{14}{32} \quad \frac{14}{40}$$

Now, 14 is the atomic weight of nitrogen, and 16 is the atomic weight of oxygen. Thus, on the atomic theory, we can very readily explain the fact that there are five compounds of oxygen and nitrogen in which the weights of the two constituents are arranged in multiple proportion, 8, 16, 24, and so on. We can explain the first compound, in which we found the ratio of nitrogen to oxygen as 14 to 8, on the atomic theory, by asserting that this compound consists of the union of two atoms of nitrogen to one of oxygen. This is obvious, if for 14 to 8 we read 28 to 16, a ratio which suggests the composition we have stated. The formula of this substance is N_2O. It is known as laughing-gas, and whenever we analyse laughing-gas we find that it consists of nitrogen and oxygen in the proportions by weight of 28 and 16. The next compound of oxygen and nitrogen, in which the weights of the two elements are in the ratio of 14 to 16, must plainly consist of molecules which have one atom each of oxygen and nitrogen. Its formula is $N\,O$. Similarly, the next compound and the two next show a simple increase in the ratio of oxygen to nitrogen.

Five Kinds of Molecules. We have to conclude that two atoms of nitrogen unite respectively with one, two, three, four and five atoms of oxygen, and form these five different kinds of molecules, whose compositions illustrate the law of multiple proportions, and can be explained only by the atomic theory. The five formulæ are as follows: N_2O, N_2O_2, N_2O_3, N_2O_4, N_2O_5—and these formulæ illustrate the relations of the substances; but it is more accurate to write $N\,O$ and $N\,O_2$ instead of N_2O_2 and N_2O_4, since it is probable that the simpler formulæ represent the actual way in which the atoms go about; though the double formulæ, when inserted in their place in the series, make more obvious the nature of the relation between the five compounds. If the reader will turn back to the ratios $\frac{14}{8}$, etc., which we gave in starting, he will see how perfectly they are explained on the atomic theory. If that theory is rejected, these ratios, and numberless others that might be cited in illustration of the law of multiple proportions, must be denied their only and obvious meaning.

The Law of Chemical Equivalents. The third law which can be explained by the atomic theory is known as the law of *chemical equivalents.* This, also, can be easily illustrated. Let us take a given quantity of hydrogen, say a gramme [for the meaning of this term, see PHYSICS]. Now, a gramme of hydrogen will unite exactly with eight grammes of oxygen, forming nine grammes of water and leaving over no oxygen and no hydrogen. Similarly, we find that if we take one gramme of hydrogen and 35·4 grammes of chlorine [refer to the table already printed, and note that this proportion is exactly the proportion of the atomic weights of hydrogen and chlorine], we find that the two will unite exactly, giving us 36·4 grammes of a compound called hydrochloric or muriatic acid, the formula of which is $H\,Cl$.

Now, the law of chemical equivalents states that chemical quantities which have equal power of forming chemical compounds are equal to one another. Thus, according to this law, eight grammes of oxygen are chemically equivalent to 35·4 grammes of chlorine, since each of these two quantities unites exactly with one gramme of hydrogen. But when we say that eight grammes of oxygen are chemically equivalent to 35·4 grammes of chlorine, we are saying in other words, on the atomic theory, that (if we double the two quantities, the relation is seen at once) two atoms of chlorine are chemically equivalent to one atom of oxygen, since two atoms of chlorine will weigh 70·8 and one atom of oxygen weighs 16. The ratio 70·8 to 16 is the same as the ratio of 35·4 to 8. Now, it is found that two atoms of chlorine are indeed equivalent to one atom of oxygen, for two atoms of chlorine will unite with two atoms of hydrogen (forming two molecules of $H\,Cl$), and one atom of oxygen will also unite with two atoms of hydrogen (forming one molecule of water, H_2O).

We may take the atomic weights of any elements at random and use them as our guides in indicating the proportions of the elements that may be expected exactly to combine with each other in the formation of compounds; and we find that the table of atomic weights is always a guide in such cases. Further confirmation of the atomic theory will be found in the subsequent chapter on the laws of chemistry.

Molecular Weight. Let us now return to the consideration of molecular weights—that is to say, the weights of molecules—which must necessarily depend upon the weights of the different atoms which compose them. The subject of molecular weights is exceedingly important, for we have already seen that elementary substances composed of only one kind of atom may appear in very different forms, having very different

properties, according to the number of the atoms that go to form each molecule. We saw this in the case of oxygen, O_2, and ozone, O_3. The importance of the subject of molecular weights is not fully realised in many text-books.

Many writers, for instance, are contented to use H and O as symbols for hydrogen and oxygen; but this will not do. H and O are simply short ways of writing the names of Hydrogen and Oxygen. The symbol for the substance we call oxygen is not O, but O_2. If we do not recognise this distinction, we are left with only one symbol, O, to describe the two very different substances, oxygen and ozone. Similarly, in the writing of equations, we must never shirk the extra trouble involved in using our formulæ properly. For instance, the easiest way of writing an equation to represent the decomposition of peroxide of hydrogen, H_2O_2, would be

$$H_2O_2 = H_2O + O.$$

But this is a very unsatisfactory way of writing the equation, unless we use it to express the fact already noted that for a moment the oxygen atoms are in a state of dissociation from each other, so that the oxygen is nascent, as chemists say. The actual result of decomposition of peroxide of hydrogen is the production of water and of ordinary oxygen—oxygen in which the oxygen atoms go about in pairs, and the formula of which is therefore O_2. Now, in order to express this properly, we must go to the trouble of doubling all the terms of the equation, and we must write it thus:

$$2\ H_2O_2 = 2\ H_2O + O_2$$

Similarly, the reader will find an illustration of the proper way of writing chemical equations if he turns back to the equation—the first we employed—that illustrates the decomposition of ozone into oxygen. It would not do at all to have written $O_3 = 3\ O$, because O stands for nothing. It is simply a short way of writing the name Oxygen; but the element oxygen is composed of two atomed molecules, and, therefore, we have to write our equation as we did write it in order to show that the product of the decomposition consists of a certain number of two-atomed molecules, which we represent by the formulæ O_2. Having corrected this common error, and having undertaken never to sanction it, we may now pass to the consideration of molecular weights.

Actual Size of Molecules. The molecular weights to which we have hitherto referred are, of course, purely relative, like the atomic weights; but we may first ask ourselves whether anything is known as to the absolute size and weight of molecules. This subject belongs rather, perhaps, to the domain of physics than to the domain of chemistry; but, nevertheless, the chemical student must be interested to learn whether anything is known as to the actual size of these molecules to which he has to devote so much attention. A great deal of labour has been expended on this subject. Hitherto we have referred only to molecules containing a very few atoms, but there is an immense number of kinds of molecules that are relatively large and heavy, and contain hundreds of atoms. It is believed that the largest and most complex molecule known is that of hæmoglobin, which is the red colouring matter of the blood. This molecule is supposed to contain more than a thousand atoms belonging to the elements carbon, oxygen, hydrogen, nitrogen, iron, and possibly phosphorus.

The actual or absolute size of this enormous molecule has not been studied; but Lord Kelvin's calculations lead us to conclude that if a drop of water were magnified to the size of the earth, its molecules would be of a size ranging somewhere between that of small shot and that of cricket balls.

So much for the absolute size and weight of molecules. We must now consider a subject of much more importance to the chemist—which is their relative weight, and which he always means when he speaks of molecular weight.

Weight of a Volume of Gas. Avogadro's law, afterwards to be discussed, states that equal volumes of all gases at the same temperature and pressure contain the same number of molecules. This may be otherwise expressed by saying that the molecules of all gases occupy precisely the same space, given that they are placed under the same temperature and pressure. From our discovery of this law we are enabled to devise a method of ascertaining the molecular weight of a substance. We take the substance in the form of a gas or vapour (if the substance is not naturally a gas, we vaporise it or make into a gas for our purpose).

Assuming the truth of Avogadro's law, we see that a given volume of any gas, under given conditions of temperature and pressure, must differ from a similar volume of hydrogen under similar conditions precisely in so far as its molecules are heavier than those of hydrogen, for the law states that we are dealing with the same number of molecules in each case. If, then, the volume of the gas possesses a weight twice as heavy as the weight of a similar volume of hydrogen, the necessary inference is that each molecule of this gas weighs twice as much as a molecule of hydrogen.

Thus we can ascertain the molecular weight of any substance that can be studied in the form of a vapour or gas; but, unfortunately, a great many substances cannot be vaporised, and in their case other methods must be employed. These will not be dealt with at length here. The most important of them depends on the fact that, when a given quantity of any substance is dissolved in a liquid which simply dissolves it and does not affect it chemically, it lowers the freezing point of the liquid in exact proportion to its own molecular weight, which can thus be determined. A similar principle can be applied in various other ways, and by means of these freezing-point and boiling-point methods a great deal of information has recently been acquired concerning the molecular weights of a large number of elements, especially the metals and their nearest allies.

GUARDIANS OF PUBLIC HEALTH

Medical Officers of Health. Sanitary Inspectors. Inspectors of Nuisances. Other Health Appointments. Posts for Women. Salaries and Duties

Continued from page 575

By ERNEST A. CARR

NO finer work is done under the direction of a local authority than that performed by its public health department. From quelling an outbreak of infection to closing foul bakehouses or abating the evils of overcrowding, the public health officials are perpetually doing battle in a thousand ways with dirt and disease, the indifference of employers on sanitary matters, and the ignorance of the employed.

The Medical Officer of Health. The command of this civil force is in the hands of the Medical Officer of Health for the borough or district. His is a very responsible post, especially in densely populated or poverty-stricken areas. As the sworn foe alike of the jerry-builder, the rapacious "house-farmer," and the exploiter of insanitary slums and "rookeries," he has to combat a vast amount of interest, apathy and guile, as well as that "sheer ignorance" to which Dr. Johnson unblushingly laid claim. This task requires not merely a highly qualified sanitary expert, but a sound administrator—impartial, shrewd, and resolute.

The position of Medical Officer of Health offers many attractions to able young medical men who have specialised in sanitary science and have had some experience as general practitioners, but are unable to purchase a lucrative practice, and unwilling to spend their best years in establishing one. Difficult as the duties are, they afford a means of serving the public welfare directly and with real effect. By comparison, at least, with the dull round of a practice in a sleepy parish, they are full of interest and variety, and they are free from the harassing conditions of fluctuating income and irregular hours which are the bane of a general practitioner's life. The salaries with which they are remunerated naturally cannot compare with those of the great consultants; but, in comparison with the low average earnings of fully qualified medical men, leading appointments in the municipal service are liberally repaid.

Qualifications. The appointment of a Medical Officer of Health rests with the Borough or District Council concerned, but is subject to the sanction of the Local Government Board, which retains practical control by authorising the payment from national funds (in most cases) of half the salaries of approved officers, and by specifying the qualifications necessary for its approval. These may be found set out in formal language in Section 18 of the Local Government Act, 1888. Briefly, the only essential for Medical Officers of Health for the smaller districts is that they shall be legally qualified to practise surgery, medicine, and midwifery. With regard to more important areas, the Board's requirements are naturally more stringent

The Value of the D.P.H. The section stipulates that (*with certain exceptions in favour* of established Medical Officers) no person shall be appointed Medical Officer of Health of a county, or of any district having a population of 50,000 or more, unless, in addition to the qualifications given above, he is registered as the holder of a diploma in Sanitary Science, Public Health, or State Medicine.

Of these three alternatives the most general is the Public Health Diploma, entitling its possessor to affix D.P.H. to his other qualifications. Almost all the universities award it on examination [see page 710], as well as the Conjoint Board of the Royal Colleges of Physicians and Surgeons. In addition, Dublin University gives a diploma in State Medicine; while that in Sanitary Science is granted by Durham, Victoria, and the Royal University of Ireland. The requisite qualification is also secured by graduating in the following special subjects: M.D. (London) in State Medicine; B.Sc. or D.Sc. (Edinburgh) in Public Health; or like degrees in Hygiene at Durham University.

For those medical men who wish to qualify specially for the D.P.H. with a view to municipal work, a valuable course of instruction is provided by the Royal Institute of Public Health. This comprises lectures and laboratory work in hygiene and public health, and in bacteriology. The course also includes under the former head practical sanitary training, fever hospital administration, and three months' instruction in sanitary law, sanitary engineering, vital statistics, and other branches of public health work, reinforced by practical demonstrations and visits to municipal and other sanitary works. A detailed syllabus of this course will be found in the official calendar, which may be obtained from the secretary of the Royal Institute of Public Health, Russell Square, London, W.C.

The Medical Officer's Work. The student who intends to win eventually a chief appointment in one of the leading towns will not rest content with the minimum requirements prescribed by statute. He will be wise to secure every degree and diploma within his grasp. In no other department of the municipal service, probably, are professional and scientific attainments so valuable in procuring advancement; and it is generally admitted that leading public health officers rank, as a class, with the most highly qualified members of the medical profession.

An Order of the Local Government Board defines the general duties of a Medical Officer of Health. Apart from advisory duties and the keeping of certain books and statistics, they may be conveniently summarised.

He shall inform himself as far as practicable respecting all influences threatening to affect injuriously the public health within the district.

He shall inquire into the origin and distribution of diseases within the district, and ascertain to what extent the same have depended on conditions capable of removal.

He shall by periodic and other inspection of the district keep himself informed of the conditions injurious to health existing therein.

On receiving information of the outbreak of any dangerous infectious or epidemic disease, he shall visit without delay the spot where the outbreak has occurred, and inquire into the causes and circumstances of such outbreak, and take due measures to prevent its extension.

He shall direct or superintend the work of the Inspector of Nuisances, and on receiving information from the latter that his intervention is required in consequence of any nuisance injurious to health, or of any overcrowding in a house, he shall, as early as practicable, take the proper legal steps thereon.

When requisite, he shall himself inspect and examine any animal, carcase, meat, fish, etc., exposed or deposited for the purpose of sale, and intended for the food of man, which is deemed to be unfit for the food of man; and thereupon shall give such directions as may be necessary.

The Work under a Small Authority. It is customary for local authorities to specify these duties more precisely and to enlarge upon them. The supplementary list that follows was recently framed by the council of a borough just large enough to make the D.P.H. diploma essential. The duties set out are typical of the class of smaller appointments that a public health diplomate might accept for his first responsible position.

He shall be the Chief of the Health Department, and have control of the Sanitary Staff.

He shall act as Medical Superintendent of the Borough Hospitals.

He shall be responsible for the scavenging and street cleansing of a specified portion of the Borough.

He shall act as Medical Supervisor under the Midwives Act, 1902.

He shall attend all Meetings of the Health Committee, and of any other Committee when required.

He shall keep himself fully acquainted with such matters as Water Supply, Drainage (with the exception of Public Sewers), Scavenging, Insanitary Dwellings, and Overcrowding in the Borough.

He shall assist and advise the Council and the Health or other Committee on any Bill in Parliament with reference to the Public Health, the Water Supply, etc., and shall give evidence in legal or other proceedings when required.

He shall give assistance and advice when required in connection with the Sale of Food and Drugs Acts; and shall perform any other duties imposed by the Council.

In larger boroughs, hospital duties are entrusted to a special officer, and the control of the street-cleansing staff to another; while the public health expert is occupied instead with the more complex and far-reaching questions of sanitation that are constantly arising in congested districts. It should be realised that in any event the medical officer's duties are advisory, controlling, and professional rather than executive—a fact which the somewhat grimly phrased list given above is calculated to obscure.

He is the council's sanitary and scientific expert, consulted by the Health Committee and by his staff on all difficult and doubtful questions within his province. He is specially called upon, as a skilled authority, to examine all food seized by his officers as unsound, and to inspect drainage works, insanitary premises, etc., in respect of which serious issues are likely to arise. Otherwise he is responsible as expert in charge of a department rather than as executive officer.

Salaries. Medical Officers of Health, like many other municipal servants, are remunerated on a scale varying with the importance of the authority employing them. The finest appointments are in busy towns, and the next best under the County and the London Borough Councils. A good idea of their general range of value may be gathered from a list of stipends actually paid:

London County Council, £1,250.
City Corporation, £1,000.
London Borough Councils, £800—£1,200.
Port of London, £650.
Manchester, £950.
Hampstead, £600.
Chester, £500.
Scarborough, £400.
Acton Urban District, £500.
Merthyr Tydfil District, £400, rising to £500.
East Ham, £400, by £25 annually to £500.
Tynemouth, £300, by £25 annually to £400.
Devonport, £300, rising to £450.

Holders of the major appointments are debarred from private practice. Many of the smaller district councils, however, have no need of a medical officer's full time services, and appoint general practitioners for partial and occasional service at small stipends ranging between £60 and £250 a year.

The Best Practical Training. The highly specialised and practical studies needed to secure the D.P.H., and the scientific nature of his duties, make previous municipal training less essential for the medical officer than for most other servants of the public. Of the towns in our list, both Devonport and Merthyr were secured by private practitioners. Yet it rarely occurs that a post of the first rank is won by men who have had no previous experience of the sort. Thus, the City Corporation's medical officer previously held the same office for the Port of London. His successor at the port was formerly Medical Boarding Officer at Gravesend, and afterwards had charge of Denton Hospital. The doctor now in medical charge of Chester held assistant rank at Stepney, and Acton's medical officer was previously chief in a smaller district.

The best practical training for a valuable post under a corporation is probably secured by a few years' service either as principal medical officer in a small district or assistant or deputy in a larger one. The county councils, however, who have to administer the Education Acts, are often favourably impressed by experience in children's or general hospitals, and by special knowledge of diseases of the eyes, ears, throat, and chest.

Deputy medical officers receive from £300 to £500 a year, and assistants between £250 and £450, the former being the more usual figure, as a beginning salary at least.

Other Medical Appointments. County hospitals and asylums, and those of the larger boroughs, afford a considerable number of fairly well-paid medical posts, both resident and visiting. The remuneration for resident appointments usually includes board, quarters, light and fuel, in addition to salaries ranging from £120 to £150 or more, for junior assistants, up to £500 or £650 for the medical superintendent in charge. Under the London County Council the scale of pay at Asylums is as follows: Medical Superintendents, £1,000, with an unfurnished house; senior assistants, £300, rising by £25 annually to £400 a year, with board and quarters of the estimated value of £85 a year; junior assistants, £180 to £220, with similar advantages. The L.C.C., it may be noted, forbids its junior medical assistants to marry, but extends that privilege to the seniors.

A principal resident appointment is seldom, if ever, given to a general practitioner, but is reserved for a specialist in mental or other diseases. Most medical superintendents have had several years' hospital experience, at least in a subordinate capacity.

Visiting appointments are usually offered to men who have reached some distinction in general or consultant practice. They are variously remunerated, the fees in some instances being merely nominal, in others as much as 200 or 300 guineas a year.

Every county or borough administering the Elementary Education Acts employs at least one chief medical officer under its Education Committee, at a salary of from £500 to £700, with several assistant or district officers receiving about half as much.

Police Surgeons. The leading police forces of the country are usually in medical charge of a salaried chief officer, and of district surgeons, repaid by fees. The Metropolitan Police surgeon's salary, for example, is £600, and a like post under the City Corporation is rewarded with £635 a year. Local practitioners of good standing are appointed divisional or district police surgeons, with fees for the actual duties performed. In London, where there is an allowance proportionate to the strength of the division, with special fees of 3s. 6d. per day visit to the station and 7s. 6d. per night call, they form a valuable addition to the earnings of a private practice, amounting in the busier districts to £400 a year or more.

Sanitary Inspectors. If the Medical Officer of Health is the professional head of his department, the Sanitary Inspector, or Inspector of Nuisances, is its trained right-hand. He is the general executive officer for the supervision of all works affecting the health of his district and the enforcement of sanitary measures against those who would imperil it. On his zeal and judgment—and especially on his integrity—very important issues depend. The inspection and testing of drainage and sanitary work of every kind, the abatement of nuisances due to dirt, neglect and overcrowding, the supervision of common lodging-houses, the seizure of diseased and adulterated food, are among the many activities of this valuable public servant.

Duties of so wide a range can only be performed by a skilled practical expert. Especially is this the case in a crowded district, where the problems of health and disease are at once more complex and more pressing. Hence it is that the Local Government Board intervenes to ensure the appointment of properly qualified persons as Inspectors of Nuisances, much as it does in respect of Medical Officers of Health, but with this important difference—that, except for London appointments, it prescribes no specific qualification.

London Sanitary Inspectors. These officials are the most highly trained members of their class. They are appointed only after furnishing satisfactory proof of training, and passing a special examination held by the Sanitary Inspectors' Examination Board, particulars of which are given in the accompanying table.

The evidence of training required is either three years' duty (prior to 1900) as inspector in a district of 5,000 or more inhabitants, or a certificate of instruction in the practical studies of an inspector, etc., from an institution recognised by the Board. According to the latest returns, the London inspectors number 281, excluding women. Their duties and the salaries they receive differ so slightly from those of provincial officers that on these points we may most conveniently discuss both classes of appointment together.

Provincial Inspectors of Nuisances. For posts outside the London area the Local Government Board imposes no standard of training, but practically leaves health authorities a free hand in their choice of candidates. Except in the smallest rural areas, however, the appointing council generally requires applicants to possess a certificate of competency issued by one of the recognised examining bodies.

The chief of these are the Sanitary Inspectors' Examination Board (already referred to), the Sanitary Institute, and the Universities of Victoria and Liverpool. The Royal Institute of Public Health examines candidates for Irish posts only. Probably the most generally accepted certificate is that of the Sanitary Institute, the examination for which is also given in the appended table. Prospective candidates may be interested to learn that the Sanitary Institute has made arrangements with a number of authorities by which suitable persons may accompany inspectors on their visits, inspections, etc., and thus gain the practical knowledge required of all applicants for the inspector's certificate. Particulars and specimen examination papers can be obtained from the secretary of the Sanitary Institute, Parkes Museum, Margaret Street, London, W. As every sanitary authority is required to appoint at least one inspector, the total number of these posts is very great.

A General Order of the Local Government Board defines the duties of sanitary inspectors

and inspectors of nuisances. It is too lengthy a document for inclusion here, but can be purchased for 6d. from Messrs. Knight & Co., Ltd., of 227, Tooley Street, S.E.

Duties and Salaries. The general character of the work is sufficiently indicated by the examination subjects given, and by what has already been said of the inspector and his professional chief, the Medical Officer of Health. It may be added that his hours of duty are irregular and often long, and his work as trying as it is useful. Candidates must usually be between 25 and 40 or 45 years of age. The London County Council, however, which employs a number of health inspectors, imposes on applicants the narrower limits of 30 to 40 years.

The average value of inspectors' posts is shown by the following salary lists:

LONDON. Chief Inspectors, £250 to £350.
L.C.C. Inspectors, £150 to £250.
Westminster, £150 by £10 to £220.
Finsbury, £130 by £10 to £180.
Southwark, £120, by £10 to £180.
Battersea Food Inspector, £180; general, £120 to begin.
Wandsworth, £188.

PROVINCES. Manchester, superintendent, £500; chief inspector, £250; smoke inspector, £200.
Newcastle, £200.
Longton, £150 to about £200.
Doncaster Rural District, £180.
Sheerness Urban District, £100, by £10 to £120.

Many men with a practical knowledge of building and sanitary work obtain assistantships, with salaries varying between £90 and £160 a year, and thus complete the all-round training requisite for an inspector's post.

Other Health Appointments. Towns with a large trade in cattle usually employ an expert staff of market and meat inspectors to supervise lairs and slaughter-houses, and to examine animals, both before and after death, for indications of disease. For the most part these officers are certificated inspectors of nuisances, holding also the special certificate in meat and cattle inspection awarded by the Sanitary Institute and kindred societies. Their average rate of pay is as follows: Inspector, from £160 to £200 or £220; chief inspector, £300; superintendent, £350 to £500. The posts available are relatively few, and are reserved for men of special training. The scope and conditions of the examinations are indicated in the table on the next page.

Among posts under the Health Committee accessible to the uncertificated may be noticed the cleansing inspector, at £110 to £160 a year, the street-keeper at a slightly lower average salary, and the manager of the dust destructor, who usually receives from £120 to £150, with a house, light and fuel in addition. Finally, we may note the positions available for women.

Work for Women. Until a few years ago there was no scope for feminine effort in the public health department, and although women are now employed there in yearly increasing numbers, there are still but three classes of appointment open to them—sanitary inspector, health visitor, or inspector of midwives.

Women sanitary inspectors are as yet but a small band, London employing 28 of them, and the provinces about 60 in all. But they have already done invaluable work in improving the sanitary condition of workrooms and factories where women and girls are employed, and there can be no doubt that this new avenue of women's activities will continue to enlarge. The qualifications required in lady inspectors are precisely the same as for men, which have already been discussed. The usual limits of age for candidates are 21 and 35, with an occasional extension to 40. These posts are well paid, as these typical appointments will show:

Westminster, £110, by £10 to £160.
Islington, £100, by £10 to £150.
Wandsworth, £120.

It is not surprising, therefore, that a number of women are training for inspectorships; but the competition hitherto has not been nearly so severe as for most other posts offered to women.

Health Visitors. Women health visitors have lately been appointed in many districts, at the instance of public medical men, with a view to checking the terrible ravages of infantile mortality among the children of the poor. On the value of such a service to the nation there is no need to dwell. The medical officer for Durham County, a persistent advocate of the new system, states that "to get in touch with mothers of to-day, and bring to their notice in a practical manner the proper methods of feeding and managing their children, I know of no better means than the appointment of women health visitors. In many of the large towns and some of the counties such women inspectors have been appointed, with excellent results in every case in which I have made inquiry."

The nature of a health visitor's work is best indicated by an extract from a recent municipal advertisement: "The duties will consist of house-to-house visitation, advising mothers as to the care and feeding of infants, visiting premises where females are employed, making inquiries into infectious cases, accompanying patients to isolation hospitals, and such other duties as the medical officer and inspector of nuisances may require." For these duties some practical training is essential, such as that of a maternity and general nurse. The salary varies from £90 to £120 a year.

Inspectors of midwives are busy county officials whose duties are sufficiently indicated by their title. The qualification usually insisted upon is that of a trained nurse; but as the salary paid is good—at least £120 a year and expenses—a number of these appointments have been accepted by qualified medical women. The lady doctor holding this office under the Manchester Corporation receives £250 a year.

NOTE. On page 320 it is stated that the Common Councilmen of the City Corporation are appointed annually by the votes of the Livery. It should read, instead, "by the votes of householders, or others holding the necessary occupation qualification, who are on the list of municipal voters."

EXAMINATIONS FOR HEALTH & SANITARY OFFICERS

1. EXAMINATION FOR THE PUBLIC HEALTH DIPLOMA

Numerous Bodies grant Degrees. The Schedule given below is typical. See text.

Examining Body, Time, and Place of Examinations.	Subjects of Examination.	Fees and Age Limit.
ROYAL COLLEGE OF PHYSICIANS, of London, and ROYAL COLLEGE OF SURGEONS, of England. January and July. London.	Candidates must possess qualifications in Medicine, Surgery, and Midwifery. Part 1 must be passed before Part 2 is attempted. Both parts are written, oral and practical. PART 1.—Chemistry, Physics, and Geology. Examination of Water and Air, including Analytical Methods. Chemical Composition of Foods, and Adulteration. Warming, Ventilation, Water Supply, and Drainage. Principles of Building Construction. Meteorology. Sanitary Engineering, including Sewage and Refuse. Microscopical Examination of Foods and Detection of Adulteration. Bacteriological Analysis. Disinfectants and Infectious Diseases. PART 2.—Laws relating to Public Health. General Epidemiology. Unwholesome Trades. Prevention of Nuisances. Parasitic Diseases. Climate. Effects of Overcrowding, Vitiated Air, Impure Water, Polluted Soil, and Bad or Insufficient Food. Duties of Sanitary Authorities. Vital Statistics. Population, Birth Rate, Marriage Rate, and Death Rate. Mortality. Sickness Rates. Occupation and Mortality. Life Tables.	£6 6 0 23 years and upwards. £6 6 0

2. EXAMINATION FOR SANITARY INSPECTORS IN LONDON

SANITARY INSPECTORS' EXAMINATION BOARD, 1, Adelaide Buildings, London Bridge, S.E. January and May of each year. London.	Evidence of practical training must be furnished by the Candidate. A. *Preliminary.* English and Arithmetic. Certain Educational Certificates exempt. B. *Technical* (written, oral, and practical). The following subjects as far as they bear upon the duties of a Sanitary Inspector. 1. Elementary Physics and Chemistry in relation to Water, Soil, Air, and Ventilation. 2. Elementary Statistical Methods. 3. Municipal Hygiene or Hygiene of Communities, including Prevention and Abatement of Nuisances, Sanitary Defects in and about Buildings, and their Remedies, Water Supplies, Sanitary Appliances, Drainage, Refuse Removal and Disposal, Offensive Trades, Disinfection, Food Inspection. 4. Statutes, and the Orders, Memoranda, and Model By-laws of the Local Government Board, and the By-laws in force in the Administrative County of London.	£1 1 0 £3 3 0 (Half fees for second attempt.) 21 years and upwards.

3. EXAMINATION FOR SANITARY INSPECTORS OUT OF LONDON

Sanitary Inspectors in the Provinces are usually called Inspectors of Nuisances.

ROYAL SANITARY INSTITUTE, Parkes Museum, London, W. Twice yearly in London; once or more in Edinburgh, Belfast, Manchester and other centres.	Evidence of practical training or of attendance at certain lectures must be furnished by the Candidate. Practical and Theoretical knowledge of the Acts and Model By-laws relating to the duties of Inspector of Nuisances. A knowledge of what constitutes a Nuisance. Inspection of Dwellings, Dairies, Markets, Slaughter-houses, etc., and Nuisances connected with Trades, including Bakehouses, Workshops, Stables, and Offensive Trades. Physical Characteristics of good Drinking Water, and Means of Preventing Pollution. Water Supply. The Characteristics of Good and Bad Food. The Regulations affecting Infectious Diseases. Disinfectants and their Use. Pure Air and the Causes of Deterioration. Principles of Ventilation, and of Good Drainage. Sanitary Appliances for Houses. Inspection of Builders' and Plumbers' work. Drain Testing. Scavenging and the Disposal of Refuse. A Knowledge of the General Duties of the Office, and Methods of Keeping the necessary Books and Records. Writing and Spelling.	£3 3 0 (Half fees for second or third attempt if within two years.) 21 years and upwards.

4. EXAMINATION FOR INSPECTORS OF MEAT AND OTHER FOODS

ROYAL SANITARY INSTITUTE, Parkes Museum, London, W. Twice yearly in London, and once or oftener in Provincial Centres, as chosen for the year.	Candidates must possess Certificate as Sanitary Inspector or Inspector of Nuisances, or Exemption Qualification, must have had training in Meat Inspection, approved by Committee, and must show Testimonials to Personal Character. Subjects of Examination: Laws affecting Inspection and Sale of Meat and other Articles of Food, including Preparation and Adulteration. Disease in Animals for Food, alive and dead. Tuberculin and other Tests. Organs of the body in Animals. Appearance and Character of Fresh Meat, Organs, Fat, Blood, Fish, Poultry, Milk, Fruit, Vegetables, and other Food. The Hygiene of Byres, Lairs, Cowsheds, and Slaughter-houses, and of Markets, Dairies, and other places. Stalling and Slaughtering Animals. Preserving and Storing Meat and other Foods.	£3 3 0 (Half fees for second and third attempt if within two years.) 21 years and upwards.

SHOPKEEPING
5

Continued from page 511

METHODS OF BEGINNING BUSINESS

Purchasing an Old Business. Starting a New Business. Partnerships. Goodwill. Terms of Credit. Hire-purchase System.

By W. B. ROBERTSON

THE man who has resolved to rise from the subordinate position of an assistant to the dignity of a shop proprietor has several courses open to him. He may purchase an established business; he may make an independent start and open a new business; he may enter an established concern as a partner, or he may join himself with a partner and set up a new sign.

Purchasing an Old Business. The purchase of an old business must be gone about with circumspection; there are so many pitfalls into which the purchaser may fall. The services of a good commercial lawyer should always be enlisted. The fear of lawyers' charges often deters from such a course, but the risk of being saddled with an apparently sound but really unremunerative business should compel the utilisation of legal advice at every step. Negotiation for the purchase of a business should be preceded by rigorous inquiry into the causes for its disposal. The man who has

the bad as well as the good points of the bargain. These the purchaser must ascertain before the specific money consideration has been decided.

Buying an Old Stock. The longer a retail shop has been established, the greater is the proportion of bad and unsaleable stock with which it is loaded. In establishments where clearing sales have been periodical features, deteriorated stock ought to be very small indeed, but in others where such a plan for turning undesirable merchandise into cash has not been adopted, the accumulations of unsaleable goods often constitute a considerable proportion of the whole stock-in-trade. We have all heard of the tradesman who advertised himself as "Established half a century," and of his rival who capped the announcement with the notice, "Established three weeks—no old stock." In estimating the cost of stock to be taken over, liberal allowance must always be made for deterioration. Usually the transfer is carried out under an arrangement of stock valuation conducted by nominees of the buyer and of the seller, with a referee in cases of disputes. This method is the most satisfactory, but it is also the most expensive. The fees paid for the services of valuers are usually from one to three guineas a day *plus* expenses, and when buyer and seller have each a representative the total charge is high. In every trade there are recognised trade valuers, experts in estimating the cost of goods and fittings, and if one of these conducts the valuation, the result is usually fair and the work not too expensive.

Goodwill. The question of goodwill usually arises in the purchase of a business. Sometimes a goodwill should be paid, but very often the business is not worth it. The question of goodwill should be decided by certain conditions not difficult to ascertain. Let an estimate be taken of the money required to maintain the business upon its existing scale, and let also the probable profit, based upon returns for some years, be gauged. Then let the purchaser or purchasers decide what salary they are entitled to for managerial services. If the balance represent not more than 5 per cent. upon the capital, no goodwill should be paid. Let us take a specific instance. Assume that two men in partnership desire to purchase a business, into which £2,000 must be sunk as price of stock and working capital, and that, based upon the returns of the previous 10 years, the money to be divided between the two annually will be £600. Let us assume further that the services of each partner are worth £200 a year, that they could

salaries from the £600 there would remain £200 for division, or 10 per cent. of the capital invested. It would be proper in such a case to pay something for goodwill, and the amount of goodwill should be estimated upon the excess of profit above 5 per cent., in this case upon £100. The proper amount to be paid as goodwill in a case such as we have taken cannot well be stated. Probably £300 to £500 would be a fair sum, but it would depend upon all the attendant circumstances.

Book Debts. Another detail in the bargaining is the question of book debts; unless, indeed, the business has been entirely cash. The purchaser naturally desires to secure any advantages which may accrue from the collection of debts—the opportunity of seeing and knowing the customers of the shop—but, on the other hand, he wishes to avoid making the bad bargain of purchasing bad and doubtful debts. He may attain both ends by arranging to collect the book debts without charge, but not to purchase them, handing over the money periodically to the vendor after receipt. Then, after six or twelve months have elapsed, the debts remaining unpaid may be handed back to the vendor for collection by any means he may deem desirable. Thus the purchaser may secure the benefit of collecting the accounts from good customers without incurring loss by the defalcations of bad payers, an arrangement which is eminently fair to the vendor.

Partnership. If, instead of purchasing an established business either alone or with a partner, our assistant desires to enter the ranks

of the employers by purchasing a partnership in an existing business, the considerations we have already recited should guide his actions. But to enter a business as a partner often works out badly. We shall assume that our man is imbued with the spirit of enterprise, that he will seek to apply his modern knowledge to the improvement and expansion of the concern with which he has identified himself. If the partner or partners who were there before him acknowledge the need for improvement and the possibility of expansion, and give him scope for the exercise of his energy, all will be well. But if, as is too often the case, the older partners insist that he should crawl in the same narrow path that they have followed, the trouble will have begun, and an inharmonious partnership will result. The man who intends to enter a firm should first of all pass a probationary period as an employee; he should satisfy himself that the policy of the concern is such as he can approve, or, alternately, that there will be no strong opposition to his efforts at modernising it. He should also preserve to himself, if possible, the liberty to withdraw from the partnership after a stipulated time if he finds that he cannot work in harmony with his fellow partners. The conservatism of age and the energy of youthful enthusiasm are often incompatible.

Beginning a New Business. We may now very briefly consider the alternative method of acquiring a right to a shop sign—the starting of a new business instead of the purchase of an old one. It is often the much wiser course. The work is much harder at first, but it pays the right man. He makes his connection instead of buying it, and thus saves the money it would have cost him. He can start with a fresh stock of his own selection, with premises and fixtures to his mind; he is not bound by the legacy of precedent, and he can at once put into practice his ideas of proper business method. Should success attend his efforts, he has also for reward the pride of personal unaided achievement. He can say to himself, "Alone I did it!" And that this is a real gratification will be certified by those who have earned the right to say it.

Cash or Credit? The chief consideration for any novitiate in the ranks of shopkeepers when he is about to determine what business policy he will pursue is that a credit business must have at command much more capital than a cash business. The young man who would establish himself upon the modest savings of his assistantship should choose a neighbourhood where the trade promises to be approximately similar to that to which he has been accustomed, but, other things being equal, he ought to give preference to a place where his turnover will be accounted for by as large a share of cash takings as possible. The advantage of the cash system from the retailer's point of view may be tabulated as follows:

1. The possibility of trading upon a smaller capital.
2. The obviation of loss by bad debts.
3. The absence of bookkeeping and the consequent reduction of working expenses.
4. The greater facility offered of meeting obligations promptly, and thereby of securing better terms.
5. The ability to take advantage of cash bargains that may offer through having cash at command.

Strictly cash terms may be possible in a city thoroughfare where the trade is chiefly casual, but where the connection is a family one in a residential neighbourhood they are impossible. The retailer who refused to depart from them would probably be banished from Suburbia by insolvency. It may be accepted, then, that the usual retail business is one run on both cash and credit lines.

One Price or Two? It must be decided whether the cash and the credit customer should be put upon different terms—if there should be two prices. The tradesman cannot deny to his cash customer a just right to consideration for ready money. He himself will insist upon it in dealing with his merchants. On the other hand, he must take care that his family customers who run accounts should not have it too prominently brought before them that they have to pay for the privilege of an open account. The most suitable system yet devised is that of graduated discounts, say ten per cent. discount for cash, five per cent. discount if the account be paid within one month, and strictly net if longer credit be taken. But on some articles such terms are impossible. They may, under stress of competition, be sold upon less than a ten per cent. margin, so that to sell them under the cash discount mentioned would be to incur a loss on every sale.

A recently introduced method of encouraging a cash trade, and of differentiating between the cash and credit customers, has much to recommend it. Every cash purchaser, of however small an amount, receives a voucher for the amount of his purchase, and when he or she has accumulated vouchers indicating that goods to the value of 20s. have been purchased, they may be exchanged for goods worth 1s. This looks like a five per cent. discount. To the customer it is, but it works out at far less than five per cent. to the retailer. Even if every voucher received were afterwards presented, the discount would be only about three per cent., because the shopkeeper has his profit upon the shilling's worth given for the sovereign's worth of vouchers. Moreover, it is found in practice that not more than sixty per cent. of the vouchers issued are presented for redemption, hence the discount upon the gross cash sales works out at less than two per cent. Another effect of the system is to induce petty customers to patronise the voucher tradesman, so as to add to the number of vouchers, many times when it would otherwise be more convenient to go elsewhere.

One system of trading which should be avoided is that under which retailers issue "trading stamps," or warrants upon independent firms, who exploit the trading-stamp idea to their own

profit. These independent firms must have a profit upon their transactions, and the retailer may retain this profit to himself by following the plan just described.

Hire-purchase System. The hire-purchase system has been making headway in retail commerce, and has become particularly associated with some departments—the trades purveying musical instruments, cycles, furniture, sewing machines, laundry machines, and baby-carriages. Much of the odium that formerly attached to it has disappeared under the examples of the many firms who conduct it upon conditions eminently fair to the customer while profitable to themselves. Into all the intricacies of the system we cannot enter here. The man who would adopt it as a business feature must study the practice of others and the law upon the subject. He may with advantage refer to the book issued by the secretary of the Hire Traders' Protection Association, at 27, Chancery Lane, London, E.C. The form of agreement issued by this association, which is reproduced by permission, embodies the points essential to the enforcement of re-delivery of any goods sold under the system.

The adoption of the hire-purchase system requires the employment of capital which the beginner may lack. If he find that a measure of this system is desirable, he may call in the services of firms who make it their business to take all risks, paying him the cash price whenever the article is delivered and the debt accepted, and taking as their profit the difference between the cash and the instalment price. It is much more profitable for the retailer to shoulder the burden himself, and the instalment agency should be patronised only when funds do not permit of the employment of capital in this branch.

Most retailers who cater for custom under the hire-purchase payments try to secure a first deposit as large as possible. One large London firm insists upon a payment of 25 per cent. before the delivery of the goods; others seem to find the business profitable without any such condition. It is usual to allow the instalments upon larger sums to extend over a longer period than small sums. A good system adopted in the furniture trade is by scale graded as follows:

Value.	Deposit. Per Cent.	Balance in equal payments. Weeks.
£1 to £10	10	20-25
£10 ,, £20	12½	40
£20 ,, £30	15	52
£30 ,, £40	20	78
£40 ,, £50	25	104

Sometimes the period of three years is allowed, but generally this is too long. It may be accepted that a large proportion of those who agree to discharge their liability within two years will not have redeemed their bargains much under three years. The hire-purchase system makes for good quality. Payments cannot well be enforced for articles that have not withstood the wear and tear of the period of instalments, and, as the hirer or purchaser has the right of return, the merchant who sells bad articles will find himself loaded with a stock of surrendered merchandise.

Memorandum of Agreement made the

day of 190 between

of

hereinafter called the Owner, of the one part, and

of

hereinafter called the Hirer, of the other part.

Witnesseth that the Owner agrees to let, and the Hirer agrees to hire, the goods mentioned at the side hereof belonging to the Owner, upon the terms and conditions following:—

1 The Hirer to pay the sum of £ on signing this Agreement (in consideration of the option of purchase herein granted) and for which credit will only be given in the event of the hirer purchasing the said goods.

2 The Hirer shall punctually pay to the Owner without previous demand the rent of for the hire of the said goods commencing with the day of

3 In case the said rent shall be in arrear more than seven days, or in case the Hirer commit any breach of this Agreement, or suffer any breach to be committed, the Owner shall thereupon be entitled to take and resume possession of the said goods and for that purpose full power and liberty are hereby given to the Owner, his servants, and agents, to enter into any house or buildings of which the Hirer may be, or appears to be, tenant and there to search for and retake the said goods without any resistance on the part of the Hirer, his relatives, friends or servants.

4 The Hirer will keep the said goods in good order and repair, damage by fire included, but fair wear and tear excepted.

5 The Hirer shall not remove or suffer the said goods to be removed without the Owner's permission, and shall keep the said goods free and exempt from all legal process.

6 The Hirer may terminate the hiring by delivering up to the Owner the said goods in good order and condition, and thereupon this agreement shall be void, subject nevertheless to the rights of the Owner in respect of rent and damages (if any) accrued previously to the delivering up of the said goods.

7 Upon punctual payment of rent as aforesaid amounting to the full sum of £ the said goods shall become the absolute property of the Hirer freed from payment of all further rent, but until payment of the said sum the Hirer shall remain Bailee only of the said goods.

8 Any relaxation or indulgence which the Owner may show to the Hirer shall not in any way prejudice his strict rights under this agreement.

HIRE-PURCHASE AGREEMENT ISSUED BY HIRE TRADERS' PROTECTION ASSOCIATION

The Keeping of all Kinds of Shops. The scheme of this course includes practical articles on every department of shopkeeping Such branches as are allied to one or other of the more important trades will be treated separately, so that the articles will be a guide to the adoption of side-line departments as well as to the establishment of independent shops. The articles begin in Part 6 of the SELF-EDUCATOR.

VULGAR FRACTIONS

Division of Fractions. Continued Fractions. Expression of Decimals as Vulgar Fractions. Fractions of Concrete Quantities. Examples

Group 21
MATHEMATICS
5

Continued from page 548

By HERBERT J. ALLPORT, M.A.

83. Division of Fractions. (i.) When the divisor is a whole number.

Suppose we have to divide $\frac{7}{9}$ by 4.

We know $\frac{7}{9} = \frac{28}{36}$. This fraction means that the unit is divided into 36 equal parts, and 28 of the parts taken. If we divide the 28 parts by 4, we get 7 of them—*i.e.* $\frac{7}{36}$. Hence $\frac{7}{9} \div 4 = \frac{7}{36}$.

Therefore, *to divide a fraction by a whole number, we multiply the denominator by that number.*

In the same way as already explained for multiplication, we cancel any common factors contained in the divisor and the numerator. Hence, if the numerator be exactly divisible by the divisor, we may *divide a fraction by a whole number by dividing the numerator by that number.*

Example 1. $\frac{27}{31} \div 18 = \frac{\cancel{27}^{\,3}}{31 \times \cancel{18}_{\,2}} = \frac{3}{62}$ *Ans.*

Example 2. $\frac{36}{41} \div 9 = \frac{4}{41}$ *Ans.*

(ii.) When the divisor is a fraction.

In the operation $24 \div 3$, we have to find the number which, when multiplied by 3, will give 24. Similarly, to find the value of $\frac{3}{7} \div \frac{5}{9}$ we have to find the fraction which, when multiplied by $\frac{5}{9}$, will give $\frac{3}{7}$.

But $\frac{3 \times 9}{7 \times 5}$ is the fraction which gives $\frac{3}{7}$ when multiplied by $\frac{5}{9}$. Therefore, $\frac{3}{7} \div \frac{5}{9} = \frac{3 \times 9}{7 \times 5}$.

Hence, *to divide by a fraction, invert the divisor and multiply.*

As in multiplication, mixed numbers must first be reduced to improper fractions.

Example 3. Divide $3\frac{1}{14}$ by $5\frac{5}{42}$.

$$3\tfrac{1}{14} \div 5\tfrac{5}{42} = \frac{43}{14} \div \frac{215}{42} = \frac{\cancel{43}}{\cancel{14}} \times \frac{\cancel{42}^{\,3}}{\cancel{215}_{\,5}} = \frac{3}{5}\ \textit{Ans.}$$

84. Brackets. Brackets are symbols used to join together two or more quantities, to indicate that they are to be treated as a single quantity.

Thus, $(3\frac{1}{2} - 1\frac{1}{8}) \div 2\frac{3}{4}$ means that $1\frac{1}{8}$ is to be subtracted from $3\frac{1}{2}$, and the result divided by $2\frac{3}{4}$. The value of this expression is, therefore,

$$2\tfrac{3}{8} \div 2\tfrac{3}{4} = \tfrac{19}{8} \times \tfrac{4}{11} = \tfrac{19}{22}.$$

Without the brackets, the value would be

$3\frac{1}{2} - \frac{9}{8} \div \frac{11}{4} = 3\frac{1}{2} - \frac{9}{8} \times \frac{4}{11} = 3\frac{1}{2} - \frac{9}{22} = 3\frac{1}{11}$.

It is necessary to have several shapes for brackets, such as ( ), { }, [ ], since parts of an expression we wish to treat as a single quantity may already be enclosed in brackets.

Example. Find the value of

$$\left[\left\{(\tfrac{1}{2} + \tfrac{1}{3}) \div (\tfrac{1}{4} + \tfrac{1}{5})\right\} - 1\tfrac{4}{9}\right] \div (1\tfrac{1}{9} - \tfrac{19}{27}).$$

Given expression

$$= \left[\left\{\frac{5}{6} \div \frac{9}{20}\right\} - 1\tfrac{4}{9}\right] \div \frac{30 - 19}{27},$$

$$= \left[\left\{\frac{5}{\cancel{6}_{\,3}} \times \frac{\cancel{20}^{\,10}}{9}\right\} - 1\tfrac{4}{9}\right] \div \frac{11}{27},$$

$$= [1\tfrac{23}{27} - 1\tfrac{4}{9}] \div \frac{11}{27},$$

$$= \frac{23 - 12}{27} \div \frac{11}{27},$$

$$= \tfrac{11}{27} \times \tfrac{27}{11} = 1\ \textit{Ans.}$$

Note that we first simplify the expressions in the innermost brackets, then proceed to the next inner bracket, and so on.

85. We have, so far, only considered fractions in which both the numerator and the denominator are integers. These are called *Simple Fractions.*

A *Complex Fraction* is one in which the numerator or denominator, or both, are fractions.

Thus $\frac{3\frac{1}{2}}{2\frac{3}{8}}$, $\frac{1}{\frac{5}{6} \times \frac{3}{4}}$, $\frac{1\frac{2}{7}}{8}$, are complex fractions.

Now, to divide a unit into 5 equal parts and take 3 of them gives the same result as dividing 3 units into 5 parts and taking one of them—*i.e.*, $\frac{3}{5}$ represents the quotient of 3 divided by 5.

Hence $\frac{\frac{5}{16}}{\frac{15}{24}}$ means $\frac{5}{16} \div \frac{15}{24}$.

Therefore, to simplify a complex fraction reduce both numerator and denominator to simple fractions, and divide the one by the other.

Example 1. Simplify $\frac{2\frac{1}{4} - 1\frac{5}{6} + 3\frac{3}{8}}{1\frac{1}{2} \div \frac{6}{13}}$.

Given expression

$$= \frac{4 + \dfrac{6 - 20 + 9}{24}}{\dfrac{\cancel{3}}{2} \times \dfrac{13}{\cancel{6}_{\,2}}} = \frac{3 + \dfrac{39 - 20}{24}}{\dfrac{13}{4}}$$

$$= 3\tfrac{19}{24} \div \frac{13}{4} = \frac{\cancel{91}^{\,7}}{\cancel{24}_{\,6}} \times \frac{\cancel{4}}{\cancel{13}} = \frac{7}{6} = 1\tfrac{1}{6}\ \textit{Ans.}$$

Example 2. Find the value of

$$\frac{\frac{1}{3}+\frac{1}{4}+\frac{1}{5}}{\frac{1}{2\frac{1}{3}}+\frac{1}{3\frac{1}{4}}+\frac{1}{4\frac{1}{5}}}.$$

Given expression

$$=\frac{\frac{20+15+12}{60}}{\frac{1}{\frac{7}{3}}+\frac{1}{\frac{13}{4}}+\frac{1}{\frac{21}{5}}}=\frac{\frac{47}{60}}{\frac{3}{7}+\frac{4}{13}+\frac{5}{21}}$$

$$=\frac{\frac{47}{60}}{\frac{117+84+65}{273}}$$

$$=\frac{47}{60}\div\frac{266}{273}=\frac{47}{\underset{20}{\cancel{60}}}\times\frac{\overset{\overset{13}{\cancel{91}}}{\cancel{273}}}{\underset{38}{\cancel{266}}}=\frac{611}{760}\ \textit{Ans.}$$

86. A *Compound Fraction* is a fraction of a fraction.

Thus, $\frac{3}{5}$ of $\frac{4}{7}$ is a compound fraction.

To obtain $\frac{3}{5}$ of $\frac{4}{7}$ we have to divide $\frac{4}{7}$ into 5 equal parts and take 3 of them. But $\frac{4}{7} \div 5 = \frac{4}{35}$. And three of these parts $= 3 \times \frac{4}{35} = \frac{12}{35}$.

Hence $\frac{3}{5}$ of $\frac{4}{7} = \frac{12}{35}$; which is also the value of $\frac{3}{5} \times \frac{4}{7}$.

Therefore, the word "of" has the same meaning as $\times$.

87. *In expressions where additions and subtractions as well as multiplications and divisions occur, the multiplications and divisions must be performed before the additions and subtractions.*

Thus $\frac{3}{4} \div \frac{7}{8} + \frac{2}{3}$ means that $\frac{3}{4}$ is to be divided by $\frac{7}{8}$, and $\frac{2}{3}$ is to be added to the result.

It does not mean that $\frac{3}{4}$ is to be divided by the result obtained when we add $\frac{2}{3}$ to $\frac{7}{8}$. This would be represented by $\frac{3}{4} \div (\frac{7}{8} + \frac{2}{3})$.

In such expressions as $\frac{1}{4} \div \frac{3}{8} \times \frac{5}{9}$, each of the symbols $\times$, $\div$, refers only to the fraction immediately following it.

Thus $\quad \frac{1}{4} \div \frac{3}{8} \times \frac{5}{9} = \frac{1}{4} \times \frac{8}{3} \times \frac{5}{9} = \frac{10}{27}.$

But, if the above expression were written $\frac{1}{4} \div \frac{3}{8}$ of $\frac{5}{9}$ it would mean that $\frac{3}{8}$ of $\frac{5}{9}$ is to be treated as a single quantity, and the value would be $\frac{1}{4} \div (\frac{3}{8} \times \frac{5}{9}) = \frac{1}{4} \div \frac{15}{72} = \frac{1}{4} \times \frac{72}{15} = \frac{6}{5} = 1\frac{1}{5}$.

88. Continued Fractions. A fraction of the following form is called a *Continued Fraction*.

$$\cfrac{1}{2+\cfrac{1}{5+\cfrac{1}{3+\cfrac{2}{1+\frac{5}{6}}}}}$$

To simplify it, we begin at the lowest line. Thus, the given fraction

$$=\cfrac{1}{2+\cfrac{1}{5+\cfrac{1}{3+\cfrac{2}{\frac{11}{6}}}}}=\cfrac{1}{2+\cfrac{1}{5+\cfrac{1}{3+\frac{12}{11}}}}$$

$$=\cfrac{1}{2+\cfrac{1}{5+\frac{11}{45}}}=\cfrac{1}{2+\frac{45}{236}}$$

$$=\frac{236}{517}\ \textit{Ans.}$$

EXAMPLES 10

Arrange in order of magnitude, writing the least first:

1. $\frac{8}{21}$, $\frac{13}{35}$, $\frac{11}{28}$.

2. $\frac{81}{95}$, $\frac{46}{57}$, $\frac{97}{114}$, $\frac{31}{38}$.

3. $\frac{23}{222}$, $\frac{31}{322}$, $\frac{41}{399}$.

Find the value of

4. $3\frac{4}{7} + 1\frac{3}{5} + \frac{13}{21} + 5\frac{4}{15}$.

5. $\frac{13}{60} + 4\frac{5}{42} - 2\frac{7}{60}$.

6. $3\frac{2}{3} - 4\frac{3}{4} + 5\frac{4}{5} - 6\frac{5}{6} + 7\frac{6}{7}$.

7. $\frac{117}{143} - \frac{13}{209} + \frac{57}{253}$.

8. $\frac{1}{8}$ of $\frac{3}{14}$ of $5 - \frac{4}{7}$ of $\frac{2}{5}$ of $\frac{3}{4}$.

9. $(2\frac{1}{2}$ of $4\frac{3}{4} - 3\frac{5}{12}) \div (\frac{5}{6} + \frac{4}{5}$ of $3\frac{1}{3})$.

10. $6\frac{7}{8} \times 3\frac{9}{11} - 7\frac{1}{16} \div 5\frac{11}{45} - 4\frac{1}{2} \times 5\frac{5}{16}$.

11. $\left\{\frac{2}{7} + (5\frac{1}{2} + 3\frac{1}{8}) \text{ of } \frac{19}{23}\right\} \div \left\{8\frac{5}{7} - (4\frac{8}{9} \div \frac{5}{9} \text{ of } 5\frac{1}{2})\right\}$.

12. $\dfrac{2\frac{1}{2}+3\frac{5}{6}}{5\frac{1}{3}-4\frac{1}{4}} \times \dfrac{12\frac{2}{7} \text{ of } 13\frac{7}{8}}{9\frac{1}{4} \text{ of } 6} \div \dfrac{(7\frac{1}{2}-\frac{3}{4} \text{ of } \frac{8}{9}) \div 8\frac{1}{5}}{(10\frac{5}{8}-2\frac{3}{8} \text{ of } 4) \div 3\frac{2}{7} \text{ of } 7\frac{1}{2}}$.

13. $\cfrac{10}{3-\cfrac{1}{1-\cfrac{2}{3+\frac{2}{7}}}}$

14. $\cfrac{1}{3+\cfrac{1}{2+\cfrac{1}{5+\frac{1}{4}}}} \times \cfrac{1}{1+\cfrac{1}{3+\cfrac{1}{3+\frac{1}{3}}}}$

15. $3\frac{1}{3} - \cfrac{1}{2-\cfrac{1}{3-\cfrac{1}{2-\cfrac{1}{1-\cfrac{1}{3+\frac{1}{3}}}}}}$

89. Expression of Decimal Fractions as Vulgar Fractions.

Example. Express 5·375 as a vulgar fraction.

$\cdot 375 = 375$ thousandths.

Therefore, $\therefore 5\cdot375 = 5\frac{375}{1000} = 5\frac{3}{8}$ *Ans.*

Hence, the rule is: Take the digits of the decimal for numerator; for the denominator

put down 1 followed by as many noughts as there are digits in the decimal. Reduce this fraction to its lowest terms.

90. Expression of Vulgar Fractions as Decimals.

We have seen [Art. 85] that a vulgar fraction represents the quotient of the numerator divided by the denominator. Therefore, to convert a vulgar fraction to a decimal fraction, we divide the numerator by the denominator.

The process is, in fact, the same as that already explained in Art. 33.

Example. Express $\frac{3}{32}$ as a decimal.

$$\begin{array}{l} 4)\underline{3\cdot0} \\ 8)\underline{\ \cdot75} \\ \quad \underline{\cdot09375}\ \textit{Ans.} \end{array}$$

Use factors of 32, and proceed as in Ex. 1, Art. 33.

It will be found in many cases that there is always a remainder, so that the quotient can be continued indefinitely. [Ex. 2, Art. 33.]

FRACTIONS OF CONCRETE QUANTITIES

91. From the definition of a vulgar fraction, it is clear that to obtain any required fraction of a given compound quantity we divide by the denominator of the fraction and multiply the result by the numerator.

Example 1. Find the value of $\frac{7}{9}$ of £3 17s. $4\frac{1}{2}$d.

$$\begin{array}{rrrl} & \text{£} & \text{s.} & \text{d.} \\ 9) & 3 & 17 & 4\frac{1}{2} \\ \hline & & 8 & 7\frac{1}{6}\ * \\ & & & 7 \\ \hline & \text{£}3 & 0 & 2\frac{1}{6}\ \textit{Ans.} \end{array}$$

* After dividing the pence by 9, there is a remainder $1\frac{1}{2}$d. $= \frac{3}{2}$d. and $\frac{3}{2} \div 9 = \frac{3}{18} = \frac{1}{6}$.

Example 2. Find the value of $4\frac{3}{8}$ of £6 18s 2d.

$$\begin{array}{rrrl} & \text{£} & \text{s} & \text{d.} \\ 8) & 6 & 18 & 2 \\ \hline & & 17 & 3\frac{1}{4} = \frac{1}{8} \text{ of £6 18s. 2d.} \\ & & & 3 \\ \hline & 2 & 11 & 9\frac{3}{4} = \frac{3}{8} \text{ of £6 18s. 2d.} \\ & 27 & 12 & 8 \ \ = 4 \times \text{£6 18s. 2d.} \\ \hline & \text{£}30 & 4 & 5\frac{3}{4}\ \textit{Ans.} \end{array}$$

To obtain the value of a given *decimal* fraction of a concrete quantity, we may reduce the decimal to a vulgar fraction and proceed as above.

Or, we may adopt the method shown in the following examples.

Example 3. Find the value of 2·13625 of £5.

$$\begin{array}{rl} 2\cdot13625 \text{ of £5} = & \text{£}10\cdot68125 \\ & \underline{\quad 20} \\ & 13\cdot62500 \text{ s.} \\ & \underline{\quad 12} \\ & 7\cdot500 \text{ d.} \\ & \underline{\quad 4} \\ & 2\cdot0 \quad \text{far} \\ & \text{£}10\ \ 13\text{s.}\ \ 7\tfrac{1}{2}\text{d.}\ \textit{Ans.} \end{array}$$

Explanation. Multiply 2·13625 by 5. Multiply *the decimal part* of the product by 20 to reduce it to shillings. Multiply the decimal part of the shillings by 12 to reduce it to pence; and so on.

Example 4. Find the value in lb. and decimal of a lb. of ·0123 of 3 tons 5 cwt. 47 lb.

$$\begin{array}{r} 3 \text{ tons } 5 \text{ cwt. } 47 \text{ lb.} \\ \underline{20} \quad\quad\quad\quad \\ 65 \text{ cwt.} \quad\quad \\ \underline{112} \quad\quad\quad\quad \\ 607 \quad\quad\quad\quad \\ 672 \quad\quad\quad\quad \\ \hline 7327 \text{ lb.} \quad\quad \\ \underline{\cdot0123} \quad\quad \\ 73\cdot27 \quad\quad \\ 14\cdot654 \quad\quad \\ \underline{2\cdot1981} \quad\quad \\ \underline{90\cdot1221 \text{ lb. } \textit{Ans.}} \end{array}$$

Reduce the tons, etc., to lb. and take ·0123 of the result.

92. The converse of this operation is to find by what fraction (vulgar or decimal) we must multiply one given quantity to produce another given quantity.

Example 1. *What fraction of* 2 *tons* 7 *cwt.* 2 *qrs. is* 1 *ton* 8 *cwt.* 2 *qrs.?*

Express each of the quantities as simple quantities in terms of the same unit.

Thus, 2 tons 7 cwt. 2 qrs. = 190 qrs.
and 1 ton 8 cwt. 2 qrs. = 114 qrs.

Hence 1 ton 8 cwt. 2 qrs. is evidently $\frac{114}{190}$ of 2 tons 8 cwt. 2 qrs.—

i.e., Required fraction $= \frac{114}{190} = \frac{3}{5}$ *Ans.*

We therefore have the following rule. To express one compound quantity as the fraction of another of the same kind, reduce the quantities to terms of the same unit; take the first quantity for numerator and the second for denominator.

Example 2. Reduce £7 3s. $2\frac{3}{4}$d. to the decimal of £5 4s. 2d.

$$\begin{array}{rrr} \text{£} & \text{s.} & \text{d.} \\ 7 & 3 & 2\frac{3}{4} \\ \underline{20} & & \\ 143 & \text{s.} & \\ \underline{12} & & \\ 1718 & \text{d:} & \\ \underline{4} & & \\ 6875 & \text{far.} & \end{array} \qquad \begin{array}{rrr} \text{£} & \text{s.} & \text{d.} \\ 5 & 4 & 2 \\ \underline{20} & & \\ 104 & \text{s.} & \\ \underline{12} & & \\ 1250 & \text{d} & \\ \underline{4} & & \\ 5000 & \text{far.} & \end{array}$$

Here we reduce the two amounts to farthings, and divide the first by the second.

$$\begin{array}{r} 5\cdot000)6\cdot875 \\ \underline{1\cdot375\ \textit{Ans.}} \end{array}$$

93. Miscellaneous Questions Involving Fractions.

Example 1. In a cricket match, one man made $\frac{1}{3}$ of the total runs; another man made $\frac{1}{3}$ of the remainder. These two scores differed by 7; what was the total?

First man made $\frac{1}{3}$ of the total.

Second man made $\frac{1}{3}$ of the remainder, $= \frac{1}{3}$ of $\frac{2}{3}$ of the total $= \frac{2}{9}$ of the total. Therefore, difference between their scores $= (\frac{1}{3} - \frac{2}{9})$ of the total $= \frac{3-2}{9} = \frac{1}{9}$ of the total.

Hence, 7 runs is $\frac{1}{9}$ of the total: so that the total $= 7 \times 9 = 63$ runs *Ans.*

Example 2. In paying two bills, one of which exceeds the other by $\frac{1}{3}$ of the less, the change out of a £5 note is half the difference of the bills. What are the two amounts ?

Difference between the bills $= \frac{1}{3}$ of smaller bill.

And, change out of £5 $= \frac{1}{2}$ difference between the bills $= \frac{1}{2}$ of $\frac{1}{3}$ of smaller $= \frac{1}{6}$ of smaller.

But, the larger bill equals $1\frac{1}{3}$ times the smaller. Therefore, since the two bills and the change make £5, we have

$(1\frac{1}{3} + 1 + \frac{1}{6})$ of the smaller bill $=$ £5;

i.e., $2\frac{1}{2}$ times the smaller $=$ £5.

Therefore,

$$\left.\begin{array}{l}\text{Smaller bill} = \dfrac{£5}{2\frac{1}{2}} = \dfrac{£5 \times 2}{5} = £2 \\ \text{and} \\ \text{Larger bill} = £2 + \frac{1}{3} \text{ of } £2 = £2\ 13s.\ 4d.\end{array}\right\} \underline{\textit{Ans.}}$$

Example 3. For one-third of a mile a submarine cable is laid overland, $\frac{1}{12}$ of it is suspended in the water, $\frac{219}{240}$ lies on the bed of the sea. Find its length.

The fraction of the cable laid overland is evidently $(1 - \frac{1}{12} - \frac{219}{240})$ of its length.

$$= \frac{240 - 20 - 219}{240} = \frac{1}{240} \text{ of its length.}$$

$\therefore \frac{1}{240}$ of its length $= \frac{1}{3}$ of a mile.

Hence, total length $= \frac{240}{3} =$ <u>80 miles *Ans.*</u>

EXAMPLES 11

1. Reduce the difference between $\frac{1}{7}$ of $\frac{5}{12}$ of a guinea and ·128 of £1 to the decimal of half-a-crown.

2. Express $\frac{2\cdot5}{\cdot375} \times \frac{4\cdot55}{3\frac{1}{4}}$ of an hour in minutes.

3. A sum of money is divided amongst three men, so that the first has $\frac{1}{4}$ of it, the second has $\frac{2}{3}$ and the third has 38s. What is the sum ?

4. A boy sold his knife for half-a-crown and gained a quarter of what it cost him. For how much should he have sold it to gain a quarter of the selling price ?

5. A man left £450 to his youngest son, $\frac{3}{8}$ of his money to his second son, and to his eldest son he left as much as to the other two together. How much money did he leave altogether ?

6. Three brothers have a sum of money divided amongst them so that each has $\frac{5}{6}$ of what his next eldest brother has. The eldest has £73 2s. 6d. more than the youngest. Find the sum of money.

7. What decimal of $\frac{3}{7}$ of $2\frac{1}{12}$ of £2 is equal to ·65375 of £17 − 14·295 crowns ?

8. In walking from one town to another, a man finds that at two o'clock he has completed $\frac{1}{4}$ of his journey, and at 2.15 he has completed $\frac{1}{3}$. At what time will he reach his destination ?

9. A woman had a certain number of oranges. She sells A half of them and one more, to B she sells half the remainder and one more, to C she sells half the new remainder and one more, and she now sells one more than half of what she has left to D. She has three oranges left. How many had she at first ?

10. At a point of his journey from one place to another, a man noticed that $\frac{4}{5}$ of the distance he had already travelled was $\frac{1}{2}$ the distance he still had to go. After another $2\frac{1}{4}$ miles he had just completed half his journey. How many miles had he still to go when he made the first observation ?

Answers to Arithmetic

Examples 1

1. 770904. 2. 395504. 3. 9712. 4. No. of third class = 389 − 177 = 212; No. of second class = 389 − 262 = 127; No. of first class = 177 − 127 = 50. 5. (*a*) 4236705; (*b*) 2494851612. 6. He sells 129 sheep for 7s. each more than they cost. Gain on these = 129 × 7 = 903s. He sells 82 sheep at a loss of 3s. each. Loss on these = 82 × 3 = 246s. On the whole, he gains 903 − 246 = 657s. 7. (*a*) 14403; (*b*) 1141 quo. 505 rem.; (*c*) 608379 quo. 196126 rem. 8. Total gain = £840 − £720 = £120. Gain on each animal = £2. ∴ No. of animals = 120 ÷ 2 = 60. ∴ Price he paid for each animal = £720 ÷ 60 = £12. 9. To give the first boy 2, the second 3, and the third 4, requires 2 + 3 + 4 = 9 marbles. Since 270 ÷ 9 = 30, the first boy can therefore have thirty 2's, the second thirty 3's, the third thirty 4's — *i.e.*, 60, 90, 120, respectively. 10. 1 lb. of coffee is worth 18 ÷ 3—*i.e.*, 6 lb. sugar. ∴ 82 lb. are worth 82 × 6 = 492 lb. sugar.

Examples 2

1. 659·71012. 2. 141·23571. 3. (*a*) 6·58476; (*b*) 677·97647. 4. (*a*) 4·2167; (*b*) 588·411. 5. (*a*) 23705·5; (*b*) 5·563296; (*c*) ·1443532. 6. (*a*) 518·4256; (*b*) 1·29519. 7. Continued

OPERATIONS IN FIELD SURVEYING

Including Tacheometrical and Plane Table Surveying. Finding the True North. The Magnetic Needle

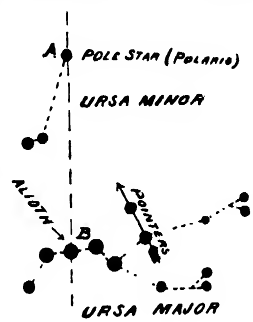
Continued from page 594

By Professor HENRY ROBINSON

Declination or Variation of the Magnetic Needle. This is the horizontal angle that the compass-needle makes with the true meridian, and is never a constant quantity. The value of the variation of the needle is given every year in "Whitaker's Almanac." It is necessary to obtain the value of the angle due to the variation of the needle when plans are being plotted to "true" north, in order that corrections may be made to the compass readings which are taken in the field, and from which the plan is being plotted.

The daily variation in the declination of the needle consists in a swinging of the needle through an arc of about 8 in., the north end having its extreme easterly variation about 8 a.m., and its extreme westerly variation about 1.30 p.m., the mean declination taking place about 10.30 a.m. and 8 p.m.

To Find the True North. The meridian of a station on the earth's surface is a great circle passing through the North and South Poles, and through the station. The inter-section of this circle with the sensible horizon of the observer is called a meridian line, and marks the north and south points of his horizon. This, of course, varies according to the geographical position of the observer. A method of finding the line of meridian by the sun has already been explained when dealing with "Chain Surveying." Another method is that known and is



the telescope of a theodolite, and carefully level the instrument. Observe the sun at some distance to the east of the meridian an hour or two before noon, as about noon the motion of the sun is nearly parallel to the horizon. In this position, take the reading on the horizontal scale of the instrument, the vertical arc being securely clamped. When the sun has passed the meridian and is descending in the west, turn the telescope so as to ...t it, the vertical arc still being clamped.

evident that the altitude is precisely the same as that observed before noon. Take the reading on the horizontal scale, then the difference between this and the reading taken before noon will be the *azimuthal*, or horizontal arc, described by the sun in the interval between the two observations.

Herschel describes the *azimuth* as the angular distance of a celestial object from the north or south point of the horizon, according as it is the north or south pole of the horizon which is elevated, when the object is referred to the horizon by a vertical circle.

It is evident that when the altitudes of the sun—or of a star—are equal on either side of the meridian, its azimuths or bearings, whether reckoned both from the north or both from the south point of the horizon, must also be equal. Consequently, a line through the north and south points of the horizon will bisect the horizontal arc thus determined, and may therefore be marked on the ground.

Allowance for the Sun's Deflection. In observing the sun very accurately, either its upper or lower limb should be taken. If much time elapses between the observations, a correction must be applied to compensate for the change in the sun's declination during the interval.

From mid-winter to mid-summer the sun gradually approaches the North Pole, and consequently a shorter period will intervene between ascending from a certain altitude to the meridian to descending from the meridian to a similar altitude on the other side (which is in northern latitudes). The reverse takes place from mid-summer to mid-winter. The change of declination is given for every hour in the "Nautical Almanac."

Another simple method is by

Alioth, which is one of the combination known as the Great Bear (*Ursa Major*) [48].

It is known that these stars pass the meridian within about nine minutes of each other. The method of obtaining the meridian from these stars is as follows: Suspend two plummets by fine thread at the end of a rod exactly between the star Alioth (B) and the eye when the former is nearing the meridian. Then, at the moment the pole star (A) is also seen along the two plumb lines, they will be nearly in the plane of the meridian, which is then fixed.

It is now proposed to give some information with regard to a few instruments that are used in connection with the work for purposes of rapid field-work.

The most usual method has been to fix the positions of points on a plan by means of the

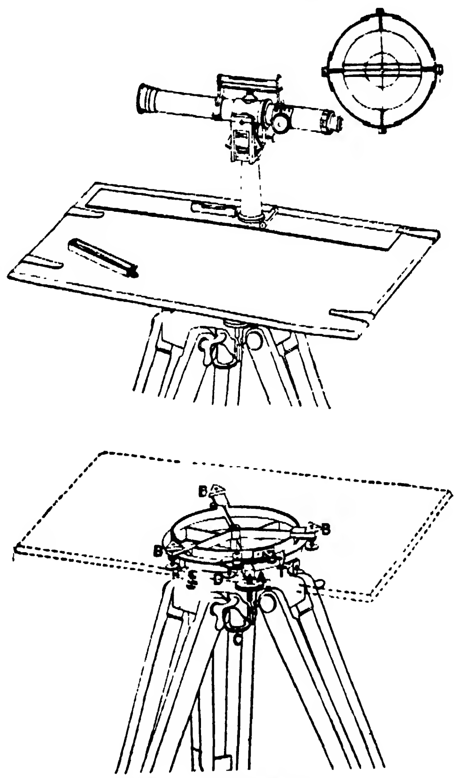
theodolite and chain, whilst their differences of vertical height have been obtained by the level. In recent years the theodolite has come into prominence on account of the accuracy that can be obtained in arriving at the differences of level of places by means of the vertical circle of the instrument, while at the same time the direction and position of points with regard to one another may be fixed by readings to an ordinary level-staff.

Another form of theodolite used for this purpose is the *Tachometer*, which is really a transit theodolite provided with "stadia" hairs and a special lens, which makes the principal inside focus of the object-glass coincide with the vertical axis of the instrument. This construction enables distances to be directly computed from the station at which the instrument is placed without the necessity of making any allowance for the focal distance falling outside the central axis, as would have to be done were the stadia hairs placed in an ordinary theodolite. The *Omnimeter* is another form of instrument for reading distances direct.

The Plane Table. The *Plane Table* is another means by which surveys may be rapidly made and plotted in the field as the work proceeds.

It is now proposed to give a brief description of the various means of surveying by the foregoing methods.

The plane table is an instrument which has not been much employed in this country, owing chiefly to the uncertainty of the climate, but abroad its use has yielded excellent results, and the various parts have been developed in order to make it more accurate. In its simplest form it consists of a plain drawing-board (on which drawing-paper is fixed) about 2 ft. square, mounted on a firm tripod, and provided with a flat rule, or "alidade," as it is termed, with a sight vane at each end, by means of which sights are taken to the required points.



44. PLANE TABLE

A compass, in a small metallic box, is used for fixing the meridian line on the paper. Abroad, this simple form of alidade has been very much improved, and means have also been introduced to enable the table to be levelled. Instead of the sight-vanes, the alidade is provided with a telescope with cross hairs for measuring the distances.

An enlargement of these hairs is shown at the side of the illustration [**44**]. The lower part of the illustration shows the arrangement of levelling screws.

The three triangular plates BBB are let in the under-side of the board, and the support is screwed into them. The table is then levelled by means of three screws, of which one (A) is shown. When this is done, the lower part of the support is clamped by the screw C. The clamp screw D and the tangent screw T are used to fix the upper part of the board either to the meridian by means of the compass, or to any desired line of sight to which the board is to be directed.

Using the Plane Table. The general method of procedure is as follows: [**45**]

A base line is first chained on the ground as AB, the plane table is set up over station A, and the position of A is marked on the paper at any convenient point to suit the various points of the survey to be obtained later. A plumb-bob should be provided, fitted to a clamp to fix to the table, for getting accurately the position of the station on the paper.

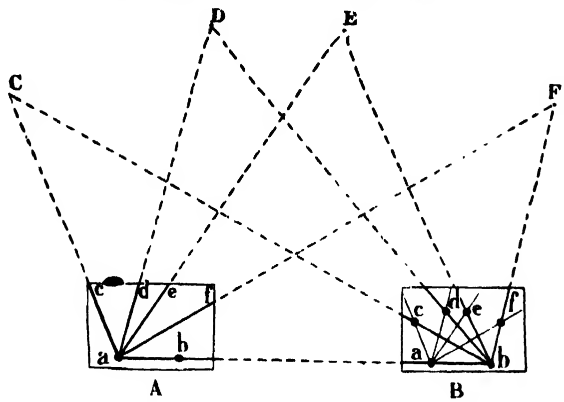
Having fixed the position A, the compass is placed on the paper and moved about until the needle becomes stationary to the north. Lines are then drawn round the box in order that the meridian line may again be used at any other station as a check. The edge of the ruler—called the *fiducial* edge—is now placed at the point a, which corresponds to A on the ground, and the ruler is moved until B is sighted. The line a b is then drawn, and its measured distance scaled off on this line. Any other required directions, as C, D, E, and F, are now sighted in the same way, care being taken to mark the lines for verification. The table is then moved to B, the alidade is placed along a b, and the table is moved until the point a is sighted. The directions from b to C, D, E and F are then sighted, and the lines drawn, their intersection points will then give the positions of these places on the plan. As in the case of the *Station Pointer*, which is explained elsewhere, care must be taken to avoid the adoption of a point in which the position of the table and the objects to be located are on the circumference of a circle, as under these conditions correct fixing is impossible.

Tacheometrical Surveying. It is impossible in the space allotted to this portion of

the work to describe every form of instrument used in the locating of points by angular measurement, commonly called *tacheometry*. This part of the subject will, however, be dealt with by the employment of the theodolite and by the tacheometer.

In the first case, readings are taken to two known points on a level-staff, whilst in the second case hairs are placed in the diaphragm of the telescope (called "stadia" hairs). The number of divisions on a level-staff that are intersected by these hairs gives the distance of the staff from the instrument, provided the telescope be truly horizontal, and the staff vertical.

In the event of the telescope being elevated, or depressed, some modification is required, for reasons which will be explained.

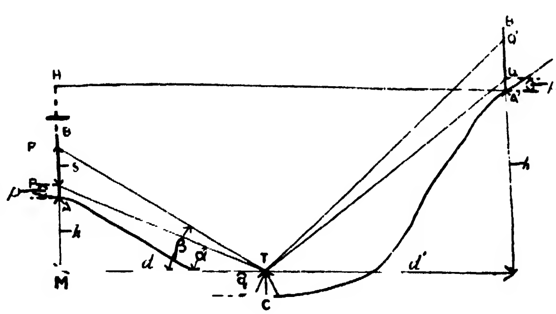


45. SURVEY WITH PLANE TABLE

If the student is desirous of going more deeply into the subject, the work of Mr. Kennedy on "Surveying with the Tacheometer," or a paper by Mr. Wilfrid Airy in the "Proceedings of the Institution of Civil Engineers," will be found valuable.

The position of the main survey lines must be fixed by traversing, or by triangulation, as we have already explained. The directions of the points may be fixed either by taking their bearings, or by their angles with some known point. In surveying by vertical angles, readings are taken to known portions of the level-staff giving a base preferably of 10 ft.—that is, by taking the readings at 2 and 12 ft. on the staff.

In the illustration [46], let PP^1 be two well-defined points on the staff to which the telescope is directed in succession, so that $AP = p$ and $PP^1 = s$, both of which are known. Let α be the angle subtended at T by PM, and β the angle subtended by P^1 M, these angles being read. Let $TM = d$ and $PM = h$. Then from the triangles PTM and P′TM



46. SURVEYING BY VERTICAL ANGLES

$P^1M = d \tan \beta$ and $PM = d \tan \alpha$

Therefore $PP^1 = P^1M - PM = d \tan \beta - d \tan \alpha$

Now $PP^1 = s$ $\qquad = d(\tan \beta - \tan \alpha)$.

$$\therefore d = \frac{s}{\tan \beta - \tan \alpha} \quad \ldots \quad \ldots \quad 1$$

Also $PM = h = \quad d \tan \alpha$

$$\therefore h = \frac{s \tan \alpha}{\tan \beta - \tan \alpha} \quad \ldots \quad \ldots \quad 2$$

In the previous formula, $\tan \beta - \tan \alpha$ will be always positive, because the angles taken below the horizontal are called negative angles, which makes $\tan \alpha$ positive when it is larger than $\tan \beta$. The height of the theodolite (q) above the ground must be measured in order to get the level of A with regard to C. The height, p, of the staff above the ground at A must also be allowed for. It must also be remembered that when long sights are taken, the correction for curvature and refraction must be allowed for. The formula for these has already been given.

With work of this kind when the tacheometer is employed the principles are the same, only that with this instrument "stadia" hairs are provided, by which any number of divisions on the staff seen between the hairs represents the distance of the staff from the observing station when the telescope is horizontal.

The measuring angle m I n [47] usually employed has a constant = 0·02, and whatever unit of measurement it is intended to adopt must be proportioned to this on the staff, so that the number of divisions seen between the stadia hairs may represent the distance of the staff from the instrument.

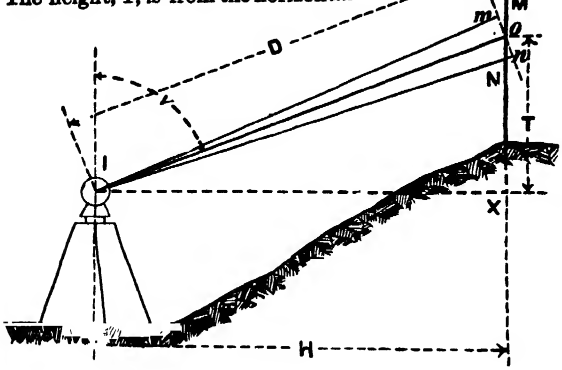
For instance, we shall assume that it is required to read distances in feet. In order to get, for example, ten divisions on the staff to show between the hairs when it is 10 ft. from the instrument, the following will have to be the size of each division when the constant of the measuring angle is 0·02—namely, $10' \times {\cdot}02 = 2{\cdot}4''$ on the staff for ten divisions, or 0·02 foot for each division, or double the size of the division on an ordinary level-staff. If, therefore, the distance from the vertical axis of the instrument to the staff be called D, then, when the telescope is horizontal, $D = g$ the number of divisions between the hairs.

Compensation for Tilting Telescope. When, however, the telescope is tilted, as is generally the case, it is necessary to employ some modification. In the illustration, Io is the central line of vision, and the staff MN is held

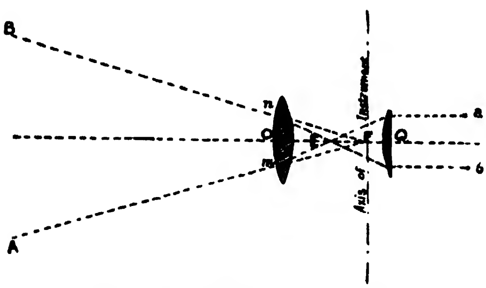
vertical, as shown. If the staff had been held perpendicular to the line of vision, as *mn*, the distance D = *g*, as previously explained, instead of which the hairs cut at MN called G. Then D = G sin V, and the horizontal distance D = G sin² V, and the height from the horizontal to the central line of vision T = H cotan V. When V is more than a right angle, as for angles of depression, the formulæ become

$$H = G \cos^2 (V—90°)$$
$$T = H \tan (V—90°)$$

The height, T, is from the horizontal



47. TACHEOMETRY



48. TACHEOMETER DIAPHRAGM

axis to the central line of vision. This is easily obtained without the use of the formula, as follows. If x and y equal the number of divisions between the bottom of the staff and the two wires, then $\frac{x+y}{2}$ is the number of divisions between the ground and the central line of sight, and if multiplied by the size of one division gives the height in units. For finding the difference of level, three combinations occur, as shown in 49. Calling the height of the instrument *q*, and the difference of level L in the upper figure

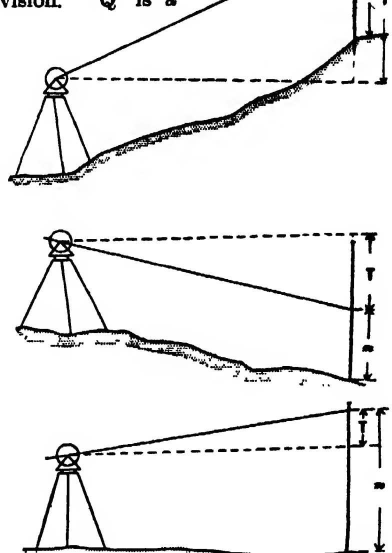
$$L = q + T - m.$$

In the next figure $L = q - T + m$.

In the lower figure $L = q - m - T$.

To ensure the verticality of the staff, the holder should carry a light plumb-line, or have a small circular level fixed to the back of the staff.

Reference has been made to the measuring angle in the tacheometer. The illustration [48] shows two horizontal hairs, *a* and *b*, placed in the diaphragm at equal distances from the central line of vision. Q is a converging lens placed between the object-glass O and the diaphragm. F (the principal inside focus of the object-glass O) coincides with the vertical axis of the instrument. Parallel rays of light pass *a* and *b*, and are deflected to E, the focal point of the lens Q. They leave the lens O in line with its principal interior focus F, forming the measuring angle BFA.



49. LEVELLING BY TACHEOMETRY

[NOTE]

THE NAVY. On page 163 of the SELF-EDUCATOR appears a paragraph indicating the course o' cadets entering the Navy. These conditions have now been modified, and the last vestige of them disappeared last month (November, 1905). The new regulations are embodied in the following paragraph, and will be dealt with at length in the course which deals fully with the Navy:

Training for Executive and Engineer branches of Royal Navy, and for Royal Marines, is identica until after examination for Sub-lieutenant. Boys must be of European descent, and sons of Britisl subjects. Entrance by examination after nomination. Age 12½—13. Nominations and examina tions three times a year in March, July, and December. Four years in the training establishments costing £100 a year inclusive, is followed by three years at sea, during which a private income o £50 a year is necessary. Then the youth passes examination as Acting Sub-lieutenant, and is sen to England to complete his training, selecting the branch of the service to which he will be attached.

OUTLINES OF EDUCATIONAL TOURS ABROAD

The Best Plan of Seeing Historical and Living Belgium in a Short Time
How to Visit France, giving a Model Itinerary and Suggstions for Cyclists

By J. A. HAMMERTON and WILLIAM DURBAN, B.A.

We shall endeavour in the smallest possible space to sketch out model tours in Europe and farther afield, and by giving lists of useful books to read, do all that is within our power to ensure the wisest application of the rules which, derived entirely from our own personal experience, we have already laid down. Bearing always in mind the readers to whom money is a prime consideration no less than time, we have framed our itineraries so that they may be of the greatest use to those who have little leisure and less money at their disposal, taking a fortnight to be the average holiday at the command of our readers, and the financial resources of the ordinary clerk or school-teacher as the measure of expenditure in our calculations.

BELGIUM

Belgium is the most accessible country on the Continent for the English tourist, the cheapest to visit, and one of the most important in any scheme of educational travel. Nowhere are there towns more potent to stir the imagination, to awaken the feeling for romance, than Bruges and Ghent; Brussels is an ideal example of a fine modern capital evolved from an old historic town, while Antwerp is full of bright and cosmopolitan life, and boasts rich treasures of art. For beginners in foreign travel Belgium has the further advantage that it may be visited in one week without undue haste, the distances between the towns being short, and the places of interest near to each other. We therefore make an exception in its case by giving an itinerary for one week.

A Week in Belgium. It is advisable to enter Belgium by way of Ostend, in order to make one's itinerary fit in with the historical interest of the country. Ostend itself is to be ignored entirely, as it is merely a Belgian Blackpool, and the traveller will proceed at once to Bruges, which is only fourteen miles inland.

FIRST DAY. Arriving at BRUGES early in the evening, sleep there, and begin sight-seeing next morning. Go first to the *Grand' Place*, the great open space in the heart of the town, now almost deserted, once the busiest scene in Flanders, if not in all Europe. Bruges in the fifteenth century was at the height of its glory, the most opulent town of Europe outside of Italy, the seat of the Dukes of Burgundy. Its treasures of art and architecture date from that era of splendid prosperity. The *Belfry* is famous all the world over; innumerable poets have written about it, notably Longfellow. Ascend to the top, where the machinery of the wonderful bells is shown, and a fine view of Flanders and Holland obtained. The Belfry was the core of mediæval Bruges, and dates from the thirteenth and fourteenth centuries. Visit the *Palais de Justice*, the *Hôtel de Ville*, and the *Chapel du Saint Sang* (Chapel of the Holy Blood), all close by. Next proceed to the *Hôpital Saint Jean*, which contains some of the rarest gems of Flemish art, the collection of Hans Memling's masterpieces (1fr. admission). The *Academy*, the *Cathedral*, and the churches of *Nôtre Dame* and *St. Jacques*, not to say the many quaint old streets, the canals, and other attractions of the town cannot be seen in one day. Go on in the evening to Ghent, a railway journey of only 25 miles.

SECOND DAY. In the fourteenth century GHENT was the leading manufacturing city of Europe, and as a republic under Jacques van Artevelde it was the ally of England. The town is still a considerable one, and is rich in memorials of its past splendour. The *Cathedral* (which contains the world-famous altar-piece, the Adoration of the Lamb, by Hubert and Jan van Eyck), the *Hotel de Ville*, the *Belfry*, the *Castle* (where the third son of Edward III. was born while Queen Philippa was a guest of the Republic, and was thus known as "John of Gaunt"- - Ghent), may all be seen in one day. These are only a few of the many interesting places in this most interesting town, where one might with advantage spend at least three days. Proceed in the evening to Brussels, 33 miles.

THIRD, FOURTH AND FIFTH DAYS. One has now got a glimpse of the country's illustrious past, and BRUSSELS offers a bright spectacle of its present prosperity. Make first for the *Grand' Place*, in point of architecture perhaps the most curious place in the world. Here are situate the famous *Hotel de Ville*, the *Maison du Roi*, and a number of the ancient *Guild Houses*, the whole square having undergone only slight change in the last four centuries. The *Cathedral* would next be visited, and then one would climb by the *Rue de Ligne* to the high town, where the *Congress Column* is worth ascending for its magnificent view over the town and the fair province of Brabant. The *Park*, the *Royal Palace*, and the *Art Galleries*, with a walk round the *Palais de Justice*, would complete a well-filled day. Next day, by making good use of the splendid tramway service, the outer parts of the town, such as the *Bois de la Cambre*, the Royal suburb of *Laeken*, the *Porte de Hal*, could be visited, and perhaps also the *Wiertz Museum*, which contains the extraordinary paintings of Brussels' mad artist. The third day could be devoted to the little excursion to the *Field of Waterloo*, leaving time for visiting some of the minor places of interest in the city.

SIXTH DAY. One of the most interesting churches in Belgium is the *Cathedral* of MALINES, which few tourists ever visit, because the town is midway between Brussels and Antwerp, and only an occasional traveller seems to think of breaking his journey there, just as there must be a hundred who go straight through from Calais to Paris for every one that gets out to see Amiens. The best plan is to book one's luggage direct on to Antwerp, and stop for two or three hours at Malines before completing the journey to Antwerp, where it would be possible to arrive early in the afternoon. ANTWERP is less rich than any of the other cities in historic buildings, as the town was well nigh destroyed by Spaniards in the sixteenth century, and its prosperity as a great commercial seaport is of comparatively recent date. Its only building of supreme interest is the splendid *Cathedral*. It has a number of minor churches which the tourist with no time to spare need not visit. The best plan would be to go to an hotel on the *Place Vert* on the afternoon of arrival and devote the remainder of the day to visiting the cathedral and wandering about the town. It is one of the most irregular towns

on the Continent, and the tram-lines are the only safe guide for the tourist to follow who does not wish to waste his time in a maze of tortuous streets.

SEVENTH DAY. The *Plantin Museum*, which was the residence and business place of the famous family of printers and publishers who, for upwards of 300 years, carried on a princely business in Antwerp, must take a morning from even the hastiest tourist, and the remainder of the day will be profitably spent in the *Picture Gallery*, with its magnificent collection of paintings by Rubens, Matsys, and the masters of the Flemish School.

Thus in one week, and at very little cost, one can make a beginning in Continental travel, which will whet the appetite for more, and urge the tyro to fare farther afield in the most delightful and most profitable of all forms of education.

Longer Tours. It should be added, of course, that as three days might be devoted to Bruges, the same to Ghent, a week to Brussels, and five days to Antwerp, while Oudenarde is not unworthy of a little excursion, and there is the whole charming region of the Ardennes to explore, one can easily spend from a fortnight to a month in seeing Belgium. But the essentially educative tour is that sketched out above, for which three weeks would allow of leisurely progress, a fortnight for doing it reasonably well, and a week for gaining a good first impression of the country.

Hotels. Hotels in Belgium are cheap and clean. In Brussels one can get accommodation from 5 francs (4s. 2d.) a day upwards. The charge mentioned is contemptibly small for food and lodging, but there are many respectable restaurant-hotels in less central parts where the expense does not exceed that figure. Ixelles is a convenient district for such a lodging. The best plan is to go to one of the better hotels in the town, where prices for bedrooms alone range from 2s. 6d. upwards, and take one's meals wherever convenient. In Bruges, Ghent, and the lesser towns, hotel charges are very modest.

Fares. Our itinerary involves a ticket enabling the tourist to travel to Brussels *viâ* Ostend, Bruges, and Ghent, returning *viâ* Antwerp, Ghent and Bruges to Ostend. There are three trains daily *viâ* Dover and Ostend to Brussels. Fares: Single, 38s. 10d., 28s. 4d.; return (30 days), 70s. 5d., 51s. 8d. Third class is limited to night service. Single, 17s. 6d.; return (14 days), 31s. A small extra payment enables the traveller to return by Antwerp.

The cheapest way is to sail from London and take third-class railway tickets in Belgium. From London to Ostend, vessels of the General Steam Navigation Co. convey passengers twice weekly from St. Katherine's Dock. Fares: Single, 7s. 6d., 6s.; return, 10s. 6d., 9s. Between Antwerp and London, *viâ* Harwich, there is a daily service (Fares: Single, 26s., 15s.; return 40s., 24s.), and two sailings weekly direct by G. S. N. boats; while the Sutcliffe line from Grimsby sails on Mondays, Wednesdays and Saturdays (Fares: Single, 15s.; return, 25s.).

Books to Read. "Cities of Belgium" (3s. 6d. net.), by the late Grant Allen. "Belgian Life in Town and Country," by D. C. Boulger (Newnes, 3s. 6d.). "Belgium and the Belgians," by Cyril Scudamore (Blackwood, 6s.). "Bruges," in the "Mediæval Towns" series, by E. Gilliat-Smith (Dent, 4s. 6d. net). "Bruges la Morte," novel by Georges Rodenbach, English translation, Sonnenschein (6s.).

FRANCE

The richest and most interesting country in all Europe, the most varied, our nearest neighbour—what shall we say of fair France? To mention its many fine provinces, with their wealth of historical and legendary lore, their diversified scenery, their intimate association with England in the days of old, when our Kings were also rulers of this magnificent country, is to sketch out a programme of travel that might well occupy one for many years, and leave the country unexhausted in the end. Picardy, with its dead old towns in the north; Normandy, rich in Gothic architecture and memories of our Norman kings; Brittany, with its natural beauty and its Celtic memorials, its people the kindred of our own friends in Wales, still speaking a language that is practically the same as Welsh; the Loire, with its wonderful castles, "the garden of France"; the Vendée, the Cevennes, Auvergne, Provençe, and all the Roman provinces of the South, boasting, as in the arenas at Nîmes and Arles, the Pont du Gard, and other treasures of classic architecture, gems worthy to rank with the best of Italy and of Greece; the Vosges, unrivalled for mountain scenery, and many more provinces not less interesting in their individual ways—each and all invite us, seeming to say: "Confine your travels to France and you will have enough to do all your days!" That is indeed true, but only the specialist can afford so great a luxury as to familiarise himself with all the glories of this glorious country. We must select from its inexhaustible possibilities of travel just enough to show the reader how he may draw sufficient thence to furnish his mind with a fair conception of its grandeur.

A Fortnight in France. In fourteen days much can be seen, but it is hopeless to attempt a comprehensive tour of France in that time. The great towns of living and historical interest are so far apart that it would be preposterous to endeavour to see many of them in so short a period. Paris, Orleans, Tours, Clermont Ferrand, Nîmes, Lyons, Bordeaux, Marseilles, Nice, Nancy—look at the map of France and you will realise how hopeless it would be to think of visiting these cities, and they are but a few, in the course of a tour that did not extend into many weeks. We must therefore devise a fortnight's itinerary which will give the beginner a good first impression of Northern France, and outline several tours, especially for cyclists, who, above all, can get the best out of the country.

FIRST DAY. By travelling at night, arrive in the morning at ST. MALO. The *Cathedral* is interesting, but the town is more so. Most of the day may be spent to advantage in rambling about the old streets within the ramparts. See the *Tomb of Chateaubriand*

on a little island near the harbour, whither one can walk at low tide. ST. SERVAN and PARAMÉ are close at hand, and may be visited, not for any historical associations, but for their importance as thriving French watering-places.

SECOND DAY. Take train to PONTORSON, stopping by the way at DOL to inspect the fine *Cathedral.* From Pontorson proceed by diligence to MONT ST. MICHEL. This is one of the greatest curiosities in France, and should on no account be omitted. We have spent days there at a time. Stay at one of the excellent hotels on the Mount.

THIRD DAY. If time will permit walk round the Mount, outside the ramparts, to gain a good idea of this most wonderful piece of mediæval architecture. About midday return to Pontorson and train to AVRANCHES, a delightful old town where a large colony of English residents used to exist.

FOURTH DAY. Travel to Bayeux, stopping for an hour at ST. LÔ to lunch and visit the fine *Cathedral.* At BAYEUX, see the beautiful *Cathedral* on the evening of arrival.

FIFTH DAY. Spend a good deal of the forenoon examining the world-famous *Bayeux Tapestry*, reputed to be the work of Queen Matilda (wife of William the Conqueror) and ladies of her Court, recording the story of the Conquest of England. Go on in the afternoon to CAEN, which is deeply interesting to the English visitor as the favourite town of the Conqueror.

SIXTH DAY. Devote to seeing the principal churches—*St. Pierre*, one of the finest examples of Gothic; the *Abbaye aux Dames* and the *Abbaye aux Hommes*, the one erected by Queen Matilda and the other by William, as their penance to Rome for having married within the degrees of consanguinity.

SEVENTH DAY. Leave by early train for FALAISE, the birthplace of the Conqueror. A most picturesque and romantic town, whose *Castle* is well worth visiting. Then in the afternoon proceed to LISIEUX, another historical and picturesque town.

EIGHTH DAY. Train to Paris, breaking the journey for an hour or two at EVREUX to see the beautiful *Cathedral* and to visit a lively, clean, military town of 17,000 inhabitants. Paris will be reached late in the afternoon.

NINTH–TWELFTH DAYS. This is all too short a time to spend in PARIS, but will suffice for a first impression. No town in Europe is of such inexhaustible interest. It may be visited scores of times. We need not outline the sights of Paris, since to do so would occupy too much space and would be of little use to the tourist, who must make up his programme for himself with the aid of a good guide-book. Among the sights, however, one frequently missed is that of the *Cluny Museum*, and this should on no account be omitted by the visitor, no matter how short a stay he may be making. And one afternoon at least should be devoted to VERSAILLES, an easy excursion.

THIRTEENTH AND FOURTEENTH DAYS. Returning home either by HAVRE OR DIEPPE (the former is much the more interesting town) the traveller should break his journey at ROUEN, either for a forenoon or for a whole day. Ourselves, we have stayed for several days in the town and revisited it twice, and advise that at least a day should be given to it if possible, as it possesses numerous fine churches and public buildings, and is of immense historical interest. Rouen was the scene of *Joan of Arc's* imprisonment, mock trial, and burning. *Gustave Flaubert* was its greatest literary son. It is the largest and most important town in our itinerary after Paris, and for that reason alone well worthy of the traveller's study.

Such a tour as we have outlined would give the student a fair impression of historical and living France, but not until he had travelled a good deal in the centre and south could he presume to judge of the wonderful resources of the country, its mighty national life.

Cycling Tours. Normandy is a fine touring ground. Boat to Le Havre, then cycle to Caudebec, Rouen, Pont Audemer (don't sleep here), Lisieux, St. Pierre-sur-Dives, Falaise, Flers, Domfront (most interesting), Mortain, Avranches, Mont St. Michel, Granville, Coutances, St. Lô, Bayeux, Caen, Cabourg, Trouville, Honfleur, Havre. This round can be done easily in the fortnight. In BRITTANY the towns are not so interesting as they are in Normandy, but the country is far more beautiful, and if the roads are not so flat they are less monotonous. Sail from Southampton to St. Malo, arriving there in the morning and setting out the same afternoon for Lamballe, passing by way of Dinan. Thence to S. Brieuc, Étables, Paimpol, Tréguier, Lannion, Morlaix, Landernau, Brest, Telgruc, Plomodierne, Quimper, Concarneau, Pont Aven, Quimperlé, Lorient, Carnac, Locmariaquer, Auray, Vannes, Rennes, St. Malo. This is a circular tour which gives the cyclist, to whom alone it is possible in all its details, a good idea of the towns, villages, and historical sights of Brittany, and may be accomplished in so short a time as eight or ten days.

Routes to France. London to Paris, *viâ* Newhaven and Dieppe: Single, 34s. 7d., 25s. 7d., 18s. 7d.; return (30 days), 58s. 3d., 42s. 3d., 33s. 3d. *Viâ* Dover and Calais, or Folkestone and Boulogne: Single, 60s., 43s. 6d., 26s. 9d.; return (30 days), 89s., 68s. 6d., 42s. *Viâ* Havre and Rouen: Single, 33s., 24s.; return (60 days), 55s., 39s. London to St. Malo: Single, 35s., 25s.; return (60 days), 52s., 40s.

Books and Guide-books. Those who read French are advised to use one of the "Guides Joanne," published at different prices by Hachette and Co., which are by far the best guide-books to the different provinces of France. For readers of English only, Baedeker's "Northern France," price 7s., and "Southern France," price 9s., are recommended. Members of the Touring Club de France can make up their itineraries from an ordinary map, and by sending an outline of their projected tour to the secretary will be supplied, at a very low charge, with sectional maps of the whole route—a most convenient arrangement. Guide-books for Paris are so numerous that we need not specify any, except the late Grant Allen's "Paris" (3s. 6d. net), which is the best of its kind. Richard Whiteing's "The Life of Paris" (Murray, 6s.) is unrivalled as a graphic picture of modern Paris. Read Flaubert's famous novel, "Madame Bovary" before going to Rouen. Read Pierre Loti's "Pecheur d'Islande" before going to Brittany. There are innumerable books of travel in Normandy and Brittany, any one of which cannot fail to be of some value to the intending tourist. "French Life in Town and Country," by the late Hannah Lynch (Newnes, 3s. 6d.), and "Home Life in France," by Miss Betham-Edwards (Methuen, 6s.), are worthy of special mention. A useful little book for those who travel by train or cycle is "The Continong" (Dent, 1s. 6d. net).

CULTIVATION OF TEXTILE FIBRES

Including Flax, Jute, Manilla, Canadian, and other Hemps. Ramie Fibre—Its History, Nature, Prospects, and Problems

By W. S. MURPHY

Flax. Common flax is the chief source of lint fibres. It is a pretty plant [15]. When the blue flower opens, the fields of flax are clothed in a robe of shimmering azure, tender and delicate in hue. "Blue were her eyes as the fairy flax," sang the sweetest of our great poets. Singularly graceful is the erect stem, about three feet high, branching out at the top, the flowers forming a lovely crown. The long, lancet-like leaves, smooth and glossy, spring from the stems to each side alternately. When the flowers fade, capsules form, and nourish within them seeds, dark brown, glossy, oval, flattened, and sharp-pointed.

Let us examine the fibre. The stem of the flax plant consists of three forms of vegetable substance—the outer bark, the bast or inner skin, and the woody central pith. The bast is the true skin of the plant, and is composed of the fibres from which lint or flax yarns and linen cloth are made.

The History of Flax. The oldest pictures of human industry are those which depict, in the ancient tombs of Egypt, the operations of the flax cultivator. Painted from four to five thousand years ago, these pictures show the agriculturist turning up the soft alluvial soil of the Nile valley, sowing the seed, and pulling up the flax stems when fully grown.

15. FLAX PLANT

Though it probably originated in a subtropical region, the flax plant grows well as far north as Sweden. Up till the middle of the eighteenth century flax was grown extensively in England, specially in Dorsetshire, Lincolnshire, Isle of Ely, and Suffolk. All over Scotland the fibre was grown for local consumption, large quantities being raised in Ayrshire, Lanarkshire, Renfrewshire, Fifeshire, and Forfarshire, where there were linen factories and roperies. In Ireland, where the linen trade had been an established industry for centuries, flax was grown extensively in the Ulster province. But the profitable market for wheat created by the growth of the factory towns in England and Scotland induced the farmers of those countries to reserve their fields for cereals.

At the close of the American War of Independence the British Government, alarmed at the decreasing supply of raw material for an important industry, instituted a premium system for the encouragement of flax cultivation. It is interesting to note that in 1786 Robert Burns, the poet, gained one of these premiums for the excellence of the flax crop raised on his farm at Mossgiel. Premiums cannot arrest economic tendencies. Year by year, decade after decade, the acreage of flax declined, till at the close of the nineteenth century flax culture in England, Scotland, and Wales scarcely covered 1,000 acres. Irish flax culture has had a somewhat different history. With temporary fluctuations, flax production increased in Ulster till 1864, when 300,000 acres were under flax. Since then the acreage devoted to the cultivation of flax has declined, and at present the great linen industry of Ireland depends on foreign countries for ninety per cent. of a raw material quite easily producible in the country.

We derive our supplies of raw flax chiefly from Russia, Belgium, Holland, Germany, and Egypt, the value of the average annual importation being about £3,000,000.

Flax Farming. When cultivating for fibre, it is not advisable to ripen the seeds, because the stems rapidly harden after the flower has faded. The flax farmer therefore buys his seed, and, if he is wise, he pays a good price for plump, heavy, shining seed, of the best brand on the market. The product of poor seed does not repay the labour spent in raising it. Irish farmers have found the seed imported from Riga, the Russian Baltic port, best suited for them.

Having selected our seed, our next care be the soil. This should be a fine dry loam, with a large proportion of silica and lime, alumina and iron in smaller quantity.

An important question comes up at this point. Pliny says of flax, "It has the property of scorching the ground where it is grown, and of deteriorating the quality of the very soil itself." Modern authorities agree with the ancient writer to a certain extent; but it is contended that our artificial manures have done away with that objection. Even without manures, the exhausting effect of flax can be obviated by a simple rotation of crops—as, for example: First year, grass; second, oats; third, potatoes; fourth, wheat; fifth, flax. If an interval of from five to seven years be allowed between the flax cropping of the same land, no injury can result, and the cultivator actually secures one crop without manuring.

Ploughing and Sowing. At the close of harvest, before the frost has taken a grip of the ground, the wheat stubble should be ploughed thoroughly, and the land well drained. In February, plough the soil well up, making a deep furrow. If the soil be light, one ploughing may suffice; but heavy soils require to be ploughed twice in the spring. After the first ploughing has settled, go over the fields again. At the beginning of April, just when the warmth of the sun has strengthened and is causing the weeds to spring, harrow the land to break up lumps and loosen the weeds. Pick out all the weeds as cleanly as possible. Throughout all these operations the level surface of the land should be kept in view, because a regular surface secures uniformity in the length of the plant stems. By giving all plants an equal start in life, you afford them an equal chance in the struggle for light, warmth, and air.

In sowing, follow the same direction as the plough. Having a clean, dry furrow over one inch below the surface, put in a liberal supply of seed, from two to two and a half bushels per statute acre. Fibre plants develop stems most vigorously when thickly sown; the fruit, of course, suffers, but our object is fibre, not seed. The sowing should be followed by a fine seed harrow, covering over with soil. Then draw the harrow up and down again, and crosswise, to make sure the settling of the seed. Smooth all down with a light roller, and leave the rest to Nature for a short time.

Weeding. Weeding is of first importance in flax culture, and calls for the utmost care. As soon as the plants have grown about four or five inches above ground, weeding begins. The weeders must be properly directed and not allowed to work ignorantly. The average labourer thinks that if he takes out enough of the rubbish he is earning his wages; and that is true enough if we are paying only for physical exertion. But flax weeding is not done by mere "strength and ignorance." In the first place, account should be taken of the direction of the wind by the weeders, who should provide themselves, or be provided, with knee mats. For the weeders press down the plants in the course of their work, and if they work with their faces to the wind it gives the plants a chance of regaining an upright position. For the same reason, the pressure on the stems, where unavoidable, should always be straight forward; twisted stems are of no use as flax fibres. Perhaps we have here an explanation of the fact that the best flax culture is carried on by peasant proprietors, assisted by their families and relatives.

Harvesting Flax. Scythe or reaping machine has no part in the harvesting of flax. When the blue flowers fade and fall, and the rough balls, or capsules, are formed, the reapers go into the field and pull the plants up by the roots, laying out the stems so that the long and the short may be readily separated. Before pulling, it should be ascertained that the seeds have just changed from the pale green of their infancy to the light brown that shows they are beginning to ripen. Another indication of the readiness of the stem for pulling is the yellowing of the stalk. The seeds should not be allowed to ripen, unless the object of cultivation be seed production.

A large amount of flax is grown for seed—in India especially—and the industry is highly important, supplying us with linseed, linseed meal, linseed oil, oil-cake for cattle-feeding, and other commodities; but as our object is fibre production, we shall not study these products of the flax plant at length.

Various Kinds of Hemp. The true hemp plant stands almost alone in the vegetable world; the other members of its family have gone out of existence. It has no other name. Even the botanists, when they say *Cannabis sativa*, are merely saying "Hemp cultivated." All nations call it by the same name, the difference in sound being only lingual, and explainable by philology. But the plant has given its name to fibre which has been derived from a large number of plants nowise related. This fact should be carefully noted.

On the face of it, nothing seems more natural than that Manilla hemp should be derived from the hemp plant growing in Manilla and cognate regions. The fact is quite contrary. Manilla hemp is a fibre derived from a kind of palm, related to the plantain and banana, and has been called "hemp" because it resembles in quality and use the fibre derived from the hemp plant. Similarly, we have *Canadian hemp*, *Bowstring hemp*, *Sunn hemp*, and *Deckannee hemp*, all different classes of plants, and yet alike in yielding a fibre which may be regarded as hemp for all practical purposes. We do not justify the nomenclature—we merely explain it.

Hemp. *Widely distributed over the globe, hemp, properly so-called, varies greatly according to climate, soil, and manner of cultivation. An annual—and probably a native of Southern Asia—it has become naturalised in all parts of the world, because the vitality of the plant is such that severity or uncongeniality of climate dwarfs but does not kill it.* The chief climatic enemy of hemp is frost, and it comes to full perfection only in those countries where the summer is long enough to last out its life—a period of nearly five months. Hemp does not favour extremes; it should be the chosen garment of philosophers. With a mild and moist climate, the plant grows to a height of twenty feet; to the torrid sun of the southern tropics and to the cold winds of the north, equally, it yields a stem of about three feet. Erect in stem, the leaves branching off in spreading groups of four or five long serrated fronds, a crop of hemp in bloom presents the appearance of being the close intermixture of two different plants. Male and female stems grow up together, the flowers of the male being clusters of small yellowish green blossoms, while those of the female form into crowded spikes, with tufts of slender fibres coming out of the capsules.

16. SEEDLING OF ABACA
The plant producing Manilla fibre

Hollow, or filled with a soft pith, the stem of the hemp plant consists of a woody material covered with a fibrous bark, the former being what is called the *reed*, or *boon*, and the latter the fibre, or *hemp*.

The plant gives off numerous seeds, large quantities of which are used for the feeding of tame birds, such as canaries. When pressed, the seeds yield an oil used in some countries as an illuminant; but chiefly known in commerce as a paint medium and material for mixing with resinous gums in the making of varnish. *Hashish*, or *bhang*, a narcotic, indulgence in which has been a vice among the Hindus for many generations, is made from the flowers and tender shoots of the hemp plant.

17. JUTE FIBRE

British supplies of hemp are chiefly derived from Southern Russia, Poland, France, and Germany. Though cultivated to some extent in the fenlands of England, and in some parts of Ireland, early in the nineteenth century, hemp has now practically ceased to be counted among British crops. The reasons for this are not far to seek. Hemp requires a rich soil and plenty of moisture; British farmers find it more profitable to devote their best soils to other crops. The argument, however, does not apply with the same force to many of our Colonies, in which conditions ideal for hemp cultivation prevail.

The first aim of the hemp cultivator is to get a long and vigorous stem before flowering begins. After flowering, the stem hardens and tends to irregularity. Hemp cultivation follows the same process as that of flax, but with less labour and attention, the plant being a noted weed-killer.

Canadian Hemp. Indigenous to North America, allied to the periwinkle and the oleander, this plant yields a very strong fibre. Long before the white man had invaded his native home, the Red Indian used this fibre for making fishing-nets, matting, and wove it into a rough canvas cloth. The plant is easily raised, and attains the height of five feet. Reliable and strong, the fibre is worthy of the attention of Canadian cultivators, and of British canvas manufacturers and rope-spinners.

Bowstring, or Rajmahal Hemp. One of the strongest and finest of Indian fibres, this plant grows on barren, sandy soils. The only difficulty in the way of general cultivation and diffusion of the Bowstring hemp plant over tropical lands, otherwise barren and useless, is its climbing habit. In other respects cultivation is easy. For many centuries the primitive native tribes have used the fibre for bowstrings, and its strength and elasticity are very remarkable. Owing to the absence of industrial demand, the fibre is chiefly consumed in the localities where it grows wild. The natives cut the leaf-stems in two lengths, which they split and dry. Then the pieces are softened in water for about an hour, the fibre being scraped off with a rough stick. Fibres prepared in that primitive way have been tested with hemp, and showed a tensile strength 150 per cent. greater.

Sunn Hemp. Closely allied to the common furze of the home moorlands, *Crotolaria juncea*, *Sunn hemp*, *Indian hemp*, or *Jubbulpore hemp*, as the plant has been variously named, grows several feet high, with slender, rigid branches. It is to be found in the Malay States, Australia, and all over the Indian Empire, but the western and southern provinces of India produce the best qualities of fibre. The plant needs a soil well drained, but of comparatively poor quality; rich soils tend to make the fibre harsh and coarse. At present the fibre is little known, because no regular supply has ever been assured to the market. We believe that, if a supply could be relied on, manufacturers would adopt it for many purposes. Large tracts of Northern Australia, seemingly useless, would produce splendid and profitable crops of Sunn hemp. The yield of poor land averages over 600 lb. per acre.

Deckannee Hemp. Of the mallow family, the *Ambari* or *Deckannee* hemp plant is cultivated in Ghutia Nagpur, the Central Provinces, Madras, and Bombay. The fibre is chiefly used by the natives for making twine, ropes, and sacking. When properly prepared, it is white, soft, and silky, and is held by many to be a possible rival to jute. The plant adapts itself readily to any soil, and it grows as far north as the shores of the Caspian Sea. Experts are strongly of opinion that the growing of this plant, requiring little or no capital, would be of immense service to poor cultivators unable to produce either jute or cotton.

Manilla Hemp. Canvas manufacturers and rope-spinners agree that Manilla hemp is the most valuable raw material they at present possess, and the market faithfully reflects their opinion. It is the highest priced of all the larger vegetable fibres. We have already indicated the character of the plant and its place in the vegetable kingdom. According to high authority, the Philippine Islands have been deputed by Nature to supply this fibre to the rest of the world.

Says Dr. Morris : " The Manilla hemp industry of the Philippines is fostered by very exceptional circumstances. The plant [16] is a native of the country. It is cultivated on virgin soil, of which there is, in that part of the world, a considerable extent, and, in addition, the labour supply is cheap and abundant. It is important to bear these facts in mind in starting the cultivation of any fibre that is likely to come into competition with Manilla hemp. Even in the Philippines, there are districts in the western and northern parts, with a drier climate, where the plants will not grow. Hence, it is useless to attempt to establish a Manilla hemp industry in any country where the soil is not rich and where there is not an abundant rainfall well distributed throughout the year."

Even with this caution, coming from a high authority, we cannot agree that the Philippines must be left in sole possession of the Manilla hemp supply. There are regions in the British Empire having all the requisites described as necessary. When we consider that the total cost of establishing a plantation is not more than from £5 to £8 an acre, and the annual charge for efficient maintenance little more than 30s. per acre, the enterprise seems far from prohibitive in its risks. Within two or three years the cultivator reaps a crop of from 500 lb. to 700 lb. per acre of cleaned fibre. Taking the average price of Manilla hemp, this means a return of about £12 per acre. The plant grows to a height of about 12 to 20 feet, and requires very little attention or cultivation of any kind.

Jute. Jute fibre [17] is derived from a plant which botanists name *Corchorus Capsularius*, grown extensively in India and China. Under fair conditions the plant grows to a height of 20 feet, yielding a fibre of great length and uniform quality. The fibre comes from the inner bark of the long stem, and so readily separates into a soft, silky tress of fine hairs that the original users of it inquired no further into its qualities, but for centuries utilised it in that form. Both Hindus and Chinese made coarse sacking and gunny bags of jute long before Europeans came to trade with them, and when the Westerns began to offer goods for goods those natives packed nuts, oil-seeds, and other produce into the gunny bags for shipment. This practice had been going on for over 200 years with British traders before it occurred to anyone to inquire into the nature of the fibre of which those bags were made.

An East India Company official, whose name is lost, conceived the idea of investigating the matter, and, having discovered the gigantic fibre, procured some samples and sent them, with all the enthusiasm of a discoverer, to London, Hamburg, and America. This was towards the close of the eighteenth century; but at that time every manufacturer was more or less absorbed in " conquering " cotton, or in watching its victorious course, and the jute fibre was forgotten. Some portion of the material had been sent to Abingdon, Berkshire, and after lying neglected for about ten years, or perhaps more, the fibre was taken out and tested. The results seemed encouraging at first, and because the fibre had a softness resembling wool, it was made into carpets. This was a blunder, and led to failure and disappointment. No effort is ever lost, however. The fact that jute had been introduced became a part of the history of the textile trade, and attention was bound to revert to it sooner or later.

Development of Jute. Indirectly, cotton, the superior rival of jute, was the cause of rousing renewed interest in jute. In 1828 a merchant in Dundee, named Watt, finding the demand for cotton bagging larger than the supply, imported 364 cwt. of gunny bags direct from India. Others followed his example and a trade in gunny bags arose.

Mr. Watt began a series of experiments with jute. The extreme length of the fibre rendered it unsuitable for British methods of spinning; but Mr. Watt devised a breaker-card, which reduced the fibre to workable length. By the

year 1832 most of the difficulties had been overcome, and jute manufacture became an accepted branch of the textile trade. Not for another 30 years, however, did jute attain its rightful place among textile fibres. At last it occurred to a Dundee manufacturer to inquire closely into the nature of the fibre, and he discovered that it was divisible into still finer fibres, and placed jute in the category of true textile materials. Formerly relegated to canvas-weaving, plaiting, rope-spinning, or other operations requiring a mere length of continuous thread, jute is now chiefly used in weaving cloths such as sackings, Hessians, baggings, and similar fabrics.

Ramie. In the year 1849 the attention of British textile manufacturers was called to sample handkerchiefs woven of a material then utterly unknown in the Western world. Inquiry brought out the fact that this material was the fibre of the plant [18] variously named *Ramie*, *China Grass*, *Chinese Nettle*, and *Rhea*, and described by botanists as a shrubby nettle, indigenous to India, and grown in China, Japan, and the Indian Archipelago. A patent was taken out for the preparation and manufacture of the fibre, and at the great Exhibition of 1851 three prize medals were awarded for ramie, or China grass fibre, as it was then called, demonstrating that, properly prepared, ramie fabrics could be made equal in every quality to the finest French cambrics.

18. RAMIE PLANT

Stimulated by the interest aroused, the authorities at the Royal Gardens, Kew, sent living plants to the principal Colonies, the climate of which appeared suitable for their cultivation. For about 14 years nothing more was heard of the fibre, but in 1865 the American Consul at Bradford brought it to the notice of his Government, advising the culture of the plant, wherever possible, for textile use in America and export to Great Britain. Responding to the suggested rivalry, the Kew authorities once again sent out specimens to the botanical gardens of all the principal Colonies, but neither from the United States nor the British Empire was any result visible. Some impression had been created, however, for in 1869 the Indian Government offered two prizes of £5,000 and £2,000 to the inventor of a machine which would prepare and clean the fibre for the European market. The sole competitor for these prizes was a Mr. Greig, but his machine was adjudged to have failed in meeting the conditions, and no award was given.

Difficulties of Preparation. The parties to this abortive competition have been blamed, but the quarrel is of little interest to the textile manufacturer. One fact, however, was brought out—the problem to be solved in the preparation of ramie is not single but two-fold. First, the fibre has to be taken from the stems; secondly, it must be freed from the natural gum inherent in all plants of the nettle variety.

For a few more years the fibre went out of public notice, but the Paris Exhibition of 1887 brought out several machines invented for the preparation of ramie fibre. These machines professed to offer solutions of the decortication problem—that is, the separation of the fibre-containing bark from the stems. Solution of that problem involves a great deal more than the success of ramie, and the trials were, therefore, watched with intense interest. None of the machines satisfied the judges, and, of course, disappointment was great. Again, in 1891, trials were held in Paris, but with no better results. For the moment these failures seemed to place ramie in the category of fibres which are incapable of being utilised under industrial conditions, and are more numerous than most people are aware.

During the later years of the 19th century the fibre was being seriously considered in Germany, France, and the United States, and employed in several minor industries, such as the manufacture of incandescent mantles, paper for banknotes, and other specialities. Within a short time, ramie had been given an

increasingly important place among textile fibres by both French and Germans.

Difficulties of Ramie. Never wholly relinquished, the subject was again brought prominently before the textile fibre-users of this country by Mr. Edwards-Radclyffe, of Staines, and from the practical interest aroused it would seem that this new fibre has come to stay, and act an important part in textile industry. When considering any new fibres offered, we must keep closely to practical fact. The Chinese and Hindus have known and used ramie fibre for hundreds of years; but those highly ingenious races have continued to prefer silk and cotton, though both require more costly methods of cultivation.

Ramie, *Bœhmeria nivea* **[18]**, is a shrubby nettle, and one of the preliminary difficulties in dealing with it arises from this fact. The stalk is knotty, and secretes a peculiar gum. Our fibre is the inner bark, growing under a thin, brown outer bark. It will readily be understood that the stripping of such a bark by mechanical means presents problems of no ordinary difficulty, and the failures described will be understood.

Decortication. Let us see, however, the way in which the stripping has actually been done. When the stem has been cut, the Chinese cultivator peels off the bark by hand while the bark is yet soft and green, separating the fibre in a very efficient manner. The ribbon of bark is drawn through a hard substance held between the finger and thumb, the operation clearing off the outer bark and a portion of the gummy substance. Another method is to draw the strip of bark over a fixed bar of wood or iron, with a rubbing motion. Then the fibre is flung into water, rinsed a little, and hung up to dry. In this condition the fibre is supplied to manufacturers. Having been imperfectly cleared of gum, and the gum having hardened, degumming is very difficult, though not insuperably so. If, as Mr. Edwards-Radclyffe advises, the whole process of decortication and degumming, or filassing, were carried through while the fibre is soft, the process would be much easier, and planters would present to the textile market a fibre irresistibly attractive—white, lustrous, soft, fine, and of great tensile strength.

Cultivation of Ramie. Though a tropical plant, ramie will grow in England and Ireland. We do not contend, however, that its cultivation should be undertaken in the British Isles. The enterprise offers scope for the energy and ability of British Colonists in every region of the Empire, and an opportunity of making large profits while serving efficiently the industrial interests of the nation.

Let us begin with the seed. Plants can be readily transported, and they take root quickly; but it is better to start at the beginning when possible. Fill a few shallow boxes, about 3 inches deep, with good mould, and sprinkle the seed very sparsely over the surface, then cover with finely sifted earth. Dip the boxes in water occasionally, to let the liquid sap through the mould, and spray regularly. When the seedlings begin to appear, keep them in a shady corner out of the direct rays of the sun. As soon as the roots have formed and the little plants begin to stand up, thin them out, leaving each plant about 3 inches of space, and plant the thinnings in similar boxes. Carefully shading and watering them till they are about 3 inches or more high, gradually harden them to weather conditions, and then plant out in a well-manured and deeply tilled nursery patch, allowing each plant 4 feet of space, to encourage lateral shoots. As the shoots branch out, splice and peg them down into the earth, so that they will take root. When rooted, remove them into another nursery, or plant them out. In this way a large plantation can be made out of a few seeds.

Plantation. Having got our plants, our next care is the plantation. As a matter of course, different climates require different methods; but a few general directions will apply to all climates. Plough deeply and manure the fields well. The plant will grow in poor soil, but the richer the soil the better the crop. Few plants are so responsive to good treatment. Set in blocks of two or three rows; leave between each block space large enough for a trolley or a plough to pass. Pay close attention to weeding, hoe well up to the roots; snip off all low lateral shoots as they appear, to encourage length and straightness of stem. The longer and straighter the stem the better the fibre.

The plantation, once started, lasts from 16 to 18 years, yielding regular crops all the time. The reaping is done by hand, the stems being cut off at the root. Now we gain the benefit of the space between the blocks; the trolley passes from block to block of the plantation, collecting the cut stems, and bringing them to the decorticator.

Claims for Ramie. As yet ramie culture is in its infancy, and there are many details in the work which can be determined only by long practical experience. China is the only country where ramie has been cultivated to any extent, and there it takes the form of a kind of cottage culture, affording us little light on the problems involved in extensive plantations.

The merits claimed for ramie have not been put to the infallible test of the industrial market, but they are worthy of record as an encouragement to inquiry and study:

1. Ramie is many times stronger than cotton, flax, hemp, and similar fibres.
2. It has a long staple, from 3 in. to 9 in.
3. It is easily grown, as it acclimatises itself almost in any zone where agriculture is possible, with varying results, giving in some latitudes as many as four crops per annum.
4. It is beautifully lustrous, resembling silk more than any other fibre.
5. It does not rot.
6. It is non-elastic, and therefore invaluable for machine belting, ropes, and measuring tapes.
7. There is nothing produced in wool, cotton, flax, hemp, or even silk, which ramie cannot imitate and in most cases excel.

COMPOSITION AND COLOUR

The Value of Composition. How to Suggest Emotion in Art. The Importance of Originality. A General Colour Scheme

Continued from page 600

By P. G. KONODY and HALDANE MACFALL

THE student will next find his drawing not only of importance in its accuracy as to form, but he will begin to realise of what immense importance it is *where in the picture he puts that drawing.* He has, in fact, realised that arrangement, or composition, is of enormous value in creating the impression he wishes to create. This will thrust its importance upon the student very early. For when his training in drawing has made him master of the great secret, he has to remember that he has only learnt that which is to enable him to build up his picture or impression.

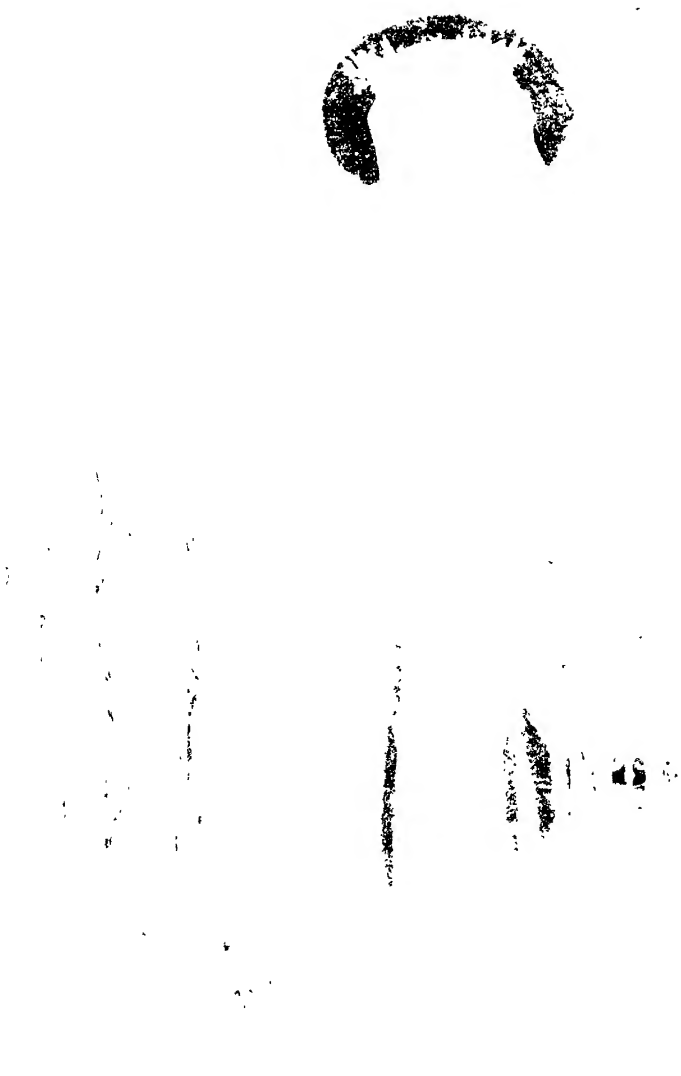
Let us take, for example, Holman Hunt's "Lady of Shalott" and Sargent's "Ellen Terry as Lady Macbeth." We shall find in both these well-known pictures, that the head of the figure being near the top of the design, a strange dignity ensues as regards the relation of that figure to the rest of the picture, as compared to the effect it would produce if placed low down. We shall also find that the effect of dignity is sti'l further increased by the height of the figure, and the fact that its main lines are vertical. The student has, indeed, had thrust upon him the beginning of the laws of composition, of which he will be a student to t e end of his days. Let us take first the single figure of "Ellen Terry as Lady Macbeth," by John Sargent. Here we find the act of usurpation, the crowning of the murderous queen by herself, set down in the composition with rare art. The crown in the upraised hand draws the eye to the agonised face, while the tall figure is draped in long upright lines of darker hue which lift the figure to tragic intensity, without one crossing horizontal line to check the tragic dignity of the face. The sheer drawing of this picture is a masterpiece. Again, in Holman Hunt's little black-and-white drawing of "The Lady of Shalott," in Moxon's Tennyson, we have the beautiful head of the lady almost pressed down by the top of the picture, giving to the figure the sense of the burden of the awful tragedy that has fallen upon her.

ELLEN TERRY AS LADY MACBETH,
BY J. S. SARGENT

A remarkable instance of majestic dignity expressed by compositional lines

Now this relation of the figure to the rest of the picture is enormous in its value in creating the impression, but an even more powerful factor in the building-up of the impression is the arrangement of the dark and the light masses in their effect upon each other and their relation to the whole. It is best to show this by example; but let the student first realise the close relation of all the arts and the sameness of their laws. He will benefit greatly by the lessons that every art has to teach him.

Painting is closely akin to music, and just as the line for drawing the forms yields the dominant effect of his composition—what may popularly be called the tune, so the arrangement of the light and dark masses of colour yields him his harmonies; just as in an orchestra the deep violoncellos and wood and brass build up the accompaniment and increase the impression. And just exactly as in music we may make the orchestra yield us the thunder and roar of the



THE LIGHT OF THE WORLD

"LAS HILANDERAS" (THE SPINNERS), BY VELASQUEZ
One of the great Spanish master's finest works

angry heavens, the tramp of armed men, the clash and fury of contending passions, the laughter of lightest merriment, the gay trip of dancing feet the subtle tenderness of the twilight or the sigh of a woman; so with colour, according to our mastery of its mighty powers, may we yield to the eye all the impressions of life that may be emotionally seen and felt through the sight, from the crash of the mightiest tragedies that fall on man to the uttermost delicacy of tendernesses that haunt the vision of a child.

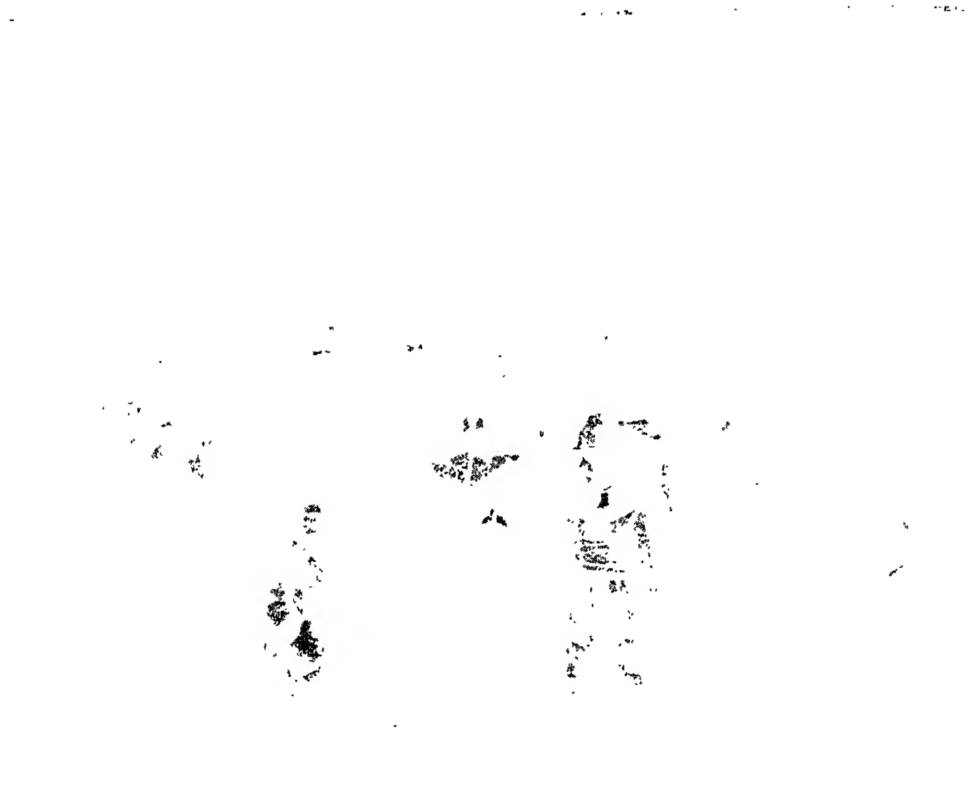
The Portrayal of Emotion. There is no emotion felt by the human being through his sense of sight which may not be rendered in colour by the mastery of the art of painting. And line and form and composition all play their equal part in building up that framework on which is to be placed the right and proper colour that gives the thrill of emotion through the eyesight, and so sends it in waves of colour into our senses, rousing, without our being able to tell why, the effect that the artist desires.

But, the student will ask, how is he to learn composition? Here again, as in drawing and colour, he must teach himself. And the only way to learn arrangement is to train the eye first through the work of the masters. By far the best and simplest way, as it is also the most delightful, is to make collections of black-and-white reproductions of pictures from every source within his reach—magazines, papers, books, photographs. The eye, thus constantly trained to good work, becomes so alert, and acquires such rightness of vision, that no amount of lecturing and theory can equal—nay, can approach. Let him begin with the pictures that are his favourites, and he will soon find his hand's skill trying to rival that of the masters. Let him from the beginning not copy the compositions of the masters, but try to evolve arrangement like theirs to express his own ideas; for he will early find that *their* arrangement makes his own brain fertile and feverishly anxious to express rival ideas, and to alter and rearrange and recast *their* ideas. From the very beginning let the student try to *create*—no matter what bad falls he may get in his endeavours.

Originality. If possible he should haunt picture-galleries and sale-rooms, and try to get any effect that has appealed to him. He will thus keep himself from being the mere imitator of one man, and will gradually evolve a style of his own, and a wide range of handling to produce results in a manner fitting to his own emotion. He will also train his colour-memory, and his copying will not be servile imitation.

There are to-day many monographs written upon the works of painters, which give a large number of reproductions of their works that are helpful in training the eye of the student.

What the artist can do with arrangement can partly be realised when we see what can be



"THE MUSTERING OF CAPTAIN COCQ'S COMPANY," CALLED "THE NIGHT WATCH," BY REMBRANDT
Illustrating "the broad, deep, resounding backgrounds of Rembrandt"

done with so rigid and hard a medium as the pen-line. Apparently the simplest of drawing effects, the pen-line is perhaps the most difficult of all. It is marvellous to see the variety in the style of artists in this medium alone. And when it comes to the use of the paint-brush, the student can in some measure grasp the fact that it will yield him a wide range of style, from the broad, deep, resounding backgrounds of Rembrandt and Velasquez (as in the examples which we reproduce) to the daintiest light brávurá effects of such painters as Le Sidaner. And the student would do well to learn all that every master can teach him. Above all, let him face the vastly encouraging truth that each generation needs its own artists—that the artist, above all things, appeals to his own age. The old masters are our great teachers, our helpers ; but for the generation in which we live we need our own poets, our own seers, our own artists.

Great Art deals with Contemporary Life. It is scarcely too much to say that all truly great art—except where it is purely decorative—deals with contemporary life, with things not invented by the artist, but actually observed by him. The old masters who devoted themselves to scriptural subjects form no exception to this rule. The subject was often merely an excuse for painting contemporary portraits in the costume of the time, or scenes that presented themselves to the painter's eye. The decline in the art of the early nineteenth century was mainly due to a departure from this rule. The learned reconstructions of the past which were then in vogue amongst academic painters are, however, rapidly falling into oblivion ; they have no real vitality. It was left to the modern French, the Barbizon men and the Impressionists, to return to the right path—to the study of Nature and contemporary life. Their efforts indicate the right direction, though their methods cannot always be recommended to the student.

Amongst the collections of studies in composition by great artists, perhaps one of the most valuable to the student is Turner's "Liber Studiorum" ; and though the originals are beyond the purse of many students, there has been published of late a capital book of reproductions in a cheap process at the price of half-a-guinea.

Detail of Secondary Importance. In making his studies for the composition of his pictures the student should not weight his hand with detail, but should use a stick of charcoal, or a water-colour brush, and sweep in broadly the masses of light and dark where he

A FRESCO, BY BENOZZO GOZZOLI, IN THE CAMPO SANTO OF PISA

Though it is meant to represent a scene from the Old Testament, it is really an exact representation of the Vintage in Tuscany

would like them to come in his colour scheme, only quite vaguely suggesting the forms that he will afterwards develop in detail. He will thus not only save himself an enormous amount of trouble, but he will be surprised to find how his mastery in composition grows by leaps and bounds. And he will start upon his picture with a good general idea of the finished effect.

It is a good thing also to get a rough effect in colours from this black-and-white scheme, as a guide for future use. These exercises in composition have an added advantage in training the hand to free, bold brushing, and will lead the student by many splendid accidents to the discovery of masterly handling which he will soon strive to get deliberately and by skill into his style. He will find Poore's "Pictorial Composition" (Macmillan) a valuable help.

Colour. Although the use of colour is primarily a matter of observation, feeling or instinct, it can only benefit the student to have an elementary knowledge of the nature and symbolism of colours. Without going into the purely scientific questions of the causes which produce the sensation of colour, and without analysing the spectrum, it is necessary to know that theoretically white is a mixture of the three primary colours—yellow, red, and blue. If the actual mixing of these paints produces a result far removed from white, this is entirely due to the impurity of the pigments. A mixture of two of these colours forms a complement to the third, thus:

Green (blue and yellow) is the complementary colour to red.

Violet (blue and red) is the complementary colour to yellow.

Orange (yellow and red) is the complementary colour to blue.

The juxtaposition of complementary colours produces a pleasurable sensasation to the eye.

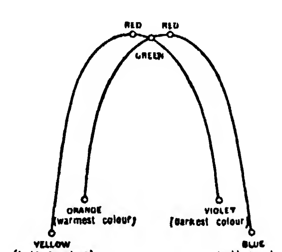
Black and white are not colours strictly speaking; that is to say, they are not contained in the spectrum, but are surrogates for pure light and pure darkness. In considering the scale of colours we must distinguish between the scale from light to darkness and the scale from warmth to coldness. Yellow, which, according to Goethe, is sunlight dimmed by the atmosphere of the earth, is the lightest colour. Though blue, if we follow the same authority, is darkness cleared up by the same cause, it is not the opposite pole to yellow. The scale from light to darkness leads from yellow to its complementary colour, violet, whilst the scale from warmth to coldness leads from orange (the warmest) to the complementary blue (the coldest).

In a diagram this can be expressed by two curves, terminating in these four colours, with red and green, which are more or less neutral in both scales near the apex of the curves.

The symbolism of colour is by no means an arbitrary convention, but is strictly based on the innate quality of the different colours which, according to their varying degrees of lightness and warmth, directly affect our senses and our imagination. Thus

a. Lightness corresponds with gaiety.

b. Darkness corresponds with seriousness.



c. Warmth corresponds with emotion, and

d. Coldness with absence of emotion.

Orange, which combines gaiety and warmth, is the opposite pole to blue, which combines seriousness and

coldness; yellow (gaiety and coldness) to violet (seriousness and warmth).

Black and white are only opposed as regards lightness, not as regards warmth, both being cold. They are the representatives of organic lifelessness, and they, as well as their mixture—grey—are therefore indicative of mourning. Through their contrast between light and dark they partake of *a* and *b* but not of *c* and *d*. Mixed with other colours they make these colours colder; but the mixture with white has a gayer, that with black a more sombre, character than the pure colour. Black is the colour of the sombre sphere of shade; white, of the glorious sphere of light.

Yellow and Violet. Yellow is the nearest approach to pure light, or white; violet to pure darkness, or black. As colours, therefore, they represent the extreme contrast between gaiety and seriousness. Yellow signifies the greatest vitality in the spiritual sense; violet the deepest renunciation, resignation and melancholy. Of all colours, yellow is the most easily soiled, and immediately loses its ideal character, producing the opposite effect. It is therefore the symbol of shame and humiliation. Impure yellow is to be found in the jaundiced complexion of an ailing person; it is the symbol of envy, malice, and hatred.

Violet expresses generally melancholy, resignation, and sombre seriousness, but signifies, through the participation of the emotional red, a seriousness which is the result of sad experience, that has not entirely overcome the recollection of lost pleasures, and therefore savours of melancholy regret.

Orange and Blue. Orange, the warmest colour, is influenced by the participation of yellow, and therefore retains to a certain extent an ideal character, which is not allowed to achieve its full effect by the sensual glow of red, the most emotional and most effective colour. It expresses pathos and dignity, and is the symbol of great splendour and majesty.

Blue, the coldest colour, expresses calmness and absence of emotion but contains sufficient colour to prevent it from sinking to the funereal stillness of black. As an ethical symbol it is not quite neutral. It signifies modesty, faithfulness, gentleness, and a certain longing without the acerbity of a melancholy resignation, which is sounded by violet.

Red and Green. Being midway in the two scales of intensity, these are, so to speak, the rulers of the entire sphere of colour—the principal colours. Red, the king of colours, being a primary colour, naturally stands higher than the secondary green, the queen of colours. Green excels in beauty and nobility the two colours which are of equal rank, orange and violet—as red excels the equivalent primary colours, yellow and blue, as regards nobility, power, and beauty.

Red expresses the height of emotion and is the symbol of passion, rage, warlike courage, and sexual love.

Green, as the complementary colour to red, symbolises kindness and gentleness, and is as soothing to the eye as the fiery red is exciting. Compared with red, green has a certain lack of emotional effect, but the yellow, which is one of its constituents, prevents it from sinking to the indifference of blue, and rather raises the impression to one of serene freshness and joy of life.

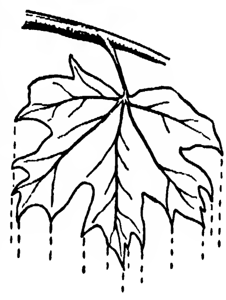
FLOWERS AND THEIR FRIENDS

Flowers and their Sources of Life. Water, Wind, and Animals in Their Relation to Flowers. How the Insects Help

Continued from page 508

By Professor J. R. AINSWORTH DAVIS

Guarding the Health of Plants. The health of a plant is prejudiced if water accumulates upon its leaves, and we accordingly find various contrivances to prevent this. A very pretty device is found in the " dripping points " into which the leaves of many trees are drawn out, and which may be seen in the lime (*Tilia*) and Norway maple (*Acer platanoides*). Rain drops from these points as from the tips of the ribs of an umbrella [91]. The arrangement is very characteristic for the trees of forests growing in wet latitudes, especially the tropics. An interesting illustration of its utility is afforded by attempts which have been made to introduce into Java and the Cameroons trees of economic value from drier climates. The leaves of these plants being unprovided with dripping points, rain is collected upon them and led to the growth of moulds, which soon put an end to the experiments.



91. NORWAY MAPLE

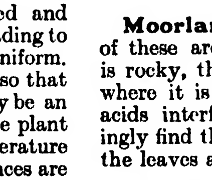
Another method by which leaves get rid of unnecessary moisture is by the development of a velvety surface, which greatly increases the area from which it can evaporate.

Since *Xerophytes*—desert or drought plants—have to make the most of the water available, we find that adaptation to this end is brought about in a variety of ways. Absorption is promoted and transpiration checked. The conditions leading to modifications of this kind are by no means uniform. It may be that the soil is rocky or sandy, so that water quickly drains out of it, or there may be an abundance of water which the roots of the plant cannot readily absorb, owing to the temperature being too low, or perhaps because substances are present which hinder absorption—*e.g.*, common salt and vegetable acids, as in peaty ground. Conditions above ground may also tend to bring about loss of water by transpiration at a greater rate than can be compensated by taking it up from the soil, as when the air is hot and dry, or there is an excess of light.

Plants of Deserts and Steppes. A well-developed system of roots, often extending very far into the ground, is typical of the plants which live in deserts and steppes, for such an arrangement is clearly necessary to suck up the scanty moisture available. In order to check transpiration, a reduction of surface is commonly brought about by reduction of leaves, and in such plants as cacti these are represented by prickles or spines, while the stem swells up and does the work that leaves usually perform [92]. The date palm, and various other plants associated with desert conditions, possess well-developed leaves, but these are covered with a tough and leathery skin, which prevents excessive evaporation of moisture.

The production of spines, thorns, prickles, and the like, is very characteristic of many plants living under arid conditions, and this has a two-fold explanation. It serves as a means of protection against browsing animals, and is also related to the reduction of surface brought about by the necessity for hindering loss of water. Illustrations are afforded by the Australian scrub and the thorny thickets of Africa.

In dry climates the leaves may assume a vertical position, which clearly checks transpiration by minimising the influence of the scorching sun. A similar arrangement is seen in the compass plants (*Silphium*) of North America, the flat surfaces of which face east and west. The excessive heat of the noonday sun is thus avoided, while the most is made of light which falls upon the plant earlier and later in the day.



92. MELON CACTUS

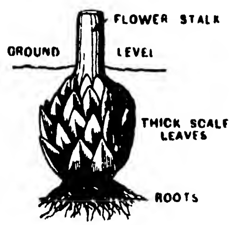
When the supply of water is scanty, it is often stored in underground shoots, such as bulbs and the like. There are South American and African plants allied to our wood-sorrel (*Oxalis*), in which the plant burrows underground during the dry season, and stores up water in its thickened scaly stem.

Moorland and Heath Plants. Many of these are xerophytes, for, where the ground is rocky, there is apt to be little water, and where it is swampy the presence of vegetable acids interferes with absorption. We accordingly find the root system well developed, while the leaves are often specialised so as to prevent undue evaporation. In gorse (*Ulex europæus*), for example, they are converted into spines; while in heather (*Calluna vulgaris*) and the various kind of heath or bell-heather (*Erica*), they are tough and somewhat narrow. Such leaves are usually grooved on their under-side, or rolled [93] in that direction, the meaning of this being apparent when we remember that the little holes (*stomata*) in the epidermis, through which transpiration mainly takes place, are on this

93. HEATH LEAF (cross-section)

side. For in dry, hot weather undue loss of water from this process needs to be prevented, and the grooving, or rolling, marks out a space in which the air is comparatively still, so that transpiration is much less rapid than if the stomata were exposed to the wind. When the moor is soaked by drizzling rain or drenched in fog, there is, on the other hand, a danger lest transpiration should be too much reduced, but the device described keeps the stomata dry, and enables them to discharge their office.

Seashore Plants. Many of these exhibit the same kind of modification which distinguishes plants growing in arid regions. It is true there is no lack of moisture, but the amount of salt present renders absorption difficult. Hence arise a well-developed root-system and over-ground parts adapted to reduce transpiration. Sometimes the leaves are leathery and prickly, as in sea-holly (*Eryngium*); while often they are thick and succulent, for the purpose of storing water, as in seawort (*Honckenya peploides*) and scurvy grass (*Cochlearia officinalis*).

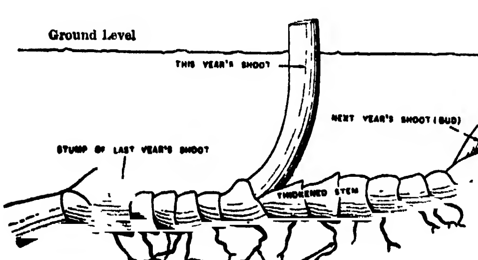


95. LILY BULB

In Alpine and Polar plants, again, we may find similar modification to those just mentioned, for a low temperature is unfavourable to absorption, and it is necessary to husband any water which may be taken up.

When there is a sharp alternation between summer and winter, or between wet and dry seasons, plants have to adjust themselves to different conditions at different times of the year. We may take as an example the winter modifications of a temperate climate such as our own.

Fall of the Leaf. This is not so much due to the direct action of cold as to its influence in more or less checking absorption of water from the soil. The supply of moisture being reduced, it is necessary for transpiration from the leaves to be correspondingly diminished. In such plants as pines and firs we find the evergreen condition, the leaves being only gradually shed. But as these leaves are very narrow, and covered with thick epidermis, there is no danger of an undue amount of transpiration.

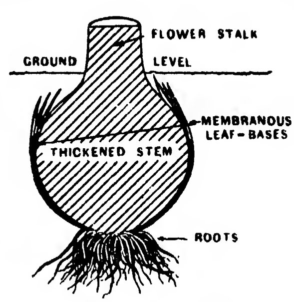


97. SOLOMON'S SEAL RHIZOME

It is far otherwise with the thin and comparatively delicate leaves of ordinary forest trees, which transpire on such a large scale that to retain them throughout the winter would be too dangerous. They are therefore discarded altogether. We have, in fact, the "fall of the leaf." This, of course, involves some waste of material, though not so much as might be imagined; for the advent of autumnal coloration is associated with the withdrawal of much of the living substance of the leaf into the twig on which it grows. This having been accomplished, a layer of cork is formed transversely at the base of the leaf-stalk, and the dead leaf readily falls off. The cork which covers the "scar," being of close texture and of waterproof nature, prevents evaporation, and stops the entry of disease germs. The same is true of the layers of cork which make up the dry outer part of the bark, by which the trunk and branches of the tree are invested.

94. HORSE CHESTNUT
Autumn twig

The leaves which are to make up the foliage of the following spring are formed before the onset of winter [94]. They are neatly packed up in winter buds, covered by firm protective scales, often of resinous nature. Cold and wet are thus excluded, and a further sheltering arrangement is often found within the scales in the form of woolly hairs, which invest the tender leaves as in a winter quilt.



96. CROCUS CORM
Section

Winter Storage of Food. In order to start work in the spring without delay, before the time when food is easily obtainable from the exterior, and while the young leaves are unfolding, a store of nutritive matter has commonly been laid in during the preceding summer. Sometimes such substances are stored above ground, as in the trunks of trees. Sometimes they are stored below, as in the thickened *bulbs* of lily [95], or *corms* of crocus [96], which are really underground shoots, as are the thickened *tubers* of potato and the pale subterranean *rhizomes* of iris or Solomon's seal [97]. Not infrequently a thickened root is the receptacle, as in turnip, carrot, and radish. These last-named plants are good examples of *biennials*—*i.e.*, they live but for two years, during the first of which they accumulate their store, while during the second they produce flowers and fruits.

We have already considered the structure and nature of seeds, which may also be regarded as a device for tiding over the unfavourable season of the year. Annual plants, the lives of

(111) Male flowers of Hazel, arranged in catkins, from which pollen is easily blown [see 99 (112 Bee sucking nectar from flowers of Willow

which do not extend beyond a single year, are commonly represented during midwinter by seeds alone.

Water, Wind, and Animals. If the egg-cells of a flower are fertilised by the agency of pollen from the same flower, they are said to be *self-fertilised;* if by pollen from another flower, *cross-fertilised.* As in the latter case healthier and more vigorous seeds are produced, it is not surprising that it should have been favoured in the course of evolution, and that innumerable devices should have come into existence by which self-fertilisation is hindered and cross-fertilisation promoted. Such devices very largely have reference to the process which precedes fertilisation—*i.e.*, *pollination*, the transfer of pollen to the stigma, or, in naked-seeded plants, direct to the ovules. They more or less prevent *self-pollination* and facilitate *cross-pollination.*

Since pollen-grains are not themselves capable of movement, it is requisite that, to secure crossing, they should be transferred by some outside agency from the anthers of one flower to the stigmas of another. This transference may be effected by water, wind, or animals, the last, of course, carrying out their important work quite unconsciously.

Water as a Pollen Carrier. In certain aquatic plants the movements of the surounding water bear the pollen to its destination. The best example is probably that of Vallisneria [**118**], commonly grown in aquariums in this country. Self-pollination is entirely prevented by a method which is adopted by many other forms. The stamens and carpels are developed in different flowers, which grow upon separate plants. The female flower is placed at the end of a spiral stalk, which uncoils when it is ready to open, and brings it to the surface.

Meanwhile the ripe male flowers have separated themselves from their stalks, and, being lighter than water, float about like so many little boats, being drifted here and there by the wind. Their perianths expand and the stamens project, lifting up their anthers so that the pollen is kept dry. Should one of them be driven against a female flower, some of the pollen is likely to adhere to the sticky surface of one or other of the three projecting stigmas, and thus cross-pollination is brought about. When the egg-cells are fertilised, the stalk of the female flower coils up again, so that the seeds mature in a sheltered situation, where they are safe from the attacks of seed-eating animals.

How the Wind Carries the Pollen. In the case just dealt with, wind plays an important part in the transfer of pollen, and in many land-plants it is the sole agent. The cone-bearers (*Coniferæ*) rely upon it for the discharge of this important office, and we may take the Scotch pine (*Pinus sylvestris*) as a common type. Here, again, self-pollination is entirely prevented by the flowers being of two kinds, male and female, which are borne on the same tree.

As is usual in such cases, vast quantities of dust-like pollen is produced, in order to ensure that some of it should be carried to the ovules, for in plants of this kind there are no stigmas. In some years the amount produced in forests of pine or fir is so enormous that the ground is thickly covered with the yellow dust. This is the origin of the so-called "sulphur showers."

Transfer by wind is facilitated by the fact that two little air-filled bladders are attached to each pollen-grain [**114**]. At the time when the pollen is shed, the ovule-bearing scales of the female cone are slightly separated, and a sticky fluid exudes from between them. By this the pollen-grains are caught, after which it gradually dries up and draws them down to the ovules, so that they can perform their office.

Hazel a Good Example. Most of the ordinary trees of temperate regions are also wind-pollinated, and open their flowers in spring before the new leaves have emerged from their buds, and when, therefore, the pollen-grains are most likely to get blown to the stigmas. A conspicuous example is hazel (*Corylus Avellana*), where the flowers are once more of two kinds borne upon the same plant. The male flowers are aggregated into long, pendulous catkins [**111**]—popularly known as "lambs' tails"—and are easily shaken by the slightest breeze, by which their dust-like pollen is carried away. The female flowers are in bud-shaped groups, from which the sticky pink stigmas project [**99**].

A number of herbs with inconspicuous flowers are also pollinated by means of wind—*e.g.*, many grasses. We may take Timothy grass (*Phleum pratense*) in illustration, for it presents us with many points of interest. The numerous flowers are here closely packed into an elongated spike [**101**], and though each of them contains stamens and pistil, there is a special arrangement by which self-pollination is hindered. In the lower part of the spike we shall find the younger flowers, with stamens still unripe, but mature stigmas projecting to the exterior ready to catch any pollen that may chance to be blown against them. The stigmas of the older flowers in the upper part of the spike have for the most part done their work and shrivelled up, while the stamens are now mature. The anthers are so attached to the long, slender filaments that they are shaken by every breath of air, and their pollen easily dispersed. Another very interesting device is found in the wind-pollinated flowers of nettles, for the ripe stamens uncoil like springs and launch the pollen on its course.

Flowers and Their Bird Friends. Pollen may be transferred unconsciously by mammals, birds, snails, and insects, about each of which it will be necessary to say something.

One of the trees (*Freycinetia*) native to Java bears flowers with beautiful pink petals, which are eagerly devoured by the kalong, or fruit-bat (*Pteropus edulis*), and there can be no doubt

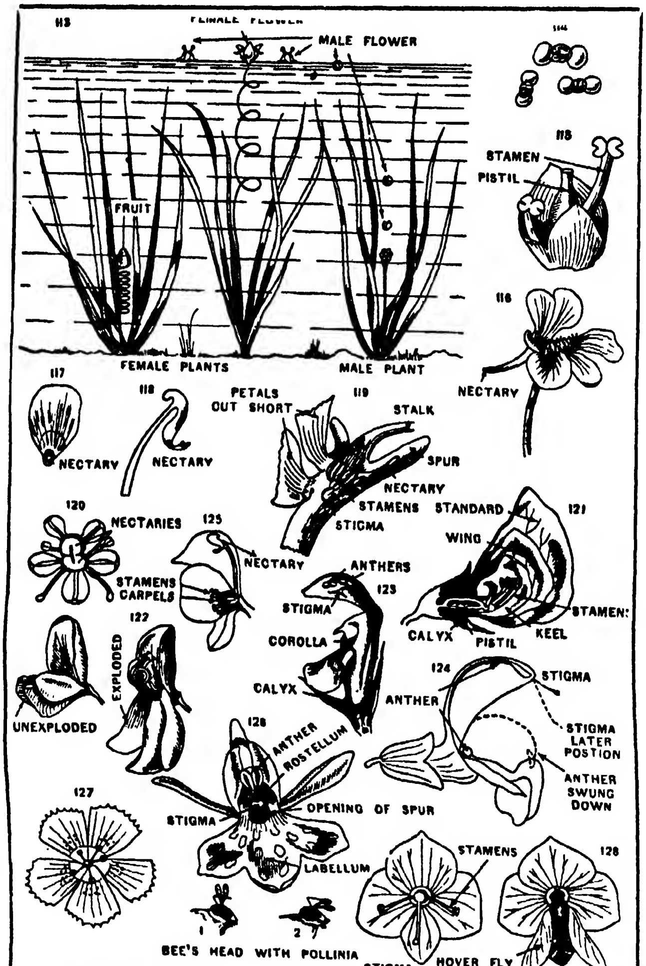
that the pollen of the male flowers which adheres to the furry snout of this animal is carried to the stigmas of the female flowers. It also appears that certain insect-eating bats in the West Indies hunt for their prey among the blossoms of certain trees, and transfer pollen in the course of their feeding operations. In Australia it is not impossible that the flowers of a common shrub (*Dryandra*) may be cross-pollinated by the agency of kangaroos.

The beautiful little humming birds (*Trochilidæ*) of America, the sun-birds (*Nectariniidæ*) of Africa, which resemble them in appearance and habits, and some few other forms, visit flowers for the sake of the sweet fluid (nectar) they contain and possibly also in the search for small insects. Such flowers are relatively large and conspicuous, and commonly of a bright scarlet hue. Those visited by humming birds are bell-shaped and pendant. Their shape is adapted to that of the heads of their guests. The work of humble slugs and snails is very important in the process of nature. Some of these voracious creatures visit certain plants with inconspicuous flowers which grow in damp places, and drag along pollen-grains in their slime from one blossom to another. Such is the case with the little golden saxifrage (*Chrysosplenium*), common in the neighbourhood of springs, and also with duckweed (*Lemna*), the small floating plants of which so commonly cover stagnant ponds and ditches with a continuous sheet of green [115].

The vast majority of conspicuous flowers are cross-pollinated by the agency of insects, and in the course of evolution an immense number of mutual adaptations have arisen between them. [See **100**, bees sucking sea-holly; **103**, bee sucking hyacinth; **112**, bee sucking flowers of willow; **98**, red admiral butterfly sucking everlasting flowers.]

The Three Kinds of Flowers. In some cases we find that, as in Scotch pine and hazel, the stamens are borne in separate flowers, which may be on the same or on different plants. Wild arum (*Arum maculatum*) [107 and 109] illustrates the former condition, and willow (*Salix*) the latter. Various compromises are also possible by ringing the changes on the three possible kinds of flower—*i.e.*, hermaphrodite (with both stamens and pistil), male and female. A given species may possess hermaphrodite and either male or female flowers, or, again, all three kinds may be present. The modes of distribution in such plants are also extremely varied. Male and female flowers may arise from hermaphrodite ones by suppression of pistil and stamens respectively.

In most flowers both stamens and pistil are present, but it by no means follows that self-pollination takes place, for, as already described for Timothy grass, the stigmas may mature before the pollen is shed, though the opposite state of things is more commonly true, as in



113. Vallisneria. 114. Pollen-grains of pine (magnified). 115. Duckweed flower. 116. Indian cress. 117. Buttercup petal. 118. Monkshood nectary. 119. Violet (section). 120. Hemlock. 121. monkshood (*Aconitum*). Besides which, it very often happens that the anthers and stigmas are so placed in relation to one another that self-pollination is impossible. Some flowers are also *self-sterile—i.e.*, if pollen reaches the stigma of the same blossom it is not able to bring about self-fertilisation. We shall see later, however, that self-pollination may be possible from the first, or may be effected as a last resort, or may even be provided for by special contrivances.

How the Flowers Invite Insects. The two chief means are colour and odour. The colour depends upon the nature of the guests to be enticed. White and yellow appear to be agreeable to a large number of small insects belonging to various groups, which visit such forms as cow parsnip (*Heracleum*) and buttercup (*Ranunculus*). A pale or white tint is also characteristic of flowers which open in the evening and cater for moths, and it clearly renders them as conspicuous as possible. Red attracts butterflies, and brownish-red is preferred by wasps, while purple and blue appeal more particularly to bees and hover-flies. Dull red and livid colours, especially when arranged in spots or blotches, are affected by flies which like carrion and other noxious substances.

Flowers of small size may be rendered conspicuous by being crowded together in large numbers, as in elder (*Sambucus*), the carrot and parsnip order (*Umbelliferæ*), and the dandelion order (*Compositæ*). The last case is particularly instructive, for it includes a variety of specialisations of different kind. The individual florets which make up the head may be all regular, as in thistles; all irregular—*e.g.*, dandelion (*Taraxacum*); or, again, the inner disk-florets may be regular, while the outer ray-florets are irregular, of which condition, sunflower (*Helianthus annuus*) [**106**, lower figure] and daisy (*Bellis perennis*) afford examples. The irregular ray-florets have given up the function of producing seeds, and may be regarded as "signal flags," by which the conspicuousness is greatly enhanced. Allusion has elsewhere been made to the odours of flowers.

The Flower's Reward to Invited Guests. These are chiefly pollen, nectar, and sweet sap. Pollen flowers, of which red poppy (*Papaver Rhoeas*) and potato (*Solanum tuberosum*) are examples, offer only the first kind of reward; while nectar flowers, as their name indicates, afford the second, and often pollen in addition. Our common British orchids are visited by insects which bore for sweet sap.

Nectar may be secreted by nectaries situated in various parts of the flower, and differing greatly in shape and character. In the wallflower order (*Cruciferæ*) they are in the form of little fleshy projections of the floral receptacle, and in the dead-nettle and foxglove orders (*Labiatæ* and *Scrophulariaceæ*) they belong to the same region, and are in the form of a fleshy ring at the base of the pistil.

The pointed spur at the back of an Indian cress flower (*Tropæolum*) [**116**] is a nectary belonging to the calyx. In a very large number of instances the petals secrete nectar, and an instructive series of cases is presented by flowers of the crowfoot order (*Ranunculaceæ*). In buttercup (*Ranunculus*) there is a nectar pit covered by a little scale at the base of each petal [**117**], while in columbine (*Aquilegia*), Christmas rose (*Helleborus niger*) [**110**], larkspur (*Delphinium*), and monkshood (*Aconitum*) [**118**], all or some of the petals are converted into tubular nectaries of various shape. Sometimes the stamens undertake the work of nectar production, a pretty instance being that of violets and pansies (*Viola*) The nectaries are here a pair of threads, which grow back from the two lowest anthers [**119**], and project into a spur belonging to the undermost petal, which serves to store up the sweet fluid until insects come to probe for it. And, lastly, nectar may be secreted by the pistil, as in the carrot and parsnip order (*Umbelliferæ*), where the nectaries are represented by a swelling on the top of the ovary [**120**].

The Insect's Guide to the Treasure House. If an insect is to do its work of transferring pollen successfully, it often happens that it must make its visit to a flower in a particular manner, which involves going straight to the nectar, without waste of time in hunting round. Hence have been evolved nectar guides, in the form of streaks, spots, or blotches, which indicate the position of the coveted treasure. In rhododendron [**108**], for instance, there are streaks on the upper part of the corolla, which converge to the opening of the cavity where nectar is stored.

In a large number of small regular flowers, mostly of white or yellow colour, which cater for a miscellaneous crowd of short-tongued insects, the nectar is fully exposed to view. We find this state of things in most members of the parsnip and carrot order (*Umbelliferæ*), and in some saxifrages. Not unlike these, but somewhat more specialised, are flowers which partly conceal their nectar, and lay themselves out for a rather more select circle of guests with somewhat more elongated mouth parts. Such are most members of the wallflower order (*Cruciferæ*), buttercups (*Ranunculus*), stitchworts (*Stellaria*) and their allies, barberry (*Berberis*) and cinquefoil (*Potentilla*). And, lastly, we have flowers which completely conceal their nectar in deep recesses or long spurs [**116** and **118**], and attract the most intelligent and highly specialised insects, such as bees and butterflies, in which the mouth-parts are drawn out into a long proboscis that forms a very efficient sucking organ. Many such flowers are irregular, and adapted to the shapes of particular guests; while red, blue, and violet are the favoured, though not the only colours. Here belong foxglove (*Digitalis*), honeysuckle (*Lonicera*), larkspur (*Delphinium*), and monkshood (*Aconitum*), together with the orchids, which offer sweet sap instead of nectar.

To deal fully with the innumerable arrangements for cross-pollination would occupy a large volume, and it will be possible here only to describe briefly a few of the more interesting native forms which are visited by the higher insects.

THE PRACTICE OF DRAIN LAYING

Intercepting Chambers. Manholes. Laying the Pipes. Iron Drainage. Stable Drains. General Arrangement of Drains

Continued from page 573

By Professor R. ELSEY SMITH

Laying Drains. We have now to consider how the various fittings already described are combined into a complete drainage system, and it will be convenient to look at the work of drain-laying before referring to the preparation of a drainage plan. For the moment, we shall assume the existence of such a plan on which the drains and all fittings are shown and on which the levels of the sewer and the inclination of the drains are fixed.

The laying of the drains is often deferred till other work in the building is far advanced, but it involves a large amount of excavators' work, and will now be described. The first operation is the excavation and strutting of the trenches, which in most cases are made of the minimum width in which a man can work. The bottom is carefully levelled to the falls shown upon the drawings—not stepped as in the case of trenches for walls—and where it is required a layer of Portland cement concrete is spread evenly over the bottom of the trench. Concrete is always desirable, but some local authorities do not insist upon it under rain-water pipes. The concrete should be 6 in. deep and should extend for a width of 6 in. beyond the outer face of the pipe on each side. The lower 6 in. of the trench should be excavated to the exact width required for the concrete, even if a greater width for working be necessary higher up. The concrete slabs on which the manholes are to be built are also put in. They are usually 9 or 12 in. thick and extend beyond the outer face of the manhole for about 9 in on all sides. Layers of concrete are also required under traps and gullys.

Connection with Sewer. The actual connection with the public sewer, for which purpose junctions are often built into the sewer, is usually made by the local authority, who bring up the branch drain to the point where the private property abuts on the road. The laying of a drain begins from the lower end, and the spigot end of a pipe should always be the lower. Every drain should be laid in a perfectly straight line from manhole to manhole, or from any gully or trap to the manhole. The fall in the same distance should also be absolutely uniform. The reason for this is, that in a drain so laid it is possible, with the help of a mirror, to see through it from manhole to manhole and to detect at once the position of any obstruction.

The illustration [35] shows a plan of a town house of considerable size and the method of draining it. Fig. 36 shows the plan of a large country house. In the latter there may be a considerable length of drain beyond that shown, so as to carry the system to a sewer or to the point where the sewage is to be dealt with, but the construction will be similar, lampholes and manholes being provided alternately at intervals.

Forming the Intercepting Chamber Floor [37]. The footings and wall of the chamber must be raised to the levels at which the drains enter it. The intercepting trap is fixed at its proper level standing on a bed of concrete and set in concrete. The necessary channels are selected from the list of the maker whose goods are specified, and are first put together dry, to see that they fit properly the positions for which they are intended, and are then laid on fine concrete, the joints being left free till they have been very carefully made in cement. The main channel is jointed to the upper end of the trap, and if this channel can be obtained in one length, the upper, or socket, end receives the main drain from the building. In a large manhole the channel may be in two or more lengths, jointed. The channels from the branch drains, if any be required, are then fixed. The bottom or invert of each discharges into the main channel, and the upper end of each is jointed to the branch pipe. When these are fixed, fine concrete is filled in between the channels, care being taken not to break the joints, and is banked up from the edges of the channels to the side of the chamber. In the case of a chamber receiving several branch drains at the sides, the banking must be curved to conform to the various branch channels, and often forms a somewhat narrow tongue between two curved channels. All this work requires great care, as the slightest flaw may allow the escape of water and result in the chamber being condemned. This banking is finally finished with a smooth trowelled face with Portland cement mixed with a little sand.

In order to avoid the complicated work of forming the bottom of a manhole as described, manufacturers now provide channels and junctions in one piece, suited to a variety of combinations. These may be utilised to form the bottoms of manholes. Some of these are also provided with covers [33, 34] to close the channels and prevent any possibility of the solid matter carried in the sewage being washed out of the channel by a sudden flush, deposited on the banks, and then left to decompose. Even when this is not provided, the fact that the bottom is in one solid piece, without a multiplicity of joints, is an advantage, but the fact of its being so may sometimes interfere with the nice adjustment of the drainpipe to the channel, possible in the ordinary method.

Building the Manholes. When the channels are set they are protected with boards, and the manhole or chamber is built up by the bricklayer to the level of the ground. If it is deep, he builds into one side or angle a series of iron steps or bars, called *climbing irons*, to render the bottom of the m nhole accessible when necessary for inspecting or cleansing the drains. The size and form of a manhole depends on the number of drains which enter it, but, except in the case of a very shallow one, it should not be less than 2 ft. 6 in. in length or width, or it is difficult to use cleaning rods. The top may be contracted by means of oversailing courses [see BRICKLAYER], or it may be covered with a single slab of stone [Fig. **31**, page 571], which is perforated and rebated [see MASON] to receive the *manhole cover*.

The Manhole Cover. The manhole cover consists of an iron frame (which should be galvanised) with a flange, which is bedded in cement on the brickwork top or in the rebate of the stone. There is a groove running all round the frame, and the top or cover has on its under side a flange which fits into the groove and seals the manhole. When closed, this groove may have sand or water placed in it to make an air-tight joint, but the best method is to make a joint with Russian tallow, though other compositions are used. The object of making the cover air-tight is to prevent the escape of sewer gas and for additional security double covers are often arranged for and should be used wherever a manhole has to be constructed within a building.

The cover, usually loose, is in some cases screwed to the frame at the angles; but if this is done, the holes must not be placed inside the frame, or, in the event of one of the screws being left out a free passage for sewer gas is provided. The top should be secured to a lug or flange outside the grooved channel. The walls of the manhole are often rendered in Portland cement [see PLASTERER] for the lower part or to the full extent of their height. In the best class of work, interiors of manholes are often built with glazed bricks.

Fresh-air Inlet. Every intercepting chamber must have a fresh-air inlet. For this, an ordinary drainpipe is taken into it near the top, which should be of the same diameter as the drain passing through it. This is taken to a selected point and connected with a vertical iron shaft, finished with a box-shaped head [Fig. 32, page 571]: in the front of this one or more diaphragms, formed of thin sheets of mica and hinged at the top, are placed, so that, in the event of there being any pressure of air from the inside, they will close the orifice and prevent its egress, but will readily open to admit fresh air to the chamber and thence to the drain. This apparatus requires periodical attention otherwise the diaphragms are liable to become fixed, and thus permit the egress of sewer gas.

The ordinary *inspection chamber* [**38**] only differs from the intercepting chamber in that it has no trap at the outlet and no fresh-air inlet, otherwise it is constructed in the same manner —a cleaning pipe replacing the intercepting trap.

Where a chamber is only required to allow of change of directi n in the drain [**39**, **40**], it may be kept smaller but is in other respects similar.

Lampholes. Lampholes [**41**] are useful in long, straight runs of drainpipes which receive no branch drains, enabling inspection chambers to be built further apart than would otherwise be the case. They are formed with ordinary drainpipes placed vertically over the drain, connected to it with a junction, which in this case must be a right-angled junction, and extending up to just below the ground level. The top is securely closed with a stopper, and may be buried two or three inches under the ground and marked, or—which is a better practice—terminate in a small chamber with a manhole cover. The object of this pipe is to permit of a lamp or candle being lowered to the level of the drain, so that it may be examined from the manhole above or below it in case of an obstruction.

Laying the Pipes. The drain from the intercepting chamber to the next manhole or to a gully, soil-pipe, or ventilating pipe is usually put together dry and carefully levelled. In very good work special chairs of earthenware are used to raise the pipes about 2 or 3 in. from the concrete bed to allow of the joints being made all round, but this is often done with pieces of brick or stone. The ordinary joint is made with Portland cement gauged with as little sand as possible. The socket of one pipe is coated with the material, and also the spigot end of the next pipe, and the latter is then thrust into the socket, care being taken to see that it is properly centred and goes well home and that the joint is at all parts well filled with cement. The joint is afterwards carefully smoothed externally with a trowel and finished with a splayed surface or collar [**13**, **14**, page 571]. The inner face of the joint is also carefully cleaned, the workman thrusting his arm into the pipe and wiping off any cement which may be forced up between spigot and socket of the two pipes, and which, if allowed to remain, would obstruct the flow of the sewage.

A *badger* is sometimes employed in this operation. It consi ts of a block of wood smaller than the pipe, but with a rubber edge and a wire handle. It is placed below the joint before it is made, and afterwards withdrawn, bringing away any cement. Every pipe should be separately laid so that this operation may take place. If two pipes are joined before being laid in the trench, the total length will be found to o great to permit of it Joints between pipes and channels or gullies are similarly made, and in any case where an inspection or cleaning eye is introduced the run of the pipes from this point to the next manhole should be perfectly straight and the fall perfectly even, as described, between manholes.

Special Joints. Other forms of joints are used between pipes. One of the most usual

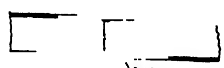
41. Lamphole.

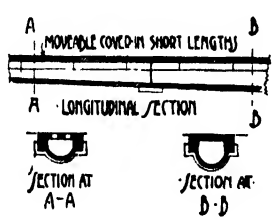
is known as Stanford's joint [15, page 571], the patent for which has expired. In this joint the socket is lined with a compo ition formed with 1 part of clean sharp sand, 1 part of boiled tar, and 1½ parts of sulphur. The surface is slightly bevelled, the spigot has a band of the same composition slightly rounded, and the two when brought together form a close joint which ensures that the pipes are truly centred. The surface of the joint is smeared with tallow before the pipes are fitted, and the spigot end must be driven well home to ensure a close internal joint. The outer edge of the joint is often finished with a cement collar. Another form of joint has the composition cast on in the form of a screw, the pipes being screwed together in fixing. A thin layer of cement composition is used with this joint.

A special joint for pipes with a deep socket is formed with two separate rings of composition with a clear space between. After the pipes are put together this space is filled with liquid cement from a hole at the top formed for the purpose. This forms a strong water-tight joint. Where a drainpipe is to be connected with a vertical soil or ventilating pipe—a connection which must always be direct, without any trap or gully—a bend must be used to connect the inclined drain and the vertical pipe. The end of the pipe, if of iron, is inserted into the socket of the bend and the joint made in cement. If the pipe is a lead one the end has a ring of brass, termed a *sleeve* or *ferrule*, fixed on its outer surface before the joint is made [see PLUMBER].

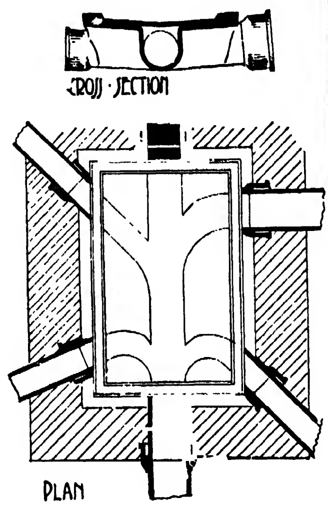
When any section of a drain is completed it should be at once tested as hereafter described. If every joint is found to be absolutely sound and no leakage occurs, concrete may be filled in around the pipes very carefully. Each joint must be examined, the upper surface by the eye, the lower surface by placing the hand below to see if there is any moisture exuding from the joint. The concrete is filled in under the pipes and the chairs or bricks used to raise the pipes are left in position. The concrete is in most cases filled in till the crown of the pipe is covered with 6 in. of it. Great care must be exercised in depositing the concrete, as any serious jar may break one of the joints, and when re-tested after the concrete has set the length may not hold water and have to be taken up and re-laid. The trench above the concrete should not be filled in till this re-testing has been done, for should a defect be found the labour will be thrown away.



42. JOINT FOR IRON PIPES.



44. SECTION OF AN IRON STABLE CHANNEL.



43. IRON MANHOLE WITH SIDE INLET.

Iron Drainage Fittings. In addition to the various forms of earthenware goods hitherto described, cast iron is employed a good deal. In any drainage scheme which involves carrying a drain under a building, the local authorities usually enforce the use of iron pipes of heavy quality for such parts of the work as pass under the buildings.

Iron pipes are described by the weight in lb. per yard run. The following weights are usual for house drains: 4 in., 54 lb.; 5 in., 72 lb.; 6 in., 91 lb. The pipes used for this purpose are cast with deep sockets at one end, and a small projecting bead at the other. They are made in longer lengths than stoneware pipes, and are usually 3, 6, 9, or 12 ft. long. The iron drain should extend from manhole to manhole, to avoid joining them with stoneware pipes, and the joints are made by inserting in the sockets of each pipe a ring of tarred yarn, then running in "blue" lead, so called to distinguish it from white or red lead. Blue lead is melted and poured into the joint, and afterwards caulked or hammered [42].

It is becoming increasingly common to use other fittings of iron, and to carry out entire systems of iron drainage. For this purpose not only pipes, but all the parts and fittings already described as of stoneware are now also made in cast iron.

Makers now manufacture intercepting and inspecting manholes cast in one piece. These consist of shallow iron frames or boxes [43] within which the channels are formed, and outside which the various sockets for receiving the main and the branch drains are cast in at the required angle. An outlet or spigot end is also cast on for jointing to the drain below. The channels may be half round, or they may be extra deep, equal in depth to the diameter of the pipe. These

chambers are stocked in a great variety of forms to suit various sizes of drains, and fitted with branches of various sizes and at various angles. Any combination not stocked can usually be supplied with little delay.

The manhole and all its branches must be set out, and the angles at which they enter measured, before the manhole is selected or ordered. When this is done, no difficulty should arise in fitting up. The great advantage of such a manhole is that, being in one piece, there is no possibility, if the casting is sound, of a leak within the manhole itself, and it is provided with a top resembling an ordinary manhole cover, fitting into a groove and secured into position, which renders the manhole both gas and water tight. There is no possibility, therefore, of sewage overflowing the channels and decomposing, as in an ordinary manhole. Such a manhole, including the cover, is only a few inches deep, and must be placed within a chamber for easy access, but the chamber need not be constructed with the same care as is necessary when an open drain passes through it.

The advantage a complete system of iron drainage possesses over earthenware is in its greater power to resist the disturbing influences due to settlements, vibration, or any external pressure under which an earthenware pipe might be cracked, and allow leakage. The surface of the iron must be protected from corrosion. This is generally done by a coating of *Dr. Angus Smith's Solution*, which consists of a mixture of coal-tar and pitch, with about 5 per cent. linseed oil, and sometimes a little resin, the whole heated to a temperature of about 300° F. The iron to be treated is plunged into the mixture and left in till it attains the same temperature, then removed, and allowed to cool in a vertical position. The best results are held to be obtained when the iron, before insertion, is heated to a tempreature of about 700° F., but this increases the cost. Glass-lined or enamelled iron channels and pipes are used sometimes, but are expensive.

The small size of the manholes used in iron drainage systems, which are in some ways advantageous, have this drawback, that in the event of the outlet being temporarily stopped, owing to the sewer being fully charged, there is very little space in which the water collected by the drain can accumulate, and it will speedily overflow; whereas the large cubic space provided in a deep manhole may, under such circumstances, temporarily accommodate the drainage till the stoppage is removed.

Stable Drainage. Stable drains are of a special character. Within the stable itself they are designed to collect and remove from every stall and loose-box the horses' urine. It is not desirable that the floor surface of the stalls should have any great inclination, nor should channels into which a horse might tread be left open.

Stoneware channels are liable to breakage, and all such drainage is best executed in cast-iron channels, the depth of which is regularly increased, so that the fall is obtained in the channel itself, while the top is kept at a uniform level, or nearly so, and may be covered with strong perforated cast-iron plates [44]. The channel may, in most cases, be run to the external wall, and discharged into a stable gully placed outside. Where this is not possible, traps, with strong iron covers, may be provided, and an underground iron drain taken outside the building.

The covers to channels and traps are easily removed for cleaning, but cannot be disturbed by the horse. Open iron gutters are also sometimes used. They consist of several small shallow parallel channels with ridges between, which are arranged to give a foothold to the horses. All iron work to be laid in a stable floor must be provided with a roughened surface, to give a foothold. Channels are sometimes formed in concrete, with iron kerbs built in on either side to receive the necessary covers.

General Arrangement of Drainage. The drainage of individual buildings as applied to systems of water-borne sewage, with few exceptions, depends upon the action of gravitation, and in arranging a system of drainage this circumstance must not be lost sight of from the first. Care must be taken to see that the levels of the building or site to be drained are such as to allow of the drainage being taken to the public sewer, or to any other required destination with a sufficient fall to ensure its efficient action. In the case of water not carrying sewage, such as water collecting in foundations, it may, if necessary, be collected into a *sump*, which is a chamber sunk below the level to which the water rises, and in which it collects, and from which it may be pumped up so as to flow into a drain; but even this is undesirable, as it means frequent attention and expense. This system is not applicable to sewage from private buildings, but it is sometimes employed on a large scale in sewerage systems.

Detailed Arrangements of Drainage. These vary so greatly under different circumstances that it will be possible only to refer to the general principles involved. The first matter to be determined is the ultimate destination of the sewage or water to be dealt with, and the level of the outfall of the drain. Where the difference of level between the lowest part of a building to be drained and the outfall is ample, it removes what may be a serious difficulty should there not be depth for an adequate fall in the drains.

Self-cleansing Drains. For a drain to be self-cleansing the liquid in it should flow with a velocity of at least 3 ft. per second. The velocity is considerably reduced when the drain is only filled to a small proportion of its capacity, which is the usual condition of domestic drainage, and most local authorities require a sufficient fall to give a velocity of approximately 5 ft. per second when the drain is running half full.

A table of the approximate inclination to which drains must be laid to secure various velocities when flowing *half-full*, and the number of gallons discharged per minute when flowing *full* bore *:

* Compiled from tables in Hurst's Architectural Surveyor's Handbook.

" ..	1 in 125	4	687
" ..	1 in 90	5	820

It is not, as a rule, convenient for the invert of the manhole at the head of the drain to be less than 1 ft. 6 in. from the ground level, and the fall being determined and the length of drain set out, the actual levels of the various manholes and of the outlet may be calculated in reference to a fixed datum. When possible, it is desirable to make the fall in the drain follow any general inclination in the surface of the ground, so as to save as much deep digging as possible; but the planning of an efficient drainage system must not be in any way sacrificed to do this. In cases where the sewer is very deep, it is usual to lay out the whole system as far as the intercepting chamber to ordinary falls, and to give the last length of pipe between the syphon trap and the sewer the necessary inclination to make the connection.

Where the depth available is ample, the open channel running through the manhole may be given a sharper fall than the general drain (say, 1 in. in 1 ft.), so that the contents before reaching an intercepting trap may attain extra velocity.

Drains not Self-cleansing. Where the depth between the head of the drain and the outfall is inadequate to give the desired fall, the levels must be worked out very closely, and care taken in planning to make the length of the drain as short as possible. It may be necessary to assist the cleansing of the drain by an *automatic flushing tank* [see PLUMBER] placed at the head of it. Water is allowed to flow into this tank at a regulated speed, and when full it discharges automatically its entire contents rapidly and with high velocity into the drain, thereby scouring it out. The outlet of the tank should be as large as the drain to be flushed, the object being to charge the drain fully. The tank should contain not less than 50 gallons for flushing a 4-in. drain, and the frequency of the flush may be regulated. Tanks with larger capacities may be used, and are necessary for larger drains.

Size of Pipes. The size of drainpipes is regulated by the work they have to do. Where the sewage system is separate the maximum flow can be readily gauged, and, as an example, the regulations of the Board of Education require a 4-in. pipe, unless it is connected to more than ten w.c.'s, in which case it must be 6 in.

If the rainwater is carried by the same pipe there is a liability in times of excessive rainfall for the drain to be choked with water if it is inadequate to carry it off. It is necessary then to calculate the area from which water is collected into the drain, and it is usual to allow for collecting the following quantities of water as the result of rainfall in ordinary districts in England:

From roofs ..	..	0·75 in. per hour.
From paved yards	..	0·75 " " "
From gravel paths	..	0·40 " " "
From meadow land	..	0·10 " " "

Occasionally, for short periods, a fall at the rate of 1 in. and even more per hour may have to be dealt with from roofs.

Position of Inspection Chambers. With a view to economy it is desirable to use as few manholes as is consistent with efficiency, and to converge as many drains as possible at each. In a soil-drain every connection and every change of direction must be made at a manhole [38, 39, 40]. In a rainwater drain the same principle should be observed as far as possible, but if the main run is laid in a straight line to true falls and only conveys rainwater, most local authorities allow junctions to be made with it. When rainwater branches must be taken into a soil-drain, and the connection cannot readily be made in a manhole, a separate rainwater pipe should be laid from manhole to manhole alongside or above the soil-drain, to receive such connections.

Position of Intercepting Chamber. The intercepting chamber [37] is usually required to be placed on the owner's land, but as near the public sewer as possible, when one exists, or near the cesspool. In some town districts where houses are built up to the edge of the footway they are permitted in the public footway. In most cases at least one other inspection chamber is necessary, placed close to the most distant point to which the drain requires to be carried.

In the town-house plan [35] the house drains and the stable drains have in each case only the intercepting chamber and one o her. In the country-house plan [36], in which the rainwater drains and soil-drains are separated, many chambers are required, due partly to the large number of branches, partly to the changes of direction. The rainwater drains are given a smaller fall than the soil-drains, which is permissible as they have not to convey solid matter. Details of some of the chambers are given, indicating the method of combining the various fittings described under different conditions [37–40].

OBJECT DRAWING & PRACTICAL GEOMETRY

Objects on Same Principle as Cone and Cylinder. Triangular Prism. Square, Hexagonal and Octagonal Pyramids. Regular Polygons

By WILLIAM R. COPE

BY this time the student ought to have made such progress in drawing rectangular, conical, or cylindrical objects to be found among household utensils, etc.—such, for instance, as **155-160**—as to enable him to draw from much larger objects. It will help him if we discuss certain principles underlying the drawing of the triangular prism, square and polygonal pyramids.

Several different views are shown in **161** to **166** of a prism which has an equilateral triangle at each end. The student should obtain one or two such prisms, or make them out of bits of cardboard, fastened at the edges by means of tape or paper. A convenient size would be about 12 in. or 15 in. long, and edges of the triangular ends about 7 in. or 8 in. Place the prisms in such positions as indicated in **161** to **166**, and study *the apparent changes* in the form of the equilateral triangle, the foreshortening, in some views, of the long edges, and the direction of the apparent convergence of certain parallel edges. It is of little use to examine only the representations given in **161-166**; the student *must train his eye to see correctly* the many apparent forms which an object takes in various positions.

It will be seen that when the prism is lying flat down on one of its oblong faces the apex A (although really vertically over the *real* centre D of the base BC) is only apparently so when the student is directly opposite the end, as in **162**. In **161**, **163**, and **165**, the apex A is apparently vertically over the point D, which is not the *apparent* centre of the base BC, for the nearer *real* half CD in **161** and **163** is apparently slightly longer than the further *real* half BD, and in **165** BD is greater than DC. In **166** the apex A is vertically under the point D, as the prism is supposed to be resting on an edge, with its upper oblong surface parallel to the ground. Beginners often make an incorrect drawing like that in **167**, because they do not see the correct apparent position of the apex A with reference to the base BC. Of course, when the object is tilted, as in **161** and **165** the apex A does not necessarily appear vertically above the point D of the base BC; when the prism is in such positions the apex may appear to be in an infinite number of places not vertically over D; and to determine these relative positions careful observation of the object must be made. It should also be noticed how varied are the *apparent* lengths of the edges of the equilateral triangle, and of the long edges of the prism. In **163** the student should observe that the base BC of the further end is apparently slightly longer than BC of the nearer end; this is only another example of what was mentioned concerning the further end of the cylinder [see **152**]. Great attention should be given to the *direction* of apparently converging edges, although no errors should be made if the student remembers that receding parallel edges always appear to converge in the direction they go *from* him, whether upwards or downwards from him, or right and left away from him.

The Square and Other Pyramids. We will next examine the square pyramid, of which several correct representations are given in **168-175**; but **176** is incorrect, and shows a very common error made by beginners, who forget, or do not observe, that when the object is standing on its base, the axis AB of the pyramid ought to be *vertical*, and therefore also the apex A *vertically* over the centre B of the base as in **168**, **169**, and **175**. The triangular faces of the pyramid vary infinitely in their apparent forms, especially when the object is lying down on a triangular face, or when tilted as in **170-174**; and to obtain a true drawing the student must exercise his perceptive powers most carefully. In **175** we have a view of the pyramid with its axis vertical, and the object above the eye level; this shows how a spire or turret might appear on a building. Some spires and turrets are similar in construction to a hexagonal or octagonal pyramid, as shown in **177** and **178**, which are all representations of vertical positions of these pyramids, **177** and **181** being the appearance when below the eye level, **178** when the base is just on the eye level, and **179**, **180**, and **182** when above the level of the eye. In all of these (**177-182**) it will be seen that the axis AB and the apex A are again vertically above the centre B of the base. The position of this centre may be easily found by drawing diagonal lines, as indicated by dotted lines on the bases of **177-182**.

The student should now be prepared to make studies of objects such as **183-185**.

PRACTICAL GEOMETRY

Regular Polygons. There are general and special methods of constructing these polygons. The general methods, as in **187**, **188**, and **193-195**, apply equally to all polygons, but in particular polygons the special method is sometimes shorter and more accurate, as in **189-191**, and **196-198**. Remember the following important facts concerning *regular* polygons:

i. Lines which bisect the angles of regular polygons meet in one point, which is the centre of the figure, and they divide the polygon into a number of equal triangles. In the hexagon these are equilateral [**189**], but in all other regular polygons they are isosceles [**191-192**].

ii. The centre of the polygon is the same

PRACTICAL GEOMETRY. REGULAR POLYGONS, ETC.

as that of the circle to which the sides of the polygon are tangent (the *inscribed* circle) and also of the *circumscribed* circle which passes through the angular points [see **187–194**].

iii. The sum of all the interior angles of a regular polygon plus four right angles is equal to twice as many right angles as the figure has sides. [Euc. I. 32.] This affords a ready method of constructing any regular polygon by means of the protractor, as in **195**, when the side is given—a fact made use of in surveying.

187. In a Given Circle to Inscribe any Regular Polygon (Approximate Method). Draw the diameter AB and divide it into the same number of equal parts as the figure has sides (say five). With A and B as centres, and AB as radius, make arcs intersecting at C. From C draw CD, *always through the second division on* AB, cutting the circle in D. Join AD, which is one side of the pentagon required. Set off AD round circle and join points as shown.

188. Another Method. Draw any radius AB. At the centre A make an angle with AB equal to 360° divided by the number of sides of the regular polygon required, say a pentagon. Thus, $360° \div 5 = 72°$. Therefore, make the angle $BAC = 72°$. Join BC, which is one side of the pentagon. Set off BC round the circle, and join the points as shown.

189. To Inscribe a Regular Hexagon in a Given Circle (Special Method). Draw any diameter AB. With centres A and B, and radius equal to that of the circle, cut the circle in 1, 2, 3 and 4. Join the points as shown.

190. To Inscribe a Regular Duodecagon in a Given Circle (Special Method). Draw two diameters AB and CD perpendicular to each other. With centres A, B, C, and D, and radius equal to that of the circle, describe arcs cutting the circumference of the circle. Join the twelve points as shown.

191 To Inscribe a Regular Octagon in a Given Circle (Special Method). Draw two diameters AB and CD as in **190**. Bisect each quadrant thus formed, cutting the circumference as shown. Join the eight points thus obtained.

192. To Describe any Regular Polygon About a Given Circle (General Method). Divide the circumference into as many equal parts as the figure is to have sides (say, five for a pentagon). From the centre C draw lines through each point. Draw AB, one of the sides of the inscribed pentagon. Bisect AB by the perpendicular CD, cutting the circumference in D. Through D draw the tangent EF parallel to AB, cutting CE in E, and CF in F. Make CG, CH, and CK each equal to CE or CF. Join F, G, H, K and E as shown.

193. On a Given Line AB to Construct any Regular Polygon (General Method). Produce AB, and with centre B and radius BA describe a semi-circle, and divide it into the same number of equal parts as the figure has sides (say five). Join B with 2. Bisect AB and $B2$ by lines intersecting at D. With D as centre and radius DA or DB, or $D2$, describe a circle. Set off AF and FE each equal to AB. Join the points thus obtained.

Note. In this construction great care is required in dividing the semi-circle correctly, which may be done with the protractor. As there are 180° in a semi-circle, divide 180° by the number of sides the polygon will have; thus, $180° \div 5 = 36°$. Then make the angle $CB1$ equal to 36°, and mark off $C1$ round the semi-circle as shown. The semi-circle may be divided into *four* equal parts with the 45° set square, and into *three* equal parts with the 60° set square.

194. Another General Method. Bisect AB by the perpendicular CD. Make CE equal to AC or BC. With centre B and radius BA describe an arc cutting CD in E. E and F are respectively the centres of circles belonging to the square and hexagon. Bisect EF in G. With centre G and GA or GB as radius, describe a circle, and set off AB round it. Join the points, and $ABMNO$ is the pentagon required. By making 6 7, 7 8, 8 9, etc., each equal to 4 5 or 5 6, we obtain centres for the heptagon, octagon, etc., as shown.

195. Another General Method, by Using the Protractor. The number of degrees in each angle of a regular polygon may be found as follows: *From twice as many right angles as the figure has sides, subtract four right angles, and divide the remainder by the number of angles in the figure.* [Paragraph iii.] Suppose a regular pentagon be required. As it has five sides, from *ten* right angles deduct four, and the remainder is six right angles. Then $(90° \times 6) \div 5 = 540° \div 5 = 108°$. At A and B make angles of 108°. Make AE and BC each equal to AB. With E and C as centres and AB as radius make arcs intersecting at D. Join the points as shown. For a nonagon the angle would be found thus: From eighteen right angles deduct four, leaving fourteen right angles. Then $(90° \times 14) \div 9 = 1260° \div 9 = 140°$.

198. To Inscribe an Octagon in a Given Square $ABCD$. Draw the diagonals AC and BD. With centres A, B, C and D, and radius AE (half the diagonal), describe arcs cutting the sides of the square in F, G, H, K, L, M, N and O. Join FG, HK, LM, and NO. Then $FGHKLMNO$ is the required octagon.

199. To Construct any Regular Polygon, having the Diameter AB Given. Through A draw CD perpendicular to AB. Take any convenient distance Ac, and make Ad equal to it. Upon cd construct, say, a regular pentagon $cdebf$. From A draw lines through e and f. From B draw BE and BF respectively, parallel to be and bf. And from E and F draw ED and FC parallel to ed and fc. Then $CDEBF$ is the required pentagon.

It should be noted that the diameter divides the polygon into two equal parts. In a polygon with an *equal* number of sides, the diameter passes through the centre, and is terminated at the middle points of two opposite and parallel sides, as DE in **196**; but in a polygon with an *odd* number of sides, it passes through the centre from one angle to the middle point of the opposite side, as AB in **199**.

By P. G. Konody and Dr. Osten

The Article.

I. The DEFINITE ARTICLE is denoted in German by der for the masculine gender (*m.*), die for the feminine (*f.*), and das for the neuter (*n.*). This grammatical gender is, however, quite arbitrary and not always associated with the sex of persons, or with its absence in the case of objects It is therefore *absolutely necessary*, when committing a particular noun to memory, to connect it inseparably with its definite article.

The definite article is often used in German when it is omitted in English, with collective and abstract nouns, names of streets, mountains, metals, seasons, months, days; before proper names preceded by adjectives.

The INDEFINITE ARTICLE is expressed by ein for masculine and neuter, and eine for feminine substantives.

II. All substantives and nouns used substantively are written in German with capitals; all other words with small letters, except those which begin a new sentence or a quotation after a colon.

Examples of Gender:

Masculine:		*Feminine:*		*Neuter:*	
der (ein) Mann;	the (a) man.	die (eine) Frau;	the (a) woman.	das (ein) Kind;	the (a) child
der (ein) Vater;	the (a) father.	die (eine) Mutter;	the (a) mother.	das (ein) Mädchen;	the (a) girl.
der (ein) Fisch;	the (a) fish.	die (eine) Schlange;	the (a) serpent.	das (ein) Wiesel;	the (a) weasel.
der (ein) Mund;	the (a) mouth.	die (eine) Hand;	the (a) hand.	das (ein) Ohr;	the (an) ear.
der (ein) Rock;	the (a) coat.	die (eine) Weste;	the (a) waistcoat.	das (ein) Hemd;	the (a) shirt.
der (ein) Tisch;	the (a) table.	die (eine) Bank;	the (a) bench.	das (ein) Bett;	the (a) bed.
der (ein) Wald;	the (a) forest.	die (eine) Wiese;	the (a) meadow.	das (ein) Feld;	the (a) field.
der (ein) Mond;	the (a) moon.	die (eine) Sonne;	the (a) sun.	das (ein) Licht;	the (a) light.
der (ein) Bach;	the (a) brook.	die (eine) Welle;	the (a) wave.	das (ein) Meer;	the (a) sea.
der (ein) Tag;	the (a) day.	die (eine) Woche;	the (a) week.	das (ein) Jahr;	the (a) year.

Personal Pronouns.

III. The personal pronouns are:

ich: I.	wir: we.
du: thou.	ihr: you.
er, sie, es: he, she, it.	sie: they.

NOTES: 1. The second person singular, which in English is only used in biblical parlance, is much more frequently employed in German, where it is the usual form of address in the family circle, or among intimate friends. The general or polite form of address is the third person plural: Sie haben (you have), Sie sind (you are) etc. To distinguish this form of address from the grammatical form, the word Sie, when used for "you," has a capital letter, whilst sie for "they" has not. The capital is, of course, retained in the declension. The first person singular „ich" only has a capital at the beginning of a sentence.

2. There are, in German literature, two other forms of address, besides the du and Sie. One of them corresponds to the English "you" (second person plural)—Ihr seid, Ihr habt—and is used in the classic drama. The other—er ist, er hat (third person singular)—is an antiquated and rather contemptuous form of addressing subordinates. Both these forms are not in use at the present time, but they will be frequently found in literature.

3. In letters Du (thou) and Ihr (you) are, for reasons of courtesy, always written with capitals.

The Verb.

IV. 1. All verbs in German terminate in en or n. Thus, the verb arbeiten (to work) is formed of the stem arbeit and the suffix -en; rauchen (to smoke), of rauch-en; geben (to give), of geb-en.

2. THE AUXILIARY VERBS OF TENSES are: sein, to be; haben, to have; and werden, to become. Note the omission of the preposition in the infinitive. These auxiliary verbs are used as in English, either independently, or for the formation of compound tenses of other verbs Their conjugation, which is irregular, is to be found in the following tables.

TABLE V.

Conjugation of the Auxiliary Verbs.

INFINITIVE.

Present:	sein	— to be.	haben	— to have.	werden	— to become.
Past:	gewesen sein	— to have been.	gehabt haben	— to have had.	geworden sein	— to have become.

PARTICIPLE.

Present:	seiend	— being.	habend	— having.	werdend	— becoming.
Past:	gewesen	— been.	gehabt	— had.	geworden	— become.

Present.

INDICATIVE.

S. 1.	ich bin	— I am.	ich habe	— I have.	ich werde	— I become.
2.	du bist	— thou art.	du hast	— thou hast.	du wirst	— thou becomest.
3.	er* ist	— he* is.	er hat	— he has.	er wird	— he becomes.
P. 1.	wir sind	— we are.	wir haben	— we have.	wir werden	— we become.
2.	ihr seid	— you are.	ihr habet	— you have.	ihr werdet	— you become.
3.	sie sind	— they are.	sie haben	— they have.	sie werden	— they become.

CONJUNCTIVE (*Subjunctive*).

S. 1.	ich sei	— I be.	ich habe	— I have.	ich werde	— I become.
2.	du sei(e)st	— thou be.	du habest	— thou have.	du werdest	— thou become.
3.	er sei	— he be.	er habe	— he have.	er werde	— he become.
P. 1.	wir seien	— we be.	wir haben	— we have.	wir werden	— we become.
2.	ihr sei(e)t	— you be.	ihr habet	— you have.	ihr werdet	— you become.
3.	sie seien	— they be.	sie haben	— they have.	sie werden	— they become.

Imperfect†.

INDICATIVE.

S. 1.	ich war	— I was	ich hatte	— I had.	ich ward (wurde)	— I became
2.	du warst	— thou wast	du hattest	— thou hadst.	du wardst (wurdest)	— thou becamest
3.	er war	— he was	er hatte	— he had.	er ward (wurde)	— he became.
P. 1.	wir waren	— we were	wir hatten	— we had.	wir wurden	— we became.
2.	ihr waret	— you were	ihr hattet	— you had.	ihr wurdet	— you became.
3.	sie waren	— they were	sie hatten	— they had.	sie wurden	— they became.

CONJUNCTIVE (*Subjunctive*).

S. 1.	ich wäre	— I were.	ich hätte	— I had	ich würde	— I became.
2.	du wärest	— thou were.	du hättest	— thou hadst.	du würdest	— thou becamest.
3.	er wäre	— he were.	er hätte	— he had.	er würde	— he became.
P. 1.	wir wären	— we were.	wir hätten	— we had.	wir würden	— we became.
2.	ihr wäret	— you were.	ihr hättet	— you had.	ihr würdet	— you became.
3.	sie wären	— they were.	sie hätten	— they had.	sie würden	— they became.

Perfect.

INDICATIVE.

S. 1.	ich bin gewesen	— I have been.	ich habe gehabt	— I have had.	ich bin geworden	— I have become.
2.	du bist gewesen	— thou hast been.	du hast gehabt	— thou hast had.	du bist geworden	— thou hast become.
3.	er ist gewesen	— he has been.	er hat gehabt	— he has had.	er ist geworden	— he has become.
P. 1.	wir sind gewesen	— we have been.	wir haben gehabt	— we have had.	wir sind geworden	— we have become.
2.	ihr seid gewesen	— you have been.	ihr habt gehabt	— you have had.	ihr seid geworden	— you have become.
3.	sie sind gewesen	— they have been.	sie haben gehabt	— they have had.	sie sind geworden	— they have become.

CONJUNCTIVE (*Subjunctive*).

S. 1.	ich sei gewesen	— I have been.	ich habe gehabt	— I have had.	ich sei geworden	— I have become.
2.	du sei(e)st gewesen	— thou have been.	du habest gehabt	— thou have had.	du sei(e)st geworden	— thou have become.
3.	er sei gewesen	— he have been.	er habe gehabt	— he have had.	er sei geworden	— he have become.
P. 1.	wir seien gewesen	— we have been.	wir haben gehabt	— we have had.	wir seien geworden	— we have become.
2.	ihr sei(e)t gewesen	— you have been.	ihr habet gehabt	— you have had.	ihr sei(e)t geworden	— you have become.
3.	sie seien gewesen	— they have been.	sie haben gehabt	— they have had.	sie seien geworden	— they have become.

* The third person stands of course for all three genders: er, sie, es: he, she, it.

† The IMPERFECT and the PLUPERFECT of the conjunctive can be circumscribed by the I. and II. Conditional.

TABLE V.—*Continued.*

Pluperfect.*

INDICATIVE.

		gewesen	been.	gehabt	had.	geworden	become.
S.	1.	ich war	—I had	ich hatte	—I had	ich war	—I had
	2.	du warst	—thou hadst	du hattest	—thou hadst	du warst	—thou hadst
	3.	er war	—he had	er hatte	—he had	er war	—he had
P.	1.	wir waren	—we had	wir hatten	—we had	wir waren	—we had
	2.	ihr waret	—you had	ihr hattet	—you had	ihr waret	—you had
	3.	sie waren	—they had	sie hatten	—they had	sie waren	—they had

CONJUNCTIVE (*Subjunctive*).

		gewesen	been.	gehabt	had.	geworden	become.
S.	1.	ich wäre	—I had	ich hätte	—I had	ich wäre	—I had
	2.	du wärest	—thou hadst	du hättest	—thou hadst	du wärest	—thou hadst
	3.	er wäre	—he had	er hätte	—he had	er wäre	—he had
P	1.	wir wären	—we had	wir hätten	—we had	wir wären	—we had
	2.	ihr wäret	—you had	ihr hättet	—you had	ihr wäret	—you had
	3.	sie wären	—they had	sie hätten	—they had	sie wären	—they had

First Future.

INDICATIVE. — CONJUNCTIVE (*Subjunctive*).

S.	1.	ich werde		I shall		ich werde		I shall	
	2.	du wirst	sein,	thou wilt	be.	du werdest	sein,	thou wilt	be.
	3.	er wird		he will		er werde		he will	
P.	1.	wir werden	haben,	we shall	have.	wir werden	haben,	we shall	have.
	2.	ihr werdet	werden,	you will	become.	ihr werdet	werden,	you will	become
	3.	sie werden		they will		sie werden		they will	

Second Future.

S.	1.	ich werde	gewesen sein,	I shall	have been.	ich werde	gewesen sein,	I shall	have been.
	2.	du wirst		thou wilt		du werdest		thou wilt	
	3.	er wird	gehabt haben,	he will	have had.	er werde	gehabt haben,	he will	have had.
P.	1.	wir werden		we shall		wir werden		we shall	
	2.	ihr werdet	geworden sein,	you will	have become.	ihr werdet	geworden sein,	you will	have become.
	3.	sie werden		they will		sie werden		they will	

I. CONDITIONAL (*of the Imperfect*). — II. CONDITIONAL (*of the Perfect*).

S.	1.	ich würde	sein,	I should	be.	ich würde	gewesen sein,	I should	have been.
	2.	du würdest	haben,	thou wouldst	have.	du würdest	gehabt haben,	thou wouldst	have had.
	3.	er würde	werden,	he would	become.	er würde	geworden sein,	he would	have become.
P.	1.	wir würden		we should		wir würden		we should	
	2.	ihr würdet		you would		ihr würdet		you would	
	3.	sie würden		they would		sie würden		they would	

The I. Conditional may be used alternately with the IMPERFECT of the CONJUNCTIVE and the II. Conditional alternating with the PLUPERFECT of the CONJUNCTIVE.

IMPERATIVE.

Singular:	sei! —	be!	habe! —	have!	werde! —	become!
Plural:	seid! —	„	habet! —	„	werdet! —	„

The student is advised to learn first the tenses in the Indicative, and to reserve the study of the Conjunctive until he is further advanced in his knowledge of German.

EXAMPLES with the present tense of sein (see Table V.).

Ich	bin	ein	Mann,	du	bist	der	Vater,
I	am	a	man	thou	art	the	father
er	ist	ein	Sohn,	sie	ist	eine	Frau,
he	is	a	son	she	is	a	woman
es ist ein Kind,				wir sind hier,		ihr seid dort,	
it is a child				we are here		you are there	
Sie sind gut,				sie sind gut.			
you are good				they are good.			

Declension.

V. 1. The German substantives have three systems of declension: the *strong*, the *weak*, and the *mixed*.

2. In the declension the substantives generally take suffixes with or without modification of the root vowels. For the sake of euphony certain consonants are sometimes doubled and vowels omitted.

* The IMPERFECT and the PLUPERFECT of the conjunctive can be circumscribed by the I. and II. Conditional.

TABLE VI.—EXAMPLES OF THE STRONG DECLENSION.

	1. MASCULINE GENDER *Genit. suffix* -es	2. MASCULINE GENDER *Genit. suffix* -s	3. FEMININE GENDER *unaltered singular*	4. NEUTER GENDER *Genit. suffix* -es	5. NEUTER GENDER *Genit. suffix* -s	6. MASCULINE GENDER *Genit. suffix* -es	7. FEMININE GENDER *unaltered singular*	8. MASCULINE GENDER *Genit. suffix* -s	9. MASCULINE GENDER *Genit. suffix* -s
S. 1.	der Mann the man	der Lehrer the teacher	die Mutter the mother	das Kind the child	das Mädchen the girl	der Tisch the table	die Maus the mouse	der Garten the garden	der Lord the lord
„ 2.	des Mann-es of the man	des Lehrer-s of the teacher	der Mutter of the mother	des Kind-es of the child	des Mädchen-s of the girl	des Tisch-es of the table	der Maus of the mouse	des Garten-s of the garden	des Lord-s of the lord
„ 3.	dem Mann-e to the man	dem Lehrer to the teacher	der Mutter to the mother	dem Kind-e to the child	dem Mädchen to the girl	dem Tisch-e to the table	der Maus to the mouse	dem Garten to the garden	dem Lord to the lord
„ 4.	den Mann the man	den Lehrer the teacher	die Mutter the mother	das Kind the child	das Mädchen the girl	den Tisch the table	die Maus the mouse	den Garten the garden	den Lord the lord
	Modification of the Vowel and Suffix -er	*1. Singular and 1. Plural alike.*	*Modification of the Vowel.*	*Suffix* -er	*Singular and Plural alike. NO Dative Inflection.*	*Suffix* -e	*Suffix* -e *and Modification of the Vowel.*	*Modification of the Vowel. NO Dative Inflection.*	*Suffix* -s
Pl. 1.	die Männ-er the men	die Lehrer the teachers	die Mütter the mothers	die Kind-er the children	die Mädchen the girls	die Tisch-e the tables	die Mäus-e the mice	die Gärten the gardens	die Lord-s the lords
„ 2.	der Männ-er to the men	der Lehrer of the teachers	der Mütter of the mothers	der Kind-er of the children	der Mädchen of the girls	der Tisch-e of the tables	der Mäus-e of the mice	der Gärten of the gardens	der Lord-s of the lords
„ 3.	den Männ-ern of the men	den Lehrer-n to the teachers	den Mütter-n to the mothers	den Kind-ern to the children	den Mädchen to the girls	den Tisch-en to the tables	den Mäus-en to the mice	den Gärten to the gardens	den Lord-s to the lords
„ 4.	die Männ-er the men	die Lehrer the teachers	die Mütter the mothers	die Kind-er the children	die Mädchen the girls	die Tisch-e the tables	die Mäus-e the mice	die Gärten the gardens	die Lord-s the lords

3. DECLENSION OF THE DEFINITE ARTICLE.

Singular.

Nom.:	der (*m.*)	die (*f.*)	das (*n.*)	the
Gen.:	des	der	des	of the
Dat.:	dem	der	dem	to the
Acc.:	den	die	das	the

Plural (alike for all three genders).

Nom.:	die	the
Gen.:	der	of the
Dat.:	den	to the
Acc.:	die	the

4. DECLENSION OF THE INDEFINITE ARTICLE.

Nom.:	ein (*m.*)	ein-e (*f.*)	ein (*n.*)	a (an)
Gen.:	ein-es	ein-er	ein-es	of a (an)
Dat.:	ein-em	ein-er	ein-em	to a (an)
Acc.:	ein-en	ein-e	ein	a (an)

It will be seen that both articles have in many cases the same inflections, and that several cases show no changes (Nom. and Acc. *f.* and *n.* and the Gen. and Dat. *f.* The indefinite article has no plural).

DECLENSION OF NOUNS.

VI. 1. *Masculine* and *neuter substantives* in the strong declension

(*a*) add in the *Gen. sing.* -es or -s,
(*b*) cast off in the *Dat. sing.* the -s of the suffix acquired in the *Genitive,*
(*c*) retain in the *Acc.* the form of the *Nominative.*

2. *Feminine substantives* remain unchanged in the *Singular* (see Table VI., 3 and 7).

3. In the *Plural* of the strong declension the substantives

(*a*) retain in the *Nom.* the form of the *Nom. sing.* (see Table VI., 2 and 5); or
(*b*) add the suffixes -e, -er or -s, with or without modification of the root vowels a, o, u, au into ä, ö, ü, äu,
(*c*) retain these forms in the *Gen.*,
(*d*) retain in the *Acc.* the form of the *Nom.* (See Table VI., 1, 3, 4, 6, 7, 8, 9.)
(*e*) add in the *Dat.* the further suffix -n, (See Table VI., 1, 3, 4, 6, 7.)

Group (*a*) remains unchanged in the *Nom.*, *Gen.*, and *Acc.*, and only takes the -n in the *Dat.* unless the words belong to the following exceptions:

4. The *Suffix* -n is not added in the *Dat. Plur.* to nouns which have the *Nom. Plur.* terminating in -n (Table VI., 5 and 8). In nouns which terminate in -s in the *Nom. Plur.* (mostly of foreign derivation: die Lords, die Jockeys, die Chefs etc.), the *Dat.* also remains unchanged (Table VI., 9).

EXAMINATION PAPER II.

1. Which are the definite and the indefinite articles for the three genders in German, and which of them coincide?
2. When is the definite article used in German and omitted in English?
3. Which personal pronoun is always written with a capital, and when are other pronouns written with capitals or with small initials?
4. How many forms of personal address are employed in German, and which is the familiar form?
5. How is the Infinitive of the verb formed in German?
6. How do you recognise the strong declension of masculines and neuters in the singular, and of all three genders in the plural?
7. Are there any parallels in the declension of the definite and the indefinite articles?
8. What is the characteristic feature of the singular in the strong declension of feminines?
9. Which class of substantives takes the suffix -s in the strong Plural?
10. Are there any exceptions to the use of the suffix -n for denoting the Dative Plural of the strong declension?
11. What is the characteristic trait of the Dative Sing. in the strong declension?
12. Is there an auxiliary verb of tense in German which has to be replaced in English by an ordinary verb?

For Examples see the preceding paragraphs.

EXERCISE I.

Insert in the blank spaces

(*a*) THE DEFINITE ARTICLE.

.... Mann (*m.*), ... Frau (*f.*), ... Kind (*n*),
the man (husband); the woman (wife); the child:
.... Bank (*f.*), ... Hemd (*n.*), ... Mond (*m.*),
the bank; the shirt; the moon;
.... Rock (*m.*), ... Hand (*f.*),
the coat; the hand;
.... Mann (*m.*) .... Frau (*f.*), ... Frau (*f.*)
the husband of the woman; the wife
... Mann-es (*m.*), ... Vater (*m.*) ... Kind-es (*n.*),
of the man; the father of the child;
.... Welle (*f.*) .... Meer-es (*n.*), ... Kind (*n.*) ....
the wave of the sea; the child of the
Frau (*f.*) und .... Mann-es [*m.*), ... Licht (*n.*)
woman and the man; the light
.... Mond-es (*m.*) und .... Sonne (*f*).
of the moon and of the sun.

(*b*) THE INDEFINITE ARTICLE.

Gib* .... Kinde (*n.*) .... Frau (*f.*) .... Apfel (*m.*),
give to the child of the woman an apple;
gib .... Frau (*f.*) .... Weste (*f.*) und .... Rock (*m.*),
give to the woman a waistcoat and a coat;
ich gab* .... Hemd (*n.*) .... Manne (*m.*) und ....
I gave the shirt to a man and a
Weste (*f.*) .... Frau (*f.*) für .... Mann (*m.*).
waistcoat to the woman for the man.

* Gib is the *imperative singular,* and ich gab the *imperfect,* of geb-en to give.

EXERCISE II.

Insert in the blank spaces:

(*a*) THE PERSONAL PRONOUNS AND THE ARTICLES.

[Mind the Initials! See **II.** and **III.**]

..... bin ..... Vater (*m.*) ..... Kind=es (*n.*)
I am a father of a child;

.... ist .... Mutter (*f.*).
she is a mother.

.... bist .... Mann (*m.*), ... sind .... Freund (*m.*).
Thou art the man; You are a friend.

.. ist ... Kind (*n.*) ... Frau (*f.*) und ... Mann=es (*m.*).
It is a child of the woman and of the man

.... seid Mann und Frau.
You are husband and wife.

(*b*) THE AUXILIARY VERB sein (to be) in the present tense and THE ARTICLES.

Ich .... Freund .... Vaters. Du ....
I am a friend of the father. Thou art the

Frau .... Mann=es und .... Mutter .... Mädchen=s.
wife of the man and the mother of a girl.

Er ... hier, sie ... dort, es .... Kind ....
He is here; she is there; it is a child of a

Freund=es, wir .... Männ=er, ihr .... Mütter und
friend; we are men; you are mothers and

sie .... Kinder. Sie .... Freund .... Mutter
they are children. You are a friend of the mother

und er .... Freund .... Mädchen=s.
and he is a friend of the girl.

FRENCH

Continued from page .50

By Louis A. Barbé, B.A.

THE ARTICLE.

The Definite Article. 1. The definite article (*article défini*) has the forms *le, la, l', les,* all meaning *the.*

2. *Le* is used before masculine singular nouns, beginning with a consonant or aspirated *h,* as: *le livre* (the book), *le crayon* (the pencil), *le papier* (the paper), *le héros* (the hero), *le haut* (the top).

3. *La* is used before feminine singular nouns beginning with a vowel or silent *h,* as: *la plume* (the pen), *la table* (the table), *la règle* (the ruler), *la hauteur* (the height).

4. *L'* is used before all singular nouns, whether masculine or feminine, beginning with a vowel or silent *h,* as: *l'encrier,* m. (the inkstand), *l'homme,* m. (the man), *l'encre,* f. (the ink), *l'herbe,* f. (the grass).

5. *Les* is used before all plural nouns. These forms are used in the same way before adjectives preceding nouns.

6. "Of" is *de,* which also means "from"; but when joined with *le*—that is, before a masculine singular noun beginning with a consonant or aspirated *h*—the two words are contracted into *du* (of the): *le cahier,* the copybook; *du cahier,* of the copybook.

7. There is no contraction of the preposition *de* with the feminine form *la,* nor with the form *l',* thus: *la chaise,* the chair; *de la chaise,* of the chair; *l'homme, de l'homme; l'herbe, de l'herbe.*

8. "To" is *à,* but when joined with *le*—that is, before a masculine singular noun beginning with a consonant or aspirated *h*—the two words are contracted into *au: le buvard,* the blotting-book; *au buvard,* to the blotting-book.

9. There is no contraction with the feminine form *la,* nor with the form *l',* thus: *la grammaire,* the grammar; *à la grammaire,* to the grammar; *l'histoire,* the history or story; *à l'histoire,* to the story.

10. *De* and the plural form *les* always contract into *des; à* and the plural form *les* always contract into *aux.*

11. The definite article must be repeated before every noun, thus: the father and mother, *le père et la mère.*

12. To form the plural of nouns and adjectives *s* is added to the singular: *les pères, les mères, les enfants.*

13. There are only two genders in French—masculine and feminine.

14. There is no possessive case. It must always be rendered by "of the," *du, de la, de l',* or *des,* thus: the father's house, *la maison du père;* the children's mother, *la mère des enfants.*

15. The definite article is required in French, though not in English, before every noun that is used to designate a whole class. Thus in *les chiens sont des quadrupèdes,* dogs are quadrupeds, the article is used before *chiens* because the statement made is applicable to all dogs. Before *quadrupèdes* only a partitive article [see next column] is used, because dogs are only a division of the class quadrupeds.

The definite article is also required before abstract nouns, the names of arts, sciences, etc., and also before the names of materials: *la charité est une vertu,* charity is a virtue: *l'arithmétique est la science des nombres,* arithmetic is the science of numbers; *l'or est un métal,* gold is a metal.

The definite article is used before a single individual designating a whole class: *le fer est utile à l'homme,* iron is useful to man.

The Indefinite Article. 1. The indefinite article (*article indéfini*) is identical in form with the numeral "one," *un.* The feminine is formed, as in the case of adjectives, by adding mute *e* to the masculine: *un, une—un homme,* a man; *une femme,* a woman.

2. There is no contraction of *de* or *à* with *un, une;* but the *e* of *de* is elided before it: *d'un mur,* of a wall; *d'une maison,* of a house.

3. The indefinite article must be repeated before each noun to which it refers: a brother and a sister, *un frère et une sœur.*

4. As regards pronunciation, *un* has a nasal sound before a word beginning with a consonant or aspirated *h*. *Une* is never nasal. There is a difference of opinion as to the pronunciation of *un* before a vowel or mute h. Some hold that the *u* should be pronounced with its natural sound, and the *n* carried on to the next word, thus: *un ami* (a friend) becomes *u-nami*. This, however, has the disadvantage of making no difference between masculine and feminine—*e.g.*, *un aide* (a helper), and *une aide* (a help), have exactly the same sound. For this reason, other authorities give *u* the sound of *eu* (approximating the slurred sound of *e* in such a combination as "the boy"), and pronounce *un aide* as *ĕ-naid*, thus distinguishing it from *une aide*—*ü-n(e)aid*.

The Partitive Article. 1. When a noun is used to indicate only a part of that to which it is applicable, it is said to be taken "partitively." In English this idea is expressed by "some" and "any," which are, however, very frequently omitted: He drinks (some) water; we have bought (some) pens.

In French, when a noun is taken partitively, it is preceded by a form of the definite article, to which the name "partitive article" is then given.

2. The partitive article (*article partitif*) is *du*, *de la*, *de l'*, *des*. These forms are used in the same way as has already been explained in the case of the definite article, thus: *j'ai du papier*, I have some paper; *il a de la patience*, he has patience; *vous avez de l'encre*, you have some ink; *ils ont des crayons*, they have some pencils.

3. When a noun used partitively is the subject of a verb, it takes the partitive article: Friends—*i.e.*, some friends—have given it to me, *des amis me l'ont donné*.

4. Although, including the preposition *de*, the partitive article may be preceded by another preposition: *j'ai parlé à des amis*, I have spoken to some friends; *j'écris avec de l'encre*, I write with (some) ink.

5. When a noun taken partitively is preceded by an adjective, only *de* is used to express the partitive sense, thus: *j'ai de bons crayons*, I have some good pencils. This rule is frequently neglected in conversation, and it has been proposed to do away with it altogether.

6. When a noun taken partitively is the object of a negative verb, only *de* (which becomes *d'* before a vowel or mute *h*) is used with it: *je n'ai pas de papier*, I have no paper; *il n'a pas de patience*, he has no patience; *vous n'avez pas d'encre*, you have no ink; *ils n'ont pas de crayons*, they have no pencils.

7. When used negatively verbs are placed between *ne* and *pas*; *ne* becomes *n'* before a vowel or mute *h*: *je n'ai pas*, I have not.

8. When a noun taken partitively is preceded by *de* (of), neither the partitive article nor another *de* is used: I have need of (some) pencils, *j'ai besoin de crayons*.

9. When a noun taken partitively is not actually expressed, but only understood in a sentence—that is to say, when "some," "any" ("not any" = "none") occur alone in English—the pronoun *en* is used instead of the partitive article or of de. Its place is before the verb: I have some, *j'en ai*; we have not any, *nous n'en avons pas*.

10. The various ways in which the "partitive sense" may be expressed are the following:

(*a*) *J'ai du papier*, I have some paper.

(*b*) *J'ai de bons crayons*, I have some good pencils.

(*c*) *Vous n'avez pas de livres*, you have not any books.

(*d*) *Nous avons besoin de papier, d'encre, et de plumes*, we have need of paper, ink, and pens.

(*e*) *Il en a, elle n'en a pas*, he has some, she has none.

11. Subject to these rules, the "partitive sense" must *always* have something to indicate it before *every word taken partitively*.

Present Indicative of Avoir, To Have

Affirmatively—

j'ai, I have (*j'ĕy*).
tu as, thou hast (*tü ăh*).
il a, he (it) has (*il ăh*).
elle a, she (it) has.
nous avons, we have (*nōō-za-vong*).
vous avez, you have (*vōō-za-vĕy*).
ils ont, they (m.) have (*il-zong*).
elles ont, they (f.) have.

Negatively—

je n'ai pas, I have not.
tu n'as pas, thou hast not.
il n'a pas, he has not.
elle n'a pas, she has not.
nous n'avons pas, we have not.
vous n'avez pas, you have not.
ils n'ont pas, they (m.) have not.
elles n'ont pas, they (f.) have not.

Present Indicative of Être, To Be.

Affirmatively—

je suis, I am (*jĕ süēē*).
tu es, thou art (*tü ĕy*).
il est, he is (*il ĕy*).
elle est, she is.
nous sommes, we are (*sŏm*).
vous êtes, you are (*āte*).
ils sont, they (m.) are (*il song*).
elles sont, they (f.) are.

Negatively—

je ne suis pas, I am not.
tu n'es pas, thou art not.
il n'est pas, he is not.
elle n'est pas, she is not.
nous ne sommes pas, we are not.
vous n'êtes pas, you are not.
ils ne sont pas, they (m.) are not.
elles ne sont pas, they (f.) are not.

Il y a.

The third person singular of *avoir*, to have, preceded by *y*, and used impersonally, takes the meaning of "to be."

Il y a, there is (or) there are; *il n'y a pas*, there is not, there are not.

Voilà, voici.

Voilà is also to be translated by "there is," "there are," but with a different meaning. It is made up of *vois* (see, behold), and *là* (there). and is used when actually pointing to some object, or objects: *voilà des livres*, there are some books; *voilà une plume*, there is a pen. Similarly, *voici* means "here is," "here are": *voici une table*, here is a table; *voici des chaises*, here are some chairs.

Exercise IV.

1. The paper of the book. 2. The hero of the story. 3. The top of the house. 4. The child's pencil. 5. There is the pen. 6. There is the ruler. 7. The ink is in the inkstand. 8. The inkstand is on the table. 9. There is an inkstand on the table. 10. The height of the house. 11. There are a book, an inkstand, a blotting-book, a ruler and a copy-book on the table. 12. From the chair to the table. 13. The father and mother are in the house. 14. Charity is a virtue. 15. Iron is a metal. 16. The man has a brother and a sister. 17. The children have grammars. 18. There is the book of one of the children. 19. I have spoken to the woman's children. 20. I write to the brother and sister. 21. I have some pencils. 22. She has no ink. 23. You have need of pens and paper. 24. He has some good books. 25. You have pencils and paper; we have none. 26. You have some good pens. 27. The child's father has a house. 28. There is the child's father. 29. She has need of ink and paper. 30. Gold and silver are useful to men. 31. Children have no patience. 32. Patience is a virtue.

Key to Exercises I., II., III.

I.

femme, woman (*fam*).
tête, head (*tate*).
histoire, history (*ees-twahr*).
aiguille, needle (*egg-wee-ĕ*).
faubourg, suburb (*fo-boor*).
doigt, finger (*dwa*).
mauvais, bad (*mō-vāy*).
Dieu, God (*Dēē-ĕ*).
Espagnol. Spaniard (*Es-pan-yŏl*).
vérité, truth (*vĕy-rēē-tey*).
soleil, sun (*sŏ-ley-yĕ*).
février, February (*fĕy-vrēē-ey*).
mardi, Tuesday (*mahr-dēē*).
monsieur, Mr., Sir (*mĕ-sēē-ĕ*).
maître, master (*māytr*).
Noël, Christmas (*Nŏ-el*).
mademoiselle, Miss (*ma-dĕ-mwa-zel*).
nord, north (*nōr*).
beaucoup, much (*bō-kŏŏ*).
quoi, what (*kwah*).
hiver, winter (*ēē-verr*).
damner, to damn (*dah-ney*).
sculpter, to carve (*skül-tey*)
prompt, prompt (*pron^g*).
cuiller, spoon (*kwēē-yey*).
maison, house (*may-zon^g*).
sous, under (*soo*).
misère, misery (*mēē-zairr*).
poison, poison (*pwah-zon^g*).
poids, weight (*pwa*).
paix, peace (*pey*).
sept, seven (*set*).
huit, eight (*weet*).
neuf, nine (*nĕf*).
dixième, tenth (*dēē-zēē-ame*).
signe, sign (*seen-ye*).
amer, bitter (*ahmerr*).
prix, prize, pri e (*prēē*).
Guise, Guise (*Gweez*).
cri, cry (*krēē*).
babil, chatter (*babee-ye*).
ville, town (*vēēl*).
œuf, egg (*ĕf*).
sœur, sister (*sĕr*).
plomb, lead (*plon^g*).
mais, but (*may*).
chef-d'œuvre, masterpiece (*shey-dĕvr*).
citoyen, citizen (*seet-wa-yawn^g*).
gloire, glory (*glwarr*).

II.

A. *Auto(m)ne, (h)istoir(e), san(g), (a)oû(t), doi(gt), septembr(e), port(e), cham(p), sud, port(ent), plom(b), dange(r), lac, vin(gt), mer, faubour(g), pai(x), outi(l), blan(c), pri(x), Jésu(s), nez, cer(f), beaucou(p), bari(l), péril, mo(n)sieu(r), amer, chez, cle(f), scul(p)te(r), ba(p)têm(e), hier, cou(p), por(c), cor(ps), dan(s), da(m)ner, (h)omm(e), hach(e), serf, dra(p), sou(s), mai(s), neuf, bor(d), genti(l), gosie(r), e(t), t(h)é.*

B. *Lau-rier, cha-lou-pe, sour-cil, plai-sir, mar-di, vé-ri-té, a-près, four-chet-te, a-gneau, poi-gnard, gé-né-ra-le-ment, a-mi, é-cri-tu-re, par-ler, mer-lan, mon-trer, troubler, den-rée, vir-gu-le, con-sen-tir, en-la-cer, beau-coup, de-voir, dé-jà.*

III.

a = aigu; g = grave; c = circonflex.

A. *Même, c; bergère, g; blé, a; mûr, c; dés, a; mère, g; déjà, a, g; paraît, c; côté, c, a; près, g; prés, a; tête, c; été, a, a; fâché, c, a; fenêtre, c; lèvre, g; être, c; à, g; où, g; dû, c; général, a, a; maître, c; succès, g; témérité, a, a, a; île, c.*

B. *Je n'ai d'autre ambition; c'est moi; l'oreille; l'homme; l'oiseau; il faut qu'il parte; la crainte qu'elle m'a causée; lorsqu'un enfant n'obéit pas; s'il vient; le héros; l'héroïne; presque en même temps; quelque autre; le onze juillet; jusqu'à Londres.*

LATIN Continued from page 605 By Gerald K. Hibbert, M.A.

SECTION I. GRAMMAR.

Peculiarities and Irregularities of the Noun. 1. Many nouns have no plural—*e.g.*, proper names and abstract nouns, and words like argentum (*silver*), aurum (*gold*), ferrum (*iron*), aër (*air*), æther (*sky*), etc.

2. Many nouns have no singular: Certain names of towns, as Thebæ (*Thebes*), Athenæ (*Athens*); parts of the body; names of feasts or days, as feriæ (*holiday*), nundinæ (*market-day*); and words like divitiæ (*riches*), liberi (*children*), manes (*ghosts*), penates (*household gods*), mœnia (*town walls*), tenebræ (*darkness*), etc.

3. Some nouns change their meaning in the plural:

Singular.	*Plural.*
castrum, *a fort*	castra, *a camp*
ædes, *a temple*	ædes, *a house*
aqua, *water*	aquæ, *a watering-place*
auxilium, *assistance*	auxilia, *auxiliary troops*
copia, *plenty*	copiæ, *supplies, troops*
impedimentum, *a hindrance*	impedimenta, *baggage*
litera, *a letter* (of the alphabet)	literæ, *an epistle*
opem (acc.), *help*	opes, *resources*
opera, *work*	operæ, *workmen*
rostrum, *a beak*	rostra, *the pulpit at Rome*
ludus, *play*	ludi, *public games*
carcer, *prison*	carceres, *the barriers* (in horse races)
etc.	etc.

4. Many nouns are defective in case:

The following have no nominative: dapem (*feast*), frugem (*fruit*), opem (*help*), precem (*prayer*), vicem (*change*).

Vis (strength), is thus declined:

	Singular.	*Plural.*
N.V.	vis	vires
Acc.	vim	vires
Gen.	(none)	virium
Dat.	(none)	viribus
Abl.	vi	viribus

Other defective nouns are forte (*by chance* [abl.]), sponte (*by one's own choice* [abl.]), fas (*right*), nefas (*wrong*), nihil (*nothing*), opus (*need*), instar (*likeness*), necesse (*necessity*), mane (*morning*). These are practically indeclinable.

The following list of nouns with their genitive singular and nominative plural will be useful. If these two cases of a noun are known, the whole noun can be declined: for if the nominative plural ends in *a*, the noun is neuter, and therefore the accusative will be the same as the nominative, both singular and plural.

Nom. singular	*Gen. singular*	*Nom. plural.*
pecus, *f.* *head of cattle*	pecudis	pecudes
pecus, *n.* *cattle*	pecoris	pecora
grus, *f.* *crane*	gruis	grues
mus, *com.* *mouse*	muris	mures
incus, *f.* *anvil*	incudis	incudes
vulgus, *n.* *common people*	vulgi	vulga
virus, *n.* *poison*	viri	vira
tellus, *f.* *earth*	telluris	tellures
supellex, *f.* *furniture*	supellectilis	supellectiles
vas, *m.* *bail*	vadis	vades
vas, *n.* *vessel*	vasis	vasa
pecten, *m.* *comb*	pectinis	pectines
cucumis, *m.* *cucumber*	cucumeris	cucumeres
pulvis, *m.* *dust*	pulveris	pulveres
cuspis, *f.* *shield*	cuspidis	cuspides
glis, *m.* *dormouse*	gliris	glires
lis, *f.* *lawsuit*	litis	lites
obex, *com.* *bolt*	obicis	obices
mas, *m.* *male*	maris	mares
seges, *f.* *crop*	segetis	segetes
merges, *f.* *sheaf*	mergitis	mergites
merces, *f.* *reward*	mercedis	mercedes
heres, *com.* *heir*	heredis	heredes
compes, *f.* *fetter*	compedis	compedes
caro, *f.* *flesh*	carnis	carnes
margo, *com.* *border*	marginis	margines
cupido, *f.* *desire*	cupidinis	cupidines
pugio, *m.* *dagger*	pugionis	pugiones
nex, *f.* *death*	necis	neces
nix, *f.* *snow*	nivis	nives
senex, *m.* *old man*	senis	senes
bos, *com.* *ox*	bovis	boves
Jupiter, *m.* *Jupiter*	Jovis	—
iter, *n.* *journey*	itineris	itinera
jecur, *n.* *liver*	jecinoris (*or* jecoris)	jecinora

Nom. singular.	*Gen. singular.*	*Nom. plural.*
gigas, *m.* *giant*	gigantis	gigantes
jus, *n.* *right*	juris	jura
falx, *f.* *scythe*	falcis	falces
vates, *com.* *prophet*	vatis	vates

NOTE. *Bos* has genitive plural *boum*; dative and ablative plural *bobus* or *bubus*.

Respublica (commonwealth) and *jusjurandum* (oath), decline both halves: accusative *rempublicam*, genitive *reipublicæ*, ablative *republica* (*res* is fifth declension like *dies*). So, accusative *jusjurandum*, genitive *jurisjurandi*, etc

[The genitive and genders of other nouns can be looked up in the dictionary.]

The following rhyme may be useful as an aid to remembering the exceptions to the rule that parisyllables form their genitive plural in *-ium*, and imparisyllables in *-um*:

"In *-ium* terminate glis, lis,
Mas, mus, and nix, falx, faux, and vis:
But *-um* ends juvenis and frater,
Ambages, vates, senex, pater,
With canis, volucris, and mater."

SECTION II. SYNTAX.

Ablative: Further Uses. *The ablative is, more than any other, an adverbial case; it is the case of circumstances which attend action, and limit it adverbially. It answers the questions: Whence? How? From what cause? When? Where?*

1. ABLATIVE OF TIME. This answers the questions *When? Within what time? How long before or after?* (Contrast this with the accusative of time, denoting *duration*—*e.g.*, decem *annis* post urbem conditam obiit = he died 10 *years after* the founding of the city; but, decem *annos* vixit = he lived *for* 10 *years*.)

2. ABLATIVE OF PLACE. This is used without a preposition, when the question is "By what road?" or (of a town or small island) "Whence?"—*e.g.*, Ibam forte *Via Sacra* = I was going by chance *on the Sacred Road*; *Corintho* fugit = he fled *from Corinth*; (So *domo* = from home; *rure* = from the country).

Under this heading we may treat the locative case, practically obsolete in classical Latin, and largely replaced by the ablative. The locative answered the question *Where?* and ended in *-i*—*e.g.*, *domi*, at home; *ruri*, in the country; *humi*, on the ground; *belli*, at the wars. The ablative is always used for the locative in names of towns and small islands of the 3rd declension, and in plural names of towns of the 1st and 2nd declension—*e.g.*, *Athenis*, at Athens; *Neapoli*, at Naples. But if the town or small island is a singular noun of 1st or 2nd declension, the genitive is used—*e.g.*, *Romæ*, at Rome (old locative was *Romai*); *Corinthi*, at Corinth.

3. THE ABLATIVE OF ORIGIN is used after verbs and participles—mostly—though not always—without a preposition—*e.g.*, *Jove* natus, born of Jupiter.

4. ABLATIVE OF INSTRUMENT AND CAUSE—*e.g.*, Boni oderunt peccare virtutis *amore* = the good hate to sin *from love* of virtue (cause); *gladio* interfectus est = he was slain *with the sword* (instrument).

5. ABLATIVE OF THE AGENT. When the "instrument" is a person, not a thing, the preposition *a* or *ab* is necessary—*e.g.*, Cæsar *a Bruto* pugione interfectus est = Cæsar was slain *by Brutus* with (*i.e.*, by means of) a dagger. (But when "with" = "*together with*," the preposition "*cum*" must be used—*e.g.*, *cum fratre meo* veni = I came *with my brother*.)

6. ABLATIVE OF MANNER. This, being purely adverbial, is one of the commonest uses of the ablative—*e.g.*, Injuria fit *duobus modis*, aut *vi* aut *fraude* = wrong is done *in two manners*, either *by force* or *by fraud*. Similarly, *hoc modo* = in this manner; *casu* = by chance; *consilio* = by design, on purpose; *jure* = rightly, by right; etc.

7. ABLATIVE OF QUALITY AND ACCOMPANIMENT.

(*a*) Quality—*e.g.*, Senex *eximio ingenio* = an old man *of wonderful ability*. (The noun in the ablative must have an adjective with it: we could not say "*senex ingenio*.")

(*b*) Accompaniment—*e.g.*, hoc feci *summa diligentia* = I have done this *with the utmost care*. (If we omitted the adjective, we should have to insert "cum"—*e.g.*, hoc feci *cum* diligentia.)

8. ABLATIVE OF PRICE. Used with verbs of *buying* and *selling*, usually when some definite figure is given. (Otherwise, and especially after verbs of *valuing* and *esteeming*, the genitive is used.) Anulum *viginti nummis* vendidit = he sold the ring *for twenty nummi*.

9. ABLATIVE OF MEASURE—*e.g.*, Sol *multis partibus major* est quam luna = the sun is *many times larger* (lit. *by many parts*) than the moon; *quo* citius, *eo* melius = the sooner, the better (lit. *by what* the sooner, *by that* the better).

10. ABLATIVE OF COMPARISON—*e.g.*, Puto mortem *dedecore* leviorem = I think death easier *than disgrace*.

11. The ablative is used after the following:

(*a*) Verbs: *Abounding, filling*, etc., and their opposites, *depriving of, being without*. Also the deponent verbs *fruor, fungor, utor, vescor, potior, dignor*. (It is really quite regular to have the ablative after these verbs; *utor*, for example, means "I serve myself *with*," and so comes to mean "I use.")

(*b*) Adjectives: *dignus* (worthy), *indignus* (unworthy), *fretus* (relying on), *contentus* (content with), *præditus* (endowed with)—*e.g.*, *laude dignissimus* = most worthy *of praise*.

(*c*) Nouns: *opus* (need), and *usus* (use)—*e.g.*, opus est mihi *argento* = I have need of silver.

Passage to be Turned into Latin.

"Come unto Me all ye who are weary and heavy laden, and I will cause that ye may rest. Take up My yoke upon you and learn from Me, because I am meek and lowly in heart; and ye shall find rest unto your souls. For my yoke is easy, and My burden is light."

Translation of Above.

(From Beza's version of the New Testament.)

Venite ad me omnes qui fatigati estis et onerati, et ego faciam ut requiescatis. Attolite jugum meum in vos, et discite a me, quod mitis sim et humilis corde; et invenietis requiem *animabus* (1) vestris. Jugum *enim* (2) meum facile est, et onus meum leve est.

Notes. (1). *Animabus* is the dative plural of *anima*, to distinguish it from *animis*, the dative plural of *animus* (cp. *filiabus* and *filiis*).

(2). *Enim*, like *autem*, can never be the first word of a sentence.

Section III. TRANSLATION.

The following passage is from Vergil's "Æneid." Vergil was a Latin poet, who lived at the beginning of the Christian era, under the Emperor Augustus. His most famous work is the "Æneid," a history of the Fall of Troy and the adventures of Æneas thereafter. There are twelve books, and this passage is from Book II., lines 234-249. It describes the stratagem of the Wooden Horse (containing armed men), by which the Greeks brought about Troy's fall. The Trojans dragged the horse into their city as a prize of war, and in the night the Greeks hidden inside the horse emerged and opened the gates to their comrades outside.

[The beginner should read a book of Cæsar and a book of Vergil as early as possible. Welch and Duffield's "Helvetian War" is strongly recommended].

Æneas is relating the events of the fatal night.

[*And* is often translated by *-que* joined to the end of a word.]

Dividimus muros, et mœnia pandimus urbis.
Accingunt omnes operi, pedibusque rotarum (*a*)
Subjiciunt lapsūs (*a*), et stuppea vincula collo
Intendunt. Scandit fatalis machina muros
Feta armis. Pueri circum innuptæque puellæ
Sacra canunt, funemque manu contingere gaudent.
Illa (*b*) subit, mediæque minans inlabitur (*c*) urbi.
O patria, O divom (*d*) domus Ilium, et incluta bello
Mœnia Dardanidum! quater ipso in limine portæ
Substitit (*e*), atque utero sonitum quater arma dedere (*f*):
Instamus, tamen, immemores cæcique furore,
Et monstrum infelix sacrata sistimus arce.
Nos delubra deum (*g*) miseri, quibus ultimus esset
Ille dies, festa velamus fronde per urbem.

Notes. (*a*). *Lapsus rotarum* = gliding wheels, or rollers (literally, glidings of wheels; *lapsus* is acc. pl., 4th decl., and is direct object to *subjiciunt*; *pedibus* is indirect object, and therefore dative).

(*b*). *Illa* = it, *i.e.*, machina: nom. fem. sing.

(*c*). *Inlabitur*, though passive in form, is active in meaning: a deponent verb.

(*d*). *Divom* = divorum = deorum.

(*e*). Perfect of *subsisto*.

(*f*). = *dederunt*.

(*g*). *Deum* is often used for deorum, gen. pl.

Key to Above Passage.

We sunder the walls, and lay open the fortifications of the city. All gird themselves for the work, and put rolling wheels under its (*i.e.*, the wooden horse's) feet, and fasten hempen bands on its neck. The fated engine climbs the walls, big with arms. Around it boys and unwedded girls sing hymns, and rejoice to touch the rope with their hand (*i.e.*, to help to pull the horse into the city). It approaches, and glides threatening into the midst of the city. O native land! O Ilium (Troy), home of the gods, and fortresses of the Dardanidæ (Trojans) renowned in war! Four times in the very gateway did it halt, and four times the arms rattled (literally, gave a sound) in its womb. Yet we press on, unmindful and blind with frenzy, and plant the ill-omened monster in our sacred citadel. We deck the shrines of the gods throughout the city with festal foliage, wretched people, to whom that day was our last.

ENGLISH

Continued from page 608

By Gerald K. Hibbert, M.A.

The Indicative Mood. There is no difficulty about this mood. It is used whenever we make a statement or ask a question about something which we regard as a matter of fact, apart altogether from our conception of it—*e.g.*, "London *is* burning," "How *fares* it with the happy dead?"

The Indicative may even be used to express condition, provided that the condition or supposition relates to some matter of fact rather than to some "matter of conception" (to use a phrase of Mason's)—*e.g.*, "If he *betrays* me, he shall smart for it." This will be more fully explained later on.

The Imperative Mood expresses a command, and is therefore strictly used only in the second person: "*Charge*, Chester, *charge!*" "*Pray* without ceasing." When we wish to express a command or exhortation in connection with the first or third person, we use either the imperative (second pers. sing.) of *let*, followed by the infinitive (as, "*Let* us not *be* weary in well-

doing," "*Let* there *be* light"), or the subjunctive mood of the verb in question (as, "Blessed *be* God"). The future imperative is not often used now; it was common in prohibitions (*cf.* the Ten Commandments: "Thou *shalt* not . . .").

THE SUBJUNCTIVE MOOD was so called because it was most often used in subordinate ("subjoined") sentences. It is impossible for the Subjunctive to be used in a simple direct statement or question. It is used chiefly in (1) Conditional clauses, introduced by *if* (though not always, as we have seen under "Indicative"); (2) Purpose clauses, introduced by "in order that" or "lest," as "Kiss the Son, lest he *be* angry"; (3) Wishes, as "O that he *were* here!"

Although the Subjunctive is usually found following conjunctions like "if," "unless," "provided that," etc., the conjunction is not a part of the mood, nor is the Subjunctive always necessary after it. It depends on whether the speaker is emphasising the fact, or his conception of the fact.

The Subjunctive Mood is becoming more and more rarely used in English. It is being replaced (1) by the Indicative (instead of "If he *were* here, all would be well," it is becoming increasingly common to say, "If he *was* here," etc.); (2) by the use of some auxiliary verb, as *may, might, should*. We should now say as a rule, "Kiss the Son, lest he *should* be angry." But in so doing we lose the delicate shade of meaning that distinguishes the one mood from the other, and we thereby rob the language of one of its priceless charms.

THE INFINITIVE MOOD. The Infinitive is a verbal noun. It is a noun because it can stand as the subject or the object of a verb, as "*To be* is nobler than *to have*" (subject), "Learn *to do* well" (object). It is a verb because it can govern an object, as "'Tis best *to keep the nerves at strain*."

Although the Infinitive is generally used with the preposition *to* before it, the *to* is not a part of the Infinitive. Many verbs are followed by the Infinitive without *to*; these include the auxiliaries *do, shall, will*, the verbs *bid, dare, make, let, can, may, must, need*, and some verbs denoting the operation of the senses, as *hear, see, feel*.

In old English the Infinitive ended in *-an* or *-en* (as, *sawan* = to sow), and had not the preposition *to* before it. The *to* was only prefixed when the infinitive was used to denote purpose, as "I come *to bury* Cæsar, not *to praise* him." Here *to* has its proper force, and = "in order to." This strictly proper use became gradually more and more extended, until the *to* came to be regarded as an indispensable part of the Infinitive.

The Infinitive is sometimes used in exclamations, as "*To think* that I could have been so foolish!"

CAUTION. (1) Beware of using what is called the *Split Infinitive*; in other words, do not insert any word or words between the *to* of an infinitive mood and its verb. It is far better to say "I must ask you *kindly to excuse me*" than "I must ask you *to kindly excuse* me."

(2) The Past Infinitive (*e.g., to have seen*) needs careful handling when used after another verb in the past tense. Many people will say "I should *have liked* to *have seen* you," which is incorrect; it should be "I should *have liked* to *see* you."

GERUNDS AND PARTICIPLES. The gerund (Latin *gerere* = to carry on) is a verbal noun like the Infinitive, and is similar in meaning to the Infinitive. The participle is a verbal adjective (Latin, *participare* = to partake, because it "partakes" of the nature both of verb and adjective). As these are not "finite" moods, they are generally classed among the "infinite" moods.

The gerund, being a verbal noun, can be used in most of the constructions of a noun. It is formed from the verb by adding *-ing*. Gerunds are often confused with abstract nouns ending in *-ing* (Anglo-Saxon *-ung*), though they are really quite distinct. Thus, it is correct to say either "By *dredging* the river" (gerund), or "By the *dredging* of the river" (noun), but it is incorrect to say "By the dredging the river," or "By dredging of the river." The rule is quite simple: "When *the* precedes, *of* must follow; but if *the* is omitted, *of* must also be omitted." We thus see that a gerund, when formed from a transitive verb, can govern an object just like any other part of the verb. The gerund, like the Infinitive, can be either the subject or the object of a verb—as, "*Walking* is capital exercise" (subject), "I like *walking*" (object). Although the gerund has the same meaning as the Infinitive, it cannot always be used instead of it; for instance, after prepositions the gerund is almost always used, as "*Of making* many books there is no end." The gerund can, of course, be used in the passive voice as well as in the active—as, "The joy of being loved."

In such expressions as "I go *a-fishing*," "The ark was *a-preparing*," "The house is *a-building*," "There came three ships *a-sailing*," (where the *a-* represents *on*) we must treat the form in *-ing* not as the gerund, but as a modern form of the old abstract noun ending in *-ung*.

Many compound nouns are formed from gerunds, as "*skipping*-rope" (a rope for skipping). Contrast such a compound noun with others like "*humming*-bird," which does not mean "a bird for humming," but "a bird which hums." "Skipping-rope" could not be rendered "a rope which skips." This shows the difference between a gerund (skipping) and a participle (humming), and we are thus brought on to—

PARTICIPLES, or verbal adjectives. These, being adjectives, cannot be used as the subject or object of a verb, or after a preposition; and, like all adjectives, they refer to some noun about which they specify something.

There are two participles formed by inflexion, the *Present* or *Imperfect Participle*, and the *Past Participle*.

1. The imperfect participle is always active and always ends in *-ing* (like the gerund, with which it is often confused). Examples:

"Him walking on a sunny hill he found."
—*Paradise Regained.*

[Here *walking* is a verbal adjective agreeing with *Him.*]

"Thinking he had come, I opened the door."

[*Thinking* is a verbal adjective agreeing with *I.*]

"But, as I rose out of the laving stream,
Heaven opened her eternal doors . . . ."

[*Laving* is a verbal adjective qualifying *stream.*]

To distinguish a gerund from an imperfect participle, ask the question "Does the word in question play the part of a noun or an adjective?" If the former, it is a gerund; if the latter, a participle. Contrast "By *talking* my throat gets tired" (gerund) with "*Talking* loudly, they left the room" (Participle, agreeing with *they*).

It is a very common mistake to use the participle where a gerund should be used. To say "I heard of *you* winning the prize" is wrong; it should be *your*, because *winning* is the gerund (*i.e.*, a noun), and it is as wrong to use *you* in this case as to say "Lend me *you* watch." *You* could only be used if *winning* were a participle—*e.g.*, "You, *winning* the prize, are a happy man." In the case of personal and relative pronouns, the gerund and the possessive (*my, thy, his,* etc.) should be used, not the participle and the objective—as, "I am sorry for *his* (not *him*) lapsing into bad ways," "They told me of *his* (not *him*) running away." In all other cases there seems to be a diversity of opinion among the authorities. Some will say "I had no knowledge of my *cousin* being there" (participle); others, "I had no knowledge of my *cousin's* being there" (gerund). The latter is preferable.

We thus see that there are three totally different classes of words in *-ing*. (1) The abstract noun, as, "The *courting* of danger is foolish." (2) The gerund, as, "He perished in *courting* danger." (3) The participle, as, "The foolish fellow, *courting* danger, met his death."

2. The past participle ends in *-d, -ed, -t,* or *-en*. It is always passive, provided that the verb from which it is formed is transitive, as "*Refreshed* by our night's rest, we resumed our journey next morning."

[Of course, the past participle can be compounded with the verb "to have" to form an active verb, as "I *have refreshed* myself."]

The Anglo-Saxon past participle was formed by prefixing *ge-* to the verb; traces of this remain in the words *ydrad* (dreaded), *yclept* (called), *yclad* (clothed), *yslaked* (slaked). *Cf.* the German method of forming the past participle, as *gefunden*, from *finden*.

Participles often come to be used as mere adjectives—*e.g.*, "a *frowning* hill," "a *broken* reed."

In addition to these two participles proper, the following compound participles are used in English:

a. The past participle compounded with "having," to form a perfect participle active, as, "*Having spoken* these words, he died."

b. The past participle compounded with "being," to form an imperfect participle passive, as, "*Being warned.*" Also the same compounded with "having been," to form a perfect participle passive, as, "*Having been warned*"

c. A loose kind of future participle, as, "*About to die,* we salute you," "*About to be killed.*"

EXERCISES.

Correct the Following Sentences:

1. I had wanted to have seen him.
2. Trusting you are well, believe me yours truly.
3. In the reading the Psalms, the clerk made many mistakes.
4. If he was to go, he would regret it.
5. Had he have gone he would have regretted it.

In the following sentence classify the words ending in *-ing* into nouns, gerunds, and participles:

"A loving father, lying dying, on seeing his children crying, said, 'Dying is easy; it is living that is trying. Prepare for dying by living noble lives.'"

Key to Sentences on Page 608.

a. "It is I" (who am there).
b. "Themselves" should be "himself."
c. Insert "who" before "is."
d. "Whom" (objective after "mean").
e. "Their" should be "his."

Tense. So far we have considered Voice and Mood of verbs: we now come to *Tense, Number* and *Person.* The different forms assumed by a verb to indicate Time are called Tenses (Latin *tempus* = time).

There are three natural divisions of time—Past, Present, and Future; and corresponding to these are three main tenses in Grammar. But an action in each of these three tenses can be looked at from three distinct points of view—as Incomplete, as Complete, and as Indefinite. We thus get *nine* Primary Tenses, as follows:

	Incomplete.	Complete.	Indefinite.
	(1)	(2)	(3)
Past *Act.*	I was loving	I had loved	I loved
,, *Pass.*	I was being loved	I had been loved	I was loved
	(4)	(5)	(6)
Pres. *Act.*	I am loving	I have loved	I love
,, *Pass.*	I am being loved	I have been loved	I am loved
	(7)	(8)	(9)
Fut. *Act.*	I shall be loving	I shall have loved	I shall love
,, *Pass.*	I shall be being loved	I shall have been loved	I shall be loved.

In addition to these nine Primary Tenses

there are three Secondary ones, called *Perfect Continuous* (in the Active voice only):

1. I have been loving.
2. I had been loving.
3. I shall have been loving.

Notice that nearly all the tenses are formed by using auxiliary verbs, *be*, *have*, etc. Such tenses are called *Compound* tenses, as opposed to *Simple* tenses, which contain only a single word (*I love*, *I loved*). An alternative form of the past and present indefinite tenses is often used, "I *did* love," "I *do* love." Sometimes the *do* and the *did* are used for emphasis, as "I *did* think you would have come earlier." But often there is no emphasis attached to them, as, "The young lions *do* lack and suffer hunger." Similarly, in the well-known passage from Samuel, "They set bread before him and he *did* eat," there is no emphasis intended, though the temptation to lay stress on the *did* is almost irresistible. *Do* and *did*, however, are commonly used in questions and in negative sentences, as "*Do* men say?" rather than "Say men?" "I *do* not like you" rather than "I like you not."

Use of the Tenses. PAST. The simple past tense (past indefinite) is used in three ways:

1. It points out, without any qualification, that something occurred in the past, as: "William of Normandy *conquered* England in 1066."

2. It is used with the meaning of an imperfect or incomplete tense: "And as they *sat* and *did eat*, He said, etc." (= *were sitting and eating*).

3. It expresses what used to happen frequently or customarily: "In those days men *travelled* well-armed" (= *used to travel*).

PRESENT. The simple present tense (present indefinite) is used in the following senses:

1. It states what is actually taking place, as "Swift to its close *ebbs* out life's little day"—*i.e.*, "is ebbing at this moment."

2. It denotes what regularly takes place, as: "Each morning *sees* some task begin, Each evening *sees* its close."

3. It often stands for the future, especially after *when*, *as soon as*, etc., as: "We *go* home to-morrow," "As soon as I *hear*, I will let you know," "When the Son of Man *cometh*, shall He find faith on the earth?"

4. It is sometimes used for the sake of vividness in describing past events, the speaker adopting the present tense in order to be more graphic, as:

"The English shafts in volleys hail'd,
In headlong charge their horse assail'd:
Front, flank, and rear, the squadrons *sweep*
To break the Scottish circle deep,
That fought around their King."
("Marmion.")

FUTURE. This tense is not simple, but compound, the two auxiliary verbs *shall* and *will* being used for its formation. There is a difference in the use of these two auxiliaries.

Shall originally denoted obligation or authority (from Anglo-Saxon *sculan*, to owe), a sense which it retains in the second and third persons of the future, as: "In the sweat of thy face *shalt* thou eat bread," "Thou *shalt* not kill," "There *shall* be no night there." But in the first person, *shall* is used for the simple future, as: "I *shall* be home by five o'clock."

Will. When *will* is used in the first person, it implies (like *shall* used with the second and third), that the action spoken of is dependent on the will of the speaker, as: "Though I should die with Thee, yet *will* I not deny Thee." But in the second and third persons, *will* usually denotes simple futurity, as: "Christmas *will* soon be here." Sometimes, however, it denotes habit or custom, as: "When the cat's away, the mice *will* play."

We thus see why it is that in the ordinary future tense, in affirmative principal sentences, *shall* is used for the first person, *will* for the second and third, as: "I *shall* be, Thou *wilt* be, He *will* be." But in dependent clauses *shall* is used for all three persons, as: "*When* the Son of Man *shall* come in His glory," etc.

Precision of Tenses in English. The use of auxiliary verbs like *do*, *have*, *be*, *shall*, etc., makes it possible to mark tense in English with the greatest possible exactness and precision. In languages that are more inflected and less analytic, this is not possible. In Latin, for example, the one word *scribo* stands for (1) I write, (2) I am writing, (3) I do write. Similarly, *scripsi* stands for (1) I wrote, (2) I have written; and so on.

Sequence of Tenses. If the verb in the principal clause of a sentence is present, future, or perfect, the verb in the dependent clause will be present or future; and if the verb in the principal clause is past, the verb in the dependent clause will be past. Examples:

$\left.\begin{array}{l}\text{“We eat}\\ \text{“We shall eat}\\ \text{“We have eaten}\end{array}\right\}$ in order that we *may* live."

"We ate in order that we *might* live."

Number. Verbs, like nouns, have two numbers, singular and plural. The plural is without inflexion in all verbs except "to be."

Person. Verbs are inflected for Person; there are three persons, First, Second, and Third (the person speaking, the person addressed, the person spoken of).

Conjugation of Verbs.

VERB "TO BE."

Infinitive Mood.

Present.	*Past.*
(To) be	(To) have been
(To) be being	(To) have been being

Participles.

Incomplete	*Perfect.*	*Compound Perf.*
being	been	having been

Indicative Mood.

Past.	Present.	Future.
	Indefinite.	
I was	I am	I shall be
	Incomplete (or Continuous).	
I was being	I am being	I shall be being
	Complete (or Perfect).	
I had been	I have been	I shall have been
	Perfect Continuous.	
I had been being	I have been being	I shall have been being

Subjunctive Mood (no future tenses).

Past.	Present.
Indefinite.	
I were, *or* might be	I be, *or* may be
Incomplete.	
I were being, *or* might be being	I be being, *or* may be being
Complete.	
I had been, *or* might have been	I have been, *or* may have been
Perfect Continuous.	
I had been being, *or* might have been being	I have been being, *or* may have been being

A third form of the Past tense is formed with *should* instead of *might*—thus, I should be; I should be being; I should have been; I should have been being.

Imperative Mood.

Singular.	*Plural.*
Be (thou)	Be (ye)

The above is the full conjugation of the verb *to be*, but, of course, there are some of these forms which are seldom, if ever, used—*e.g.*, "I had been being," "I should have been being." We use instead the participle of some such verb as *become, grow, get*, as: "I had been growing tired."

The four simple tenses are now given in full:

Indicative Mood.

Present Indefinite.		*Past Indefinite.*	
(I) am	(We) are	(I) was	(We) were
(Thou) art	(You) are	(Thou) wast *or* wert	(You) were
(He) is	(They) are	(He) was	(They) were

Subjunctive Mood.

Present Indefinite.		*Past Indefinite.*	
(I) be	(We) be	(I) were	(We) were
(Thou) be	(You) be	(Thou) wert	(You) were
(He) be	(They) be	(He) were	(They) were

In the compound tenses there is no inflexion, except of the auxiliary verbs "have, shall," etc., which will be given later.

The conjugation of the verb *to be* is made up from three different roots: (1) *as*, Latin *es*, which gives *am* (as-m), *art* (as-t), and *are* (as-e); (2) *be*; (3) *wes*, which gives *was* and *were*.

All the tenses of *be* can be used as auxiliaries to form the compound tenses of other verbs ("I shall have been writing"), but the Incomplete and Perfect Continuous tenses are used only for the Passive Voice ("I was being robbed").

Verb "To Have."

Infinitive Mood.

Present.	Past.
(To) have	(To) have had
(To) be having	(To) have been having

Participles.

Incomplete.	*Perfect.*	*Compound Perf.*
having	had	having had

Indicative Mood.

Past.	Present.	Future.
	Indefinite.	
I had	I have	I shall have
	Incomplete.	
was having	I am having	I shall be having
	Complete.	
I had had	I have had	I shall have had
	Perfect Continuous.	
I had been having	I have been having	I shall have been having

Subjunctive Mood.

Past.	Present.
Indefinite.	
I had I might have I should have	I have I may have
Incomplete.	
I were having I might be having I should be having	I be having I may be having
Complete.	
I had had I might have had I should have had	I have had I may have had
Perfect Continuous.	
I had been having I might (*or* should) have been having	I have been having I may have been having

Imperative Mood.

Singular	*Plural.*
Have (thou)	Have (ye)

The four simple tenses in full:

Indicative Mood.

Present Indefinite.	
(I) have	(We) have
(Thou) hast	(You) have
(He) hath, *or* has	(They) have

Past Indefinite.	
(I) had	(We) had
(Thou) hadst	(You) had
(He) had	(They) had

SUBJUNCTIVE MOOD.

Present Indefinite.

(I) have	(We) have
(Thou) have	(You) have
(He) have	(They) have

Past Indefinite.

(Same as Indicative.)

Had is shortened from *haved*, *hast* from *havest*, *hath* from *haveth*. *Hath* is now very rarely used.

Only the Indefinite tenses of *have* can be used as auxiliaries to form compound tenses of other verbs.

Analysis of Sentences

We can now turn aside for a moment from our study of words as independent units (the study of *Accidence*), and can deal with them in their relationship to other words grouped with them to form a sentence. The unit of speech is the sentence, and it is quite as important to be able to break a sentence up into its component parts as it is to be able to compare an adjective or conjugate a verb. We cannot properly parse a word—*i.e.*, say to what part of speech it belongs—until we see it in a sentence; and before we can parse it then as it should be parsed, we must make a mental analysis of the sentence. Analysis, therefore, logically comes before parsing.

Analysis of a Simple Sentence—*i.e.*, a sentence that has only one Subject and one Predicate. In every sentence there must be a subject and a predicate; this is the irreducible minimum, as "Fire burns." In addition, there may be a word or words limiting or qualifying either the subject or the predicate, or both, as: "*This* fire burns *well*." Finally, if the predicate is a transitive verb it will take an object, and this object, too, may have a word or words limiting it, as: "Fire burns your finger" (*finger* being object, and *your* limitation of object).

As a rule, a simple sentence does not consist of more than these six parts:

1. Subject.
2. Limitation of Subject.
3. Predicate.
4. Limitation of Predicate.
5. Object.
6. Limitation of Object.

For example: "The freshening breeze of eve unfurled that banner's massy fold" consists of the following five parts:

Subject.	*Limitation of Subject.*	*Predicate.*	*Object.*	*Limitation of Object.*
breeze	1. The freshening 2. of eve	unfurled	fold	that banner's massy

Again: "Here rests his head upon the lap of earth A youth, to fortune and to fame unknown."

Subject.	*Limitation of Subject.*	*Predicate.*	*Limitation of Pred.*	*Object.*	*Limitation of Object.*
youth	1. A 2. to fortune and to fame unknown.	rests	1. Here 2. upon the lap of earth	head	his

Sometimes the predicate consists of a verb and a complement, especially after verbs of *making*, *calling*, etc. For example: "Cromwell's enemies have often called him a bloodthirsty monster." This is analysed as follows:

Subject	*Limitation of Subject.*	*Predicate.*		*Limitation of Complement.*	*Limitation of Predicate.*	*Object.*
		Incomplete Predicate.	*Complement.*			
enemies	Cromwell's	have called	monster	a bloodthirsty	often	him.

Although analysis robs a passage of its beauty and poetry of expression, it nevertheless lays bare the structure of the sentence. From a grammatical point of view a sentence is not grasped until it has been mentally analysed and all its component parts set forth in their *utter nakedness*.

KEY TO EXERCISES ON PAGE 757.

1. I had wanted to see him.
2. Trusting you are well, I remain, yours truly (in the faulty sentence the participle *trusting* agrees with *you*, which is the suppressed subject to *believe*; it therefore means: "Do you, trusting you are well, believe me," which is nonsense).
3. Either "In *reading* the Psalms" (gerund) or "In the *reading* of the Psalms" (abstract noun).
4. If he were to go, he would regret it (subjunctive).
5. If he had gone (*or*, had he gone), etc.

Continued

DUTIES OF THE UPPER SERVANTS

The Butler's Duties at Table. The Wine-cellar. The Housekeeper's Duties. Care of the Linen-press and Store-cupboard. The Valet

Continued from page 616.

By A. EUNICE T. BIGGS

THE BUTLER

The butler is the chief manservant in the household, except in the case of a few wealthy families where a very large retinue of menservants is kept, at their head being the house-steward and chamberlain. All the menservants whose duties are executed indoors live in the house; those whose duties are concerned with outdoor work, such as the gardeners and the coachman, etc., live out of the house. The head-gardener and coachman are generally each given the use of a small house or cottage, either on the estate or in the vicinity, this being in addition to their ordinary wages. Certain indoor servants have special privileges connected with their duties. For example, the valet will have little expense connected with his own wardrobe, since he has no livery, and can therefore wear his master's discarded clothes.

The butler, together with the housekeeper, takes precedence of all the other servants, and his duties are very responsible ones. Besides being expected to superintend the other menservants, and to see that their duties are properly executed, he has charge of all the valuable articles in daily use, and he is entirely responsible for the management of the wine-cellar. It is therefore obvious that the moral integrity of the butler should be above suspicion. He will have many temptations, since he is placed by the execution of his duties in a position in which it would be exceptionally easy to defraud his master.

The Butler's Duties when Waiting at Table. The butler waits at table during breakfast, assisted by the footman. He is responsible for the proper arrangement of the table and for the serving of the breakfast dishes. He is also expected to see that the china in use at the meal is clean and the silver properly polished. After breakfast he will clear the table, taking away the plate, which is under his care. At luncheon the arrangement of the table falls to his share, as well as the waiting. At this meal the butler usually waits single-handed, as the footman is engaged in other duties. The butler's most onerous duties are performed at dinner-time. Before dinner is served he has to supervise the laying of the table, and see that the flowers, table centre, and table decorations are prettily arranged. He will also place the silver on the table, and see that every necessary article is in readiness.

When the dinner is ready, he brings in the first course, and announces in the drawing-room that dinner is on the table. He then stands near the dining-room door as the family come into the room, and closes it after the last to enter. When the diners are all seated he approaches the table. In some houses the master serves many of the dishes, which are, in such a case, placed in front of him. The butler stands behind his chair, removes the covers, and hands them to the other servants-in-waiting to carry out. If, on the other hand, the dishes are served at the side table, the duty of dispensing them will devolve on the butler. He will serve the soup, and then cross to the sideboard to pour out the sherry and madeira taken after that course.

The Serving of Wine, and Carving. When the first course is ended, the butler rings the bell to warn the cook that the second course may be served. He then collects the plates and dishes of the first course, hands them to the other servants to remove, takes the second course from them, places it on the table, and, after removing the covers, returns to the sideboard to dispense the wines. If the joints are served at the side table, it will be the butler's duty to carve them; he should therefore be an expert carver. Of course, at a very large dinner-party help will be needed for this part of the work, but in ordinary cases a well-trained butler will carve sufficiently quickly to serve everyone present at the table with but little delay. When the dinner is finished, the butler, assisted by the footman, removes the wine-glasses and extra silver and cutlery, and sets the table for dessert. He places the finger-bowls and fruit knives and forks before each guest, and the fruits and sweetmeats on the table. He then hands round the various dessert dishes, and stands behind his master's chair to hand the wines, etc. He sees that the room is in order, that the fire, if lighted, is replenished, that the lights are in order, and then, at a signal from the master, he and the footman leave the room.

Care of the Wine-cellar. While the guests are in the dining-room he goes to the drawing-room, arranges the windows, makes up the fire, tidies the hearth, and sees that the lights are in order. He then returns to his pantry. While the footman is clearing the table and cleaning the plates and glasses, the butler must be in readiness to answer the bell. When the guests are again assembled in the drawing-room, he will, either alone or assisted by the footman, serve the coffee. The latter is brought in on a tray, together with hot milk, cream, and sugar, and is handed to the guests in turn, each person pouring out his or her own portion, and adding milk, sugar, and cream to taste.

The chief and most important duty of the butler is to take proper charge of his master's wine-cellar, and this he must be fully competent to do. We shall deal later with this part of his work; for the present we have confined

ourselves to the minor portions of his daily routine. In brief, his duty is to be in attendance at every meal, including that of tea, to see that the table is properly set and that the service is as it should be in every way. In the evening the butler brings the candles at a time fixed by the master and mistress.

The Butler's Duties at Night. After the family have retired it is his duty to go the round of the house, seeing that all the doors and windows are safely bolted and barred, that all lights are extinguished, and that the fires are safe. He must be particularly careful to see that the wine-cellar is locked, and that the plate and valuables for which he is responsible are safely locked up for the night. If the master of the house has no valet, the butler may be called upon to perform some of his duties, but these will not be arduous, and need not interfere with the performance of his regular duties.

The butler must see that the wine-cellar is kept in a clean and proper condition. He should be familiar with the qualities and treatment of the various wines, and so be able to advise his master as to the best choice. The butler must know what is the proper treatment of the various wines under his care, and he should spare himself no pains in his endeavour to secure for his master the reputation of "keeping a good wine-cellar."

Although the wines are often purchased ready bottled, it is sometimes the butler's duty to fine and bottle them, in which case he should be familiar with the process. A portion of wine is drawn off from the cask, mixed with the white of four eggs, and thoroughly stirred. This mixture is then returned to the cask by the bunghole, together with the rest of the wine previously withdrawn. The contents of the cask must be stirred round by means of a wooden rod inserted through the bunghole. All bubbles rising to the top should be removed when the mixing is finished, the bunghole plugged, and the cask left to stand for three or four days. Wine so treated will fine 12 to 14 gallons of port or sherry.

Some butlers prefer other clearing ingredients than the white of eggs. Small pieces of isinglass or gelatine, cut into tiny fragments and dissolved in the withdrawn wine, may be used instead.

Bottling Wine. This is an important operation. A small hole is bored at the bottom of the cask, a gimlet being used for the purpose. The bottles are in turn placed under the hole and a strainer is used to prevent "grounds" from entering the bottle. As the cask becomes nearly empty a piece of muslin placed over the strainer will filter the wine more effectually.

The corks should be soaked in hot water and then squeezed dry. The bottle to be corked is placed in the bottling-boot, which is strapped on to the knee of the person doing the corking; the cork is then forced in with several smart blows from a broad, wooden mallet. The corks should then be sealed, or the heads of the bottles dipped into quicklime or petroleum, in order to keep insects away.

The bottles of wine should be carefully counted and a written record of them kept by the butler. By reference to this notebook the butler should know the exact contents of the wine-cellar and particulars as to when the wine was used The bottles of wine are laid on a wine-stand in layers. The alternate layers will be with either head or bottom of the bottles outwards, and between the layers there will be sawdust or straw.

The "Cellar-book." A careful butler will wash the empty wine-bottles and keep them carefully sorted. This is a great saving of trouble when bottling is in full swing. If the wine is purchased ready bottled, it will not be so necessary to keep the different kinds of bottles sorted, but whenever a fresh supply of wine is bought, the butler will do well to return a corresponding number of bottles to the merchant.

The casks should be well rinsed with boiling water and kept scrupulously clean. Should there be any trace of a sour or musty smell, the cask must be cleansed with lime and boiling water, and well rinsed and dried before being used again.

The butler should also keep a "cellar-book," in which to make a careful entry of every bottle of wine used. This book should be a complete record of all the wine drunk, and enable one to see the contents of the wine-cellar at a glance. In advising his master as to the ordering of fresh wines to replenish the wine-cellar, the butler should be careful not to allow himself to be influenced by bribes from wine merchants. These are occasionally offered, but a scrupulous butler will not allow himself to give way to temptations that are derogatory to his master's interest.

The Butler's Wages. The head-butler's wages vary considerably with different localities, ranging from £60 to £80 per annum. The under-butler's duty is to assist the butler in every way. He will carry up the wine and do the greater part of the cleaning and tidying of the wine-cellar, the washing of the wine-bottles, etc. If there is no under-butler, these duties will have to be performed by the butler, who will himself carry up the wines to the dining-room.

THE HOUSEKEEPER

The housekeeper must never allow herself to forget that she is the immediate representative of her mistress. She is responsible for the comfort of the servants working under her direction, and it is her duty to see that each domestic gets his or her meals at suitable times, and that these are served in a satisfactory manner. She must supervise the other conditions of the servants' also lives, seeing that each in turn gets reasonable time for rest, recreation, and exercise, and that the various duties are fairly apportioned.

Although the housekeeper's room is a sanctum in which butler, valet, and lady's-maid alone associate with the housekeeper, this room should not be far removed from the servants' hall and kitchen. It should be sufficiently near for the housekeeper to have every opportunity of seeing that all is satisfactory in these other rooms; but, on the other hand, it should not be so near

that the servants feel an uncomfortable sense of restraint. Servants dislike nothing so much as the idea that they are being "spied on," whether by mistress or housekeeper, and petty deceptions and deceit are more than likely to be bred by a system of espionage. A tactful housekeeper will make it evident that she is quite ready to detect wrongdoing or neglect of duty without making her attitude annoyingly aggressive. The ideal housekeeper should possess the same moral and mental gifts as those previously enumerated as desirable in a good mistress, and she should also endeavour to promote a good tone among the domestics of her household. Her punctuality should be unimpeachable; she should be neat and methodical in the execution of her duties, and her love of order and cleanliness should make itself felt in her organisation and control of the work of the household.

Accounts. The disposal of a considerable amount of money devolves upon the housekeeper, and she must keep a careful record of all money that passes through her hands. For this purpose she must be well skilled in the keeping of accounts and abl to extend her neatness and method to the keeping of certain books and records of expenditure. Her account-books should present a methodical register of the outlay of the household in current expenses, such as wages and tradespeople's bills. Every time money is spent its expenditure should be entered, and then the different items sorted out and re-entered under the various headings as food, wages, etc. The housekeeper will also find her expenditure easier to control if she keeps a record of all things ordered and received. She can compare this list with the accounts sent in by the various tradespeople, and so detect any attempts at fraud and overcharging. The housekeeper's accounts should be carefully kept and balanced by the master or mistress at stated intervals. This examination is most desirable and satisfactory to all parties concerned.

The housekeeper's salary will depend much on the conditions under which she is engaged, varying from about £20 to £50, or more in large households.

The Housekeeper's Duties. The housekeeper's duties vary considerably according to the size of the ménage which she has to superintend. If the household is large and she has a great number of domestics under her control, she will of necessity be kept very busy if she is to carry out her duties satisfactorily. She should rise early, and see that the early morning work is properly performed. She should also see that breakfast preparations are well made, so that the meal can be punctually and comfortably served at the appointed time. After breakfast she will be busy making various arrangements for the day.

She will have to superintend the orders sent to the various tradespeople, such orders always passing through her hands before they are sent off. She will then make a tour of inspection through the house, and see that the servants are all conscientiously performing their allotted tasks. She should be quick to notice where repairs are necessary—if cushion-covers and upholstered furniture need mending, if the windows are in good working order, and well cleaned, and that the furniture is not scratched or badly polished; in fact, a well-trained housekeeper is always on the alert, and no detail of housewifery or household management will escape her notice.

The Care of the Linen-press. One of the housekeeper's principal duties is to look after the stock of linen in the house. This will occupy a portion of more than one day in each week. An inventory should be made of the contents of the linen-press and the linen in use. A housekeeper should know how many tablecloths, sheets, etc., her stock should comprise, and she should systematically examine each set of articles with a view to ascertaining whether her stock needs replenishing. In many cases, by arranging for a little judicious darning and mending, the life of some articles may be much prolonged. The best time for a housekeeper to arrange for such replenishing of her stock of linen is during the summer. The ordinary household routine is then considerably lightened; there are no fires to tend, and the hours of daylight being lengthened, more work can be done without fatigue. The linen-press should be so carefully overhauled that the stock of linen is never allowed to get low, for directly the housekeeper notices that an article is wearing out, she should take steps to replace it. The same method should characterise the housekeeper's care of everything under her charge. She should at intervals make lists of all the different articles for which she is responsible, and by this means detect any loss or deficiency caused by breakage or wear.

The Store-cupboard. The care of the store-cupboard will occupy a good deal of the housekeeper's time, and she will do well to let each season add to her store of preserves or pickles. In very large establishments she will have little or nothing to do with the cooking, except to see that the kitchen arrangements are satisfactory, and that the meals are served punctually and well. In most cases, however, the housekeeper takes some share in the preparation of a few dainties and preserves. Thus she will perhaps be responsible for the dessert, and particularly for the sweetmeats, crystallised fruits, ginger, and salted almonds used at that course. During the summer and early autumn months she will find herself busy in assisting with the making of jams, jellies, and pickles of various kinds.

In the spring the housekeeper is responsible for the proper conduct of the spring cleaning. She should carefully supervise the turning-out of each room, and, with the sanction of her mistress, get rid of all unnecessary articles, which only serve to fill up the house and accumulate dirt and dust. She should notice carefully if any particular part of the house calls for the attention of the painter or paperhanger, and, if so, bring the matter before her mistress.

The housekeeper must take the greatest care

to preserve her own dignity and authority in her dealings with the servants of the household. To her lot will fall the task of engaging the women-servants, and she will, therefore, have to make all inquiries as to the character and previous experience of the servant making application for the situation. In doing so she should take the same precautions as those indicated in the earlier part of this section as being desirable for a mistress. In the exercise of her duties, the housekeeper should avoid all semblance of being overbearing and exacting, but she should never lose sight of the dignity and responsibility of her position.

THE VALET

The valet is, of course, the personal attendant of the master, and his duties chiefly consist in looking after his comfort and well-being. The valet has exceptional opportunities of showing his loyalty and zeal in serving his master. He must also possess no small amount of tact and patience, and be able to bear petty annoyances and retain his good temper and respectful manner, even on occasions when his master may be overbearing and irritating.

A good valet will always maintain a respectful demeanour, never allowing himself to lapse into undesirable familiarity. The valet must be absolutely trustworthy, since in his intimate dealings with his employer he has abundant opportunities of defrauding him. He should be very careful in his conversation in the housekeeper's room, and should never repeat any private family matter which has come to his notice, or which he may accidentally learn in his confidential position. In the matter of his own personal appearance, the valet should take pains to be neat and well-dressed. He never wears a livery, but he is, as a rule, the recipient of the clothes his master no longer cares to wear.

The Valet's Daily Routine. The valet's first duty will be to see that his master's dressing-room has been properly swept and dusted by the housemaid. Then, if the weather is cold, he should see that the fire is alight and well tended, and that the room has been properly aired. He should then put all his master's clothing in readiness. The linen and woollen garments should be well aired, and the suit carefully brushed and folded. Everything that his master will need for his toilet should be in readiness; soap, towels, and brushes should be in their proper places. The valet should also put hot water in readiness for washing and shaving, and see that the razors are ready for use. When the master does not shave himself, the valet must be competent to perform the operation.

This servant should also be skilled as a hair-dresser, since he will have to brush and arrange his master's hair, and should he possess beard or moustache, these must also be given attention. While the master is dressing, the valet should be in attendance, handing him in turn each article he requires, and adjusting his necktie, etc.

The valet will doubtless be required to perform various little commissions for his master, such as taking notes and messages. He must, however, find time to keep his master's wardrobe in good order, be careful of his master's appearance, see that his clothes are well brushed and all stains removed, and his silk hat ironed when necessary. He should also see that the master's toilet is irreproachable, and that all necessary repairs are executed. The valet should never allow his master's stock of underwear and smaller articles, such as socks, gloves, ties, collars, etc., to get very low, and should advise him in the matter of replenishing his wardrobe.

The Valet's Duties. During the absence of the master, the valet has not very many duties to perform; but he should be in readiness to wait on his master at all times, and particularly when dressing for dinner. After his master's toilet is completed, the valet should set his dressing-room in order. He should brush and put away discarded suits, and tidy the dressing-table, cleaning and setting in order razors, brushes, and comb, etc. Should he be in attendance on an elderly master, he may be required to give rather closer personal attendance, such as sleeping in an adjoining ante-chamber, accompanying his master out of doors, etc. He may also be required to wait at table, in which case he will stand behind his master's chair and confine his whole attention to administering to his wants.

Sometimes the valet is required to travel with his master. In this case he will doubtless be more or less responsible for looking out routes, taking the tickets, and securing a comfortable seat. Whenever there is a change of carriage or a long delay, the valet should seek his master's carriage, and wait on him. He may be required to get tea or newspapers, and he is also responsible for the luggage. He must see that it is properly labelled and put in the van, and keep his master's dressing-case, or bag, under his personal supervision in his own carriage.

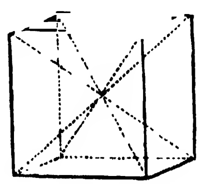
MINERALS IN THE EARTH'S CRUST

Determination of Minerals by Appearance, Properties, and Chemical Composition. Rocks are Built up of Minerals in the Earth's Crust

Continued from page 624.

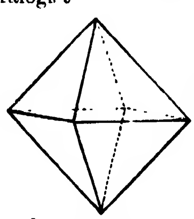
By W. E. GARRETT FISHER

Minerals Form Rocks. All rocks are made up of one or more minerals. In the case of a rock which—as is most common—has several mineral constituents, it is necessary to distinguish between the *essential* and the *accessory* minerals. An essential mineral is one which could not be removed from the rock without materially altering its character; thus, quartz is said to be an essential constituent of all granites, whereas the crystals of topaz and beryl, which often occur in granite, are accessory—their absence would not affect the granitic character of the rock. Again, we have to distinguish between *original* and *secondary* minerals. The original minerals are those which formed part of the rocks when they were first laid down, while the secondary ones have been added later, by chemical changes, or by the intrusion of water holding them in solution, or by similar methods. The veins of ore which are so important a part of the mineral resources of a country afford good examples of secondary minerals which have been introduced long after the formation of the rocks in which they occur.

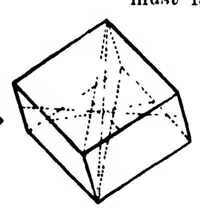


8. CUBE

The business of the mineralogist is, in the first instance, to be able to identify any specimen which is submitted to his examination, and to state the conditions under which it is likely to be found in association with other and perhaps more valued minerals. This part of his work, as will be obvious, is of great value to the miner, but it is possible or necessary to give here only a brief outline of the principles by which it is directed. In an elementary course of geology we need concern ourselves only with a small number of the existing minerals—those, namely, which chiefly compose the more common rocks of the earth's crust. The methods by which these minerals are identified, and their characteristics, can be learnt so simply in the laboratory and the museum that it would be a waste of time to give more than the briefest outline of them now.



9. OCTAHEDRON



10. RHOMBOHEDRON

Testing Minerals. Minerals are distinguished by (1) their external appearance, (2) their physical properties, (3) their chemical composition. Of course, the third of these tests is the most valid and satisfactory, and is always applied when the resources of a proper laboratory are at hand. But the practical geologist has to do the greater portion of his work in the field, with only the aid of such simple instruments and reagents as he can carry on his person. The prospector, who is searching for specimens of ore, is in the same position. Consequently, it is eminently necessary that he should be able to identify the more important minerals by means of the first and second tests—by their general appearance, supplemented by such physical properties as he can examine off-hand. To these he is able to add such chemical tests as can be applied by means of the simple apparatus and reagents which can be carried on a geological tour or added to the camp outfit of the prospector. By these methods the trained mineralogist can satisfactorily determine the nature of practically every specimen with which he is likely to meet, though here and there a puzzling mineral may have to be left for thorough inspection in a properly equipped laboratory.

There is no royal road to the power of identifying readily the more common minerals. The student must familiarise himself with their appearance by practice. He may usefully begin with one of the boxes containing fifty or a hundred typical specimens which are sold by most of the scientific instrument dealers, and then extend his research in the wider collection of a geological museum, such as that of the Geological Survey, in Jermyn Street, the Natural History Museum, in Cromwell Road, London, or in the collections attached to any of our provincial universities. The following outline will show him the main points for which to look.

Determination of Minerals—External Form and Structure. Minerals, though varying so widely in their outward appearance, can all be classified in this respect under one of four heads. They are (*a*) *Crystalline*, (*b*) *Vitreous*, (*c*) *Colloid*, (*d*) *Amorphous*.

Crystalline minerals are those which occur in the shape of regular geometrical solids, bounded by smooth, shining faces. A very large number of minerals are found in Nature in these forms. The phenomena of crystallisation is explained in the course on PHYSICS. It is enough here to remind the student that they always imply

that the substance which presents them has been solidified from a state of fusion or solution. It is a law of Nature that every substance which is susceptible of taking on a crystalline form adheres to it under all conditions and in all places where it is found—although it must be noted that many minerals have apparently more than one crystalline form, which they assume in accordance with the physical conditions under which they are deposited. Thus, calc-spar [12] (*carbonate of lime*, $Ca\ CO_3$) is found in nature under many crystalline forms, such as the familiar dog-tooth spar [11]; but each of these is reducible to what is known as the fundamental form of calc-spar, a rhombohedron [10]. The fundamental form of fluor-spar (*calcium fluoride*, $Ca\ F_2$) [15] is a cube [8], but it is found in many other forms, such as the regular octahedron [9], each of which is a modification of the cube by the slicing off of successive corners.

Crystallography. A crystal is a geometrical solid bounded by plane surfaces. These bounding surfaces are called the *faces* of the crystal. The lines in which they meet are called its *edges*, and the point where three or more edges meet is called an *angle*. The vitally important thing in the study of crystals is that these angles always remain the same in similar crystals. A crystal as it occurs in nature often looks very different from the trim figures of the text-book. It may have grown up under conditions which have truncated it in one direction and exaggerated it in others. But its angles always remain constant to the form to which it belongs, and by measuring them it can be assigned to its proper system with certainty. Consequently, the most important piece of apparatus used by the crystallographer is the *goniometer* (angle measure·), which enables him to measure the angles of any crystal with rapidity and care, either by directly laying two hinged arms fitted with a scale on the faces of the crystal (*contact goniometer*) or by measuring the deflection of a beam of light which is reflected from adjoining faces (*reflecting goniometer*).

After the angles of a crystal, the most important thing to examine is its *cleavage*. All crystals have the curious property of splitting more or less readily along planes which are called *cleavage planes*, and which in all cases are parallel to the faces of a fundamental form, or to the diagonals of a face. Some crystals, like dog-tooth spar [11], can be split along their cleavage planes by a mere tap; even the diamond, though the hardest of minerals, can be shaped by chipping away its corners along the planes of cleavage.

Classes of Crystals. There are 32 different classes of crystals, of which all but two or three are known to occur in nature. They are divided into six systems, of which the following typical examples may be examined in a museum:

System of Crystallisation	Example
(i) Anorthic	Axinite.
(ii) Monoclinic	Gypsum.
(iii) Orthorhombic	Barytes.
(iv) Hexagonal	Quartz, Calcite.
(v) Tetragonal	Zircon.
(vi) Cubic	Galena.

Enough has been said to indicate the importance of a knowledge of crystallography to the practical mineralogist. The great law of crystalline form tells us that bodies of the same chemical composition always crystallise in the same fundamental form, or in a form which can be reduced to it by simple cleavage, and conversely we know that crystals of a certain form must belong to one or other of a limited group of minerals. Often the crystal is so distinctive—like the diamond, ruby, or dog-tooth spar—that the mineral can at once be named. At any rate, we have a guide for the application of further tests.

Non-Crystalline Minerals. *Vitreous*, or glassy, minerals are easily recognisable. As their name indicates, they are a kind of natural glass, which may, or may not, be translucent. Obsidian [14], the well-known "volcanic glass," is a familiar example. These minerals have mostly been fused, as in the lava of a volcano, and have cooled too quickly for crystallisation to occur.

Colloid minerals consist of a substance which reminds the observer of a petrified jelly. Silica is the most abundant mineral which takes this form. Opal [13] is a hardened variety of it.

The rest of the minerals are called *amorphous*, or shapeless, because they assume no definite form, but are found in more or less coherent masses, tufts, or granules. The soapstone [16] used by tailors, under the name of French chalk, is a good example.

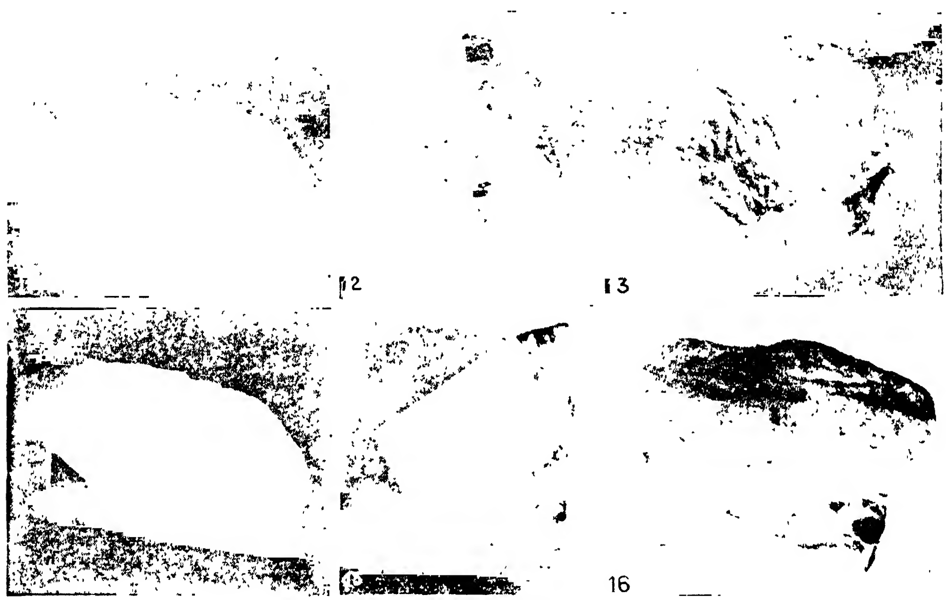
Physical Properties of Minerals. Every mineral has a distinctive set of physical properties which are of great service to the mineralogist in determining its place in the series of nature. First comes the *specific gravity* [see PHYSICS], or weight of a mineral, compared with that of an equal volume of water. This is tested by weighing the specimen first in air and then in water; but the practical geologist soon learns to make a rough but fairly accurate guess of the specific gravity by poising the specimen in his hand. Next comes the *hardness* of the specimen, measured in terms of a series of ten minerals ranging from talc up to diamond: the mineral is placed between the last which it will scratch, and the first which will scratch it. The *colour* of the mineral and of the *streak* which it leaves on paper, or which a knife leaves on it, its *lustre* and *transparency*, are also noted. The nature of its *fracture* when broken is important. It may have a characteristic *taste* or *odour*. Lastly, its *optical*, *electrical*, and *magnetic* properties have to be observed; but this usually involves the possession of apparatus, such as

the polariscope and the electrometer, which cannot be taken into the field, and belong to the mineralogical laboratory rather than to the camp outfit.

Chemical Composition of Minerals. The only absolutely satisfactory test of a mineral is that afforded by a complete chemical analysis, which can, of course, be carried out only in a properly equipped laboratory. A few rough tests, indeed, may be applied in the field, such as the use of an acid to see if a carbonate is present, when a little carbon dioxide (CO_2) is given off with visible effervescence. Beyond these simple tests, the business must be learnt by practice, and the average geologist is content to depute it to the chemist.

Large masses of such visitants are still lying on the soil of Greenland and Arizona. Carbon occurs uncombined in two forms—as *graphite*, or *plumbago*, which, from its property of producing a black streak on paper, is utilised in the manufacture of the so-called lead pencil; and as the most splendid of gems, the diamond, which is simply a crystalline form of pure carbon. Sulphur is also found native, as a product of volcanic action: the Spanish conquistadores obtained the sulphur for their gunpowder from the crater of a volcano.

Oxides. Certain *Oxides*, or compounds of oxygen in another element, form important constituents of the rocks. The two which we need to note here are the oxides of silicon and iron.



TYPICAL MINERALS

11. Dog-tooth spar (Matlock, Derbyshire). **12.** Calc-spar (Cumberland). **13.** Opal (Hungary). **14.** Obsidian (Lipari Isles). **15.** Fluor-spar (Cumberland). **16.** Soapstone (North Carolina)

Classification of Minerals. Minerals have been classified in various ways, but the most satisfactory system, on the whole, is that which depends on chemical composition. We shall be content to glance briefly at the twenty or thirty more important minerals which chiefly go to build up the rocks of the earth's crust. These leading minerals may be classified for convenience according to their composition under various heads—to understand which some knowledge of elementary chemistry, such as can be obtained from the course on the subject, must be assumed.

Native Elements. Certain *native elements* occur as minerals. Gold, copper, and iron are found in small quantities in the metallic form. There is reason to believe that most of the native iron found as a terrestrial mineral reached our planet in the form of meteorites.

Silica ($Si\ O_2$) is a compound of silicon and oxygen, which is best known in the form of the ubiquitous and beautiful mineral known as *quartz*. It is crystalline—indeed, the Greeks called it "crystal," and held it to be petrified ice—and its fundamental form is that of a six-sided prism. But there are innumerable varieties of silica, which is the most abundant of all minerals. Some of these, like amethyst and catseye, are so beautiful as to be regarded as precious stones. Other forms of silica are chalcedony, opal, onyx and agate. Flint, on which the beginnings of human civilisation depended, is also almost pure silica, which has grown into nodules in the chalk-beds.

Iron oxides play a great part in our scenery. *Hæmatite* ($Fe_2\ O_3$), is the red oxide of iron which colours so many of our rocks—*e.g.*, red sandstone and clay (red ochre). It occurs very

abundantly, and is largely worked in the Lake Superior mines and in Cumberland. *Limonite* ($2\ Fe_2\ O_3 + 3\ H_2\ O$), or brown iron-ore, is a hydrated oxide of iron which has been largely deposited from chalybeate springs, as yellow ochre, or bog iron-ore. *Magnetite* ($Fe_3\ O_4$) is the magnetic iron oxide which was early known as the lodestone, from its remarkable property of attracting iron and of causing a needle rubbed with it to point to the north—the mariner's compass. Vast deposits of it occur in Scandinavia, and it is one of the main sources of the world's iron supply.

Corundum ($Al_2\ O_3$) is an oxide of aluminium which may be mentioned (although it does not occur largely in nature) because two of its varieties are the ruby and the sapphire, whilst in the less precious form of emery it gives us a valuable polishing material.

Silicates. The *Silicates*—compounds of silica, or silicic acid, with various metallic oxides—constitute by far the most important group of minerals. "By themselves they constitute at least nine-tenths of the terrestrial crust, and make up practically all the rocks, except the sandstones, quartzites and carbonates." (Geikie).

The *Felspars* are composed of silicate of aluminium, combined in varying quantities with the silicates of potassium, sodium, and calcium, with traces of magnesia and iron oxide. They vary in character according to their composition. The most typical felspar is *Orthoclase*, or potash felspar ($K\ Al\ Si_3\ O_8$). It is an abundant constituent of granite. *Albite* ($Na\ Al\ Si_3\ O_8$) is the corresponding soda felspar, and *Anorthite* ($Ca\ Al_2\ Si_2\ O_8$) is a lime felspar. There are numerous other felspars of varying but generally similar composition. The group is often divided by the cleavage of its crystals into *orthoclase*, with cleavage at right angles; *plagioclase*, with cleavage at an acute angle, and *oligoclase*, with ill-defined cleavage.

Next comes the *Mica* group of silicates. All these minerals share the well-known property of common mica—that they can easily be separated into thin flakes, or *laminæ*. *Muscovite* is the common mica—of which lamp-shades and furnace-windows are made—so called because it comes from Russia, and was once known as "Muscovy glass." It is a silicate of aluminium and potassium of which no exact formula can be given as its proportions vary considerably. *Biotite* is another mica, differing in the presence of magnesium. The glittering flakes of mica are nearly always visible in granite.

The third group of silicates is that represented by *Hornblende* and *Augite*, which are bisilicates of calcium, magnesium, iron, and manganese. These two minerals are closely related, and play a considerable part in the constitution of the granitic and volcanic rocks. Allied to them are *Diallage* and *Hypersthene*. *Olivine* is a silicate of magnesium, iron, and manganese, which forms an essential ingredient of *basalt*.

The fourth group contains *Talc*—the well-known soapy mineral—and *Chlorite*, which are hydrated silicates of magnesium. *Serpentine* is of similar composition, with the addition of aluminium and iron. It is harder, but can still be cut with a knife, and gets its name from the beautiful mottling of its brown and green surface.

Carbonates. A large proportion of the rocks which form the earth's crust are composed of *carbonates*, or compounds of certain metals with carbonic acid, the gas which is produced by combustion or breathing. [See CHEMISTRY.] The most important of these is the carbonate of calcium, which occurs in nature in two forms, alike in chemical composition but differing in external appearance and physical properties. *Calcite* ($CaCO_3$), or calc-spar, is the essential basis of the great masses of limestone rock which are so abundant in many parts of the world, as in Derbyshire. It crystallises in the fundamental form of the rhombohedron. A particular variety which has become famous by its optical properties is the doubly refracting Iceland spar, which gives a twofold image of all objects seen through a transparent slice of it. *Aragonite* ($CaCO_3$) is a harder and more durable form of calcium carbonate, which is much less abundant than calcite, and occurs in rhombic crystals. *Bitterspar* ($CaMgCO_3$) is a double carbonate of calcium and magnesium, found in greatly varying proportions of the two metals, which is chiefly interesting as the basis of the Dolomite rocks which form the great mountain masses of magnesian limestone in the Tyrol and Carinthian Alps. *Siderite* ($FeCO_3$), or brown ironstone, is a carbonate of iron often found in nodules in shaly beds.

Sulphates, Sulphides, Fluorides, Chlorides, Phosphates. The remaining minerals which, in smaller quantities, help to build up the rocks of the earth's crust, call for only brief mention here. Sulphate of calcium is found in two shapes, *Anhydrite* ($CaSO_4$) and the well-known *Gypsum* ($CaSO_4 + 2H_2O$). Sulphate of barium is barytes ($BaSO_4$), known from its heavy weight as *Heavy Spar*, which is often found in association with metal ores. Sulphides of various metals (lead, silver, copper, zinc) are of great commercial importance, but the only one which the geologist need consider is iron sulphide, which occurs as *Pyrite* (FeS_2), the familiar *Iron Pyrites* or "fool's gold," which ignorant prospectors often mistake for a valuable source of the precious metal, and as *Marcasite* (FeS_2) which plays a large part in the decomposition of rocks by its power of producing sulphuric acid on exposure to damp air. There are only two important compounds of the haloid elements found as minerals. Sodium chloride, or *common salt* ($NaCl$), is found in vast beds at places like Nantwich, where it is of great commercial importance. Calcium fluoride is the beautiful *Fluor-spar* (CaF_2) **[15]** used, from its property of giving off fluoric acid when treated with an acid by the glass etcher. Lastly, one may mention *tricalcium phosphate* or *Apatite*, which occurs in Norway and elsewhere, and has great importance to the agriculturist from its use as a fertiliser.

A NEW FIELD FOR LOCAL TRADE

"Back to the Land" with Trade. The Commercial Possibilities of Rural England. Food Supply of the Village. The Motor Van as Distributor

By ERNEST A. BRYANT

"BACK to the land" is now a popular cry, a cry which, it is to be hoped, will become still more popular. Specialists show in other courses in the SELF-EDUCATOR how profitable it may prove to the men in overcrowded towns to go back to the land, and how those already on the land may better their positions. New ideas and new processes are as desirable for agriculture as for any other industry which employs a considerable number of men. At present, however, we concern ourselves only with the life of the villager and the affairs of his tradespeople.

Assuming that a certain proportion of the men now seeking in the markets for employment where no employment is—assuming that a certain proportion of these do go back to the land, what is their prospect in the village? It might be thought that, so far as the domestic economy of the home is concerned, all that man and his wife desire must be available; that in an agricultural and fruit-growing district there will be abundance of cheap fruit and vegetables, eggs, milk, and cream. The opposite is the case. We refer mainly, of course, to villages whence London may readily be reached by rail or cart. The same conditions apply, in a lesser degree, in the villages of which the great provincial cities are the centre. There is no local trading.

A Limited Market. The money of his neighbour does not appear to possess any value for the grower of agricultural produce. Unless his fruit and vegetables go to Covent Garden, or his milk, cream, and eggs to the big dairies of the metropolis or lesser centres, he does not, apparently, find any satisfaction for his labours. The consequence is that the average villager is worse off for the bare necessities of life than the man who herds with the million in crowded city areas. Take strawberries, for example. The cost of these to the consumer, if he buy them in the heart of the district in which they are grown, is 50 per cent. more than if he had got them in town. The grower has to pay railway charges, and then sell at such a price as to yield profit to the Covent Garden merchant, then, perhaps, to a middleman, and finally to the retailer. If he gets a penny or three-halfpence per pound for his crop he is a fortunate man. Yet the same man is not anxious to sell his fruit privately at less than sixpence per pound where it is grown, though London retail rates at the time may be 50 per cent. lower.

Wasted Food. The same rule applies to vegetables. As soon as they are grown they are carted, or sent by rail, to London, to take their chance in a market which may, or may not, be over-stocked. On the spot where they are grown it is a favour to be able to purchase any at much more than the Covent Garden tariff. Milk has the same fate. There is no place in which it is so scarce as in the country. Farmers give thousands of gallons of separated milk to their pigs rather than sell it. Only in the country is it necessary to give several days' notice if cream be wanted. It pays foreign firms to send over commercial representatives to exploit cream and butter. Both go into villages, and are, therefore, bought by villagers whose local milk and cream supply goes all to London at absurdly low prices. There seems to be a universal tradition that you shall not buy in a given place that which forms the staple industry of such place. Nobody buys lace at Nottingham, or cutlery at Sheffield; nobody ever bought locally-made calico at Bolton, Bury, or Blackburn.

The Purchasing Power of Money. All this is discouraging to the man who has gone back to the land. He finds in the season when eggs are most plentiful that they cost him more than the London resident must pay; that the milk with which he is supplied is not of as good quality as that sent to London—the cream is conspicuous by its absence; all kinds of fruit are scarce and dear. He is in the midst of plenty, but it is not for him. He must live, hence he must eat. He must buy his produce at the shop which has obtained its hamper of potatoes or other vegetables, not from the surrounding fields, but from the middleman, who has purchased from Covent Garden or some correspondingly central depot. He may actually find that his wages have less purchasing power in the country than in a city where competition is keen and tradesmen satisfied with small profits from quick returns. If he ventures to use gas as an illuminant, he inevitably pays a higher rate than the townsman; his meat, perhaps, is more expensive; boots, clothes, coal—everything costs more. Where, then, is the advantage of returning to the land?

What the Villages Need. All these conditions, it must be repeated, apply chiefly to villages adjacent to London and other great towns and cities; in places more remote, the circumstances are necessarily modified. There is room for considerable development in village trade. The rural districts want good stores. Some have them already, establishments whose stocks are miracles of comprehensiveness. But these are the places that sell foreign cream when the local supply is sent away by train to fetch starvation prices. These are places at which are sold American and other foreign apples, while in the orchards around them English fruit is rotting on the trees. These are the places at which are sold

cheese from Holland and America, while that made in the village is allowed to bear the cost of cartage and railway to the markets of the cities.

We want new stores or developments in old stores. That money is to be made from the stores conducted even on the present lines is manifest from the fact that private companies here and there control series of them in adjoining villages. But the time has come for a distinct advance upon the old methods. The villages ought to have a regular service of goods by motor-van. One of these, starting in the morning from some central depot, would serve in the course of the day village after village. It would dispose of its wares either to shops or stores, or at the houses of individual customers.

A carrier manages to keep a couple of vans and four or five horses by carrying to and from the market towns such small bulk or wares as he is able to manage. His efforts, however, in comparison with the possibilities of the motor-van, are as those of the old coach proprietor contrasted with a first-class railway.

The motor-van runs at very few pence per mile and in the course of a day can cover a vast area. It could supply everything needed upon its round, conferring a boon upon the villages and bringing a solid profit to its proprietors.

The Village Trader's Opportunity. In the towns competition between traders is already so keen as often to reduce profits to vanishing point. Within a few miles of such towns is virgin soil, with crops of custom, so to speak, ready to the hand of the man who has a disposition to reap. For the prosperity of those already on the spot, it is, of course, desirable that they themselves should take the lead.

There is no reason why they should not. Every village trader knows that his neighbours are compelled every week to go into the nearest town to buy goods which he cannot secure locally. That means the outlay on the part of the purchaser of money in fares which might otherwise be devoted to additional purchases. With the motor-van regularly plying there would be no excuse for the village stores not keeping stocks as representative and up-to-date as those of rivals a dozen miles away in the town. Money which now goes unnecessarily into the cities would thus be kept in the country areas. It needs no argument to demonstrate that the greater the amount of money available, the greater the possibilities for the district. We would not, of course, have it appear that the motor-van is to be regarded as the embodiment of all efficacy; but it is undoubtedly a means to a desirable end. With facilities in this manner multiplied, there is the greater inducement for substantial business men to go farther afield; to set up house in the country and spend money there for the advantage of the whole community—their own not excepted. At present the "shopping" problem is a serious one. The housewife, accustomed to dealing with large establishments in London, finds her country home in what proves practically barren land. She cannot purchase what she needs in the village. If she sends to town for household requirements, she has to trust to the railway, and, as likely as not, her perishables will reach her several days late, and spoilt.

A Library for Every Village. Another item of the village problem, which at first sight may seem insignificant, has really an important bearing. The intellectual needs of the villager deserve attention. At present, life in many a rural centre in England is as dreary, monotonous, and unenlivened by any healthy recreation as if such village were in the heart of Russia. Men and women pass weeks and months without seeing a book or paper. After the day of toil, there is nothing for the cottager but to sit through the long, dark evening with nothing to deflect his attention from the sad monotony of his unlovely lot. Either he must sit and brood or—go to the public-house. Every village has its inn; how few possess a library! Granted, every rural authority has the power to establish a public library out of the rates. But to the mind of the villager this is too ambitious an undertaking; he would as readily avail himself of the right to light his dark lanes, or erect public baths and washhouses.

This blank in the lives of the village poor could be profitably filled by resident storekeepers. Every store in every village might have its little circulating library. Books are cheap and readily to be had. They can be bought new for far less than the formidable figures in the publishers' lists suggest. They can be bought cheaper still at the auction mart. By the expenditure of a few shillings it is possible to buy great bundles of classified second-hand books—novels, history, travel, biography, and more or less modern text books. These do not represent the pick of the literary basket, it is true, but any book which a man is not ashamed to put upon his shelves is better than no book. The main point is to get a start.

The Village Book-shop. It should not be a difficult arithmetical problem for the purchaser to determine what rate he must impose for the hire of his books. The smaller the price at which he can afford to lend a work, the better will be his prospects of increasing his connection. Books which have cost at auction a few pence might yield hundreds per cent. profit. The gain would come only in pence, it is true, but that is the sum in which the village merchant has chiefly to be content to count his results. Old magazines are to be had at waste-paper price and are often just as good reading a year after the date of issue as upon the day they leave the press. These afford scope for the man with the little lending library. [See Libraries.] The opportunity to devote an hour or two at night to wholesome reading is a greater boon to the man far from books than can be realised by those who live in close proximity to the libraries and newspaper offices of the towns.

It may be that with knowledge enlarged by

reading, the rustic may feel the more anxious to enter the town. But that is a difficulty which will always have to be faced. The man who is fittest for town employment will get town employment. On the other hand, the thoughtful person will be the more contented with his lot if he has at his hand some of the amenities of the life of the town against whose lure he is striving.

Skilled Nursing in the Village. A consideration for girls and young women which, with the passage of time, will become increasingly important is the scope for village nursing. Every village throughout the land is to have its trained, certificated nurse. At present there are not nearly sufficient nurses to meet the demand. All who have had experience of the country will know of places where for miles there is neither doctor nor nurse. Hundreds of young women are now taking up nursing as a profession. [See Nursing.] Too many of them do not look beyond the walls of the great hospitals in the towns. The villages offer excellent openings, as well for the practice of midwifery as for the general routine of the sick-room. It may savour rather of the fanciful to suggest that the villages should have their dentists. The average man is but now awaking to the urgent necessity for maintaining his teeth in a healthy condition. There is no reason why the qualified man, who is now content to drag out a miserable existence as an underpaid assistant in town, should not build up a practice for himself in the country. He must be prepared to do his extractions and fillings cheaply; but he can make a living out of his work, and a living in far greater comfort than the overcrowded condition of his market in town permits.

Everything which more nearly approximates the possibilities of the village to the facilities of the town makes for a solution of the problem of the congested labour market of the urban areas. Men and women who have lived in towns may be persuaded to go back to the land, but they will with less persuasion go back from it after an experience of the manifold disabilities which now exist in too many places. Inferior food at high prices, the absence of all avenues for intellectual exercise, the lack of all the amenities of everyday life are tolerable only to those bred to the conditions, and who have had no opportunity of contrasting them with other and better. Nowadays it is too often the case that men go from the towns into the country to die. Country life is stagnant, colourless. To it there might be brought the infinite variety and change of town life without in the least destroying the inherent charm of residence far from the madding crowd.

Handicapping the Countryman. It is too absurd that if your stove suddenly goes wrong, the local ironmonger, having waited three weeks for the part necessary to effect repairs, finds that his order must be transferred to a foundry in Scotland, then wait another three weeks, and finally receive something for which he is compelled to pay, although it is not of the slightest use to himself or to his patron. The countryman should not have to go to the market; the market should send its wares to him.

With projects such as these carried out, the village, while not sacrificing one whit of its rusticity, might become a real factor in the industry of that part of the country to which it belongs. The storekeeper should be able to deal with local growers of produce on terms as advantageous as those accorded to the autocrat of the market. The local fruit-grower, finding that he could command a steady sale in his own neighbourhood, would speedily see the wisdom of accepting a certain price for his goods in the local market in preference to sending all to town on the off-chance of a profitable sale. He would see the folly of charging in his own village 1½d. each for eggs the like of which he would have to sell at about 14 a 1s. in London, after paying the cost of carriage; he would realise that a good price for his fruit sold in the country is worth more than the smaller price gained at Covent Garden; the cowkeeper would understand that village money paid for village milk, cream, butter, and cheese, has just as great purchasing power as that which comes from town, even if it lack the halo of romance with which the latter appears to be invested.

Village Problems. To the student of rural life many other considerations conducive to the betterment of the villagers' condition will present themselves. The importance of arousing the public spirit of the rustic community must be manifest to all who interest themselves in this phase of our national life. When there comes the quickening of this spirit, the voice of the villager will be raised to insist upon the provision of habitable dwellings in which families may reside in decency and in health. The builder will find it to his advantage to meet that demand. Nowadays it is not uncommon to find people herded together in country cottages in a manner which would constitute a scandal if it were discovered in the slums of the cities.

The villages have their housing problem in as acute form as the greater hives of population. They have their difficulties as to drainage, water supply, and general health conditions. Until we see the countryman roused to a sense of his right to a healthy environment, to sanitary conditions of irreproachable character, and to a water supply of unimpeachable purity, the villages must still lack attractiveness.

There is in these unambitious schemes that which in the aggregate represents much to life and labour in the country. Until they are carried out the trend of the many will continue from the land into the already overcrowded towns. The accomplishment of such plans as these may go far to settle the "back to the land" problem by a simple process. Those already in possession will find their lot too pleasant to leave, while eligible hands from the overstocked labour markets of the towns will be only too glad to return.

HISTORY

THE GOLDEN AGE OF GREECE

Continued from page 668

Victory of Marathon. The Persian Invasion. Formation of the First Great Fleet. Themistocles. Pericles. The Life and Conquests of Philip of Macedon

By JUSTIN McCARTHY

THE Athenians showed themselves the most vigorous and the most closely united in resistance to the Persian invasion, and under the leadership of Miltiades won by their own efforts the victory of Marathon. Miltiades had been chosen one of ten generals entrusted with the defence of Greece.

It was his resolute policy to risk a battle at once, and he won a complete victory. Marathon has been fairly described as one of the decisive battles of the world. It made Greece for the first time into a distinct and consolidated nationality.

A Greek Warrior. The career of Miltiades was not destined to be one of complete success. He was commissioned to undertake the conquest of the Cyclades Islands, but his attack upon Paros, one of the islands, proved a failure. On his return to Athens he was charged with treason to the state in not having faithfully followed his instructions. It was alleged that his having chosen the island of Paros for his first attack was owing to his desire to gratify some personal hostility, and he was condemned to pay a heavy fine. Miltiades was unable to pay this fine, and he was therefore thrown into prison. He had received a severe wound in the attack on Paros, and the effects of the wound, added to the troubles of his trial and imprisonment, ended in his death.

A more melancholy close to a career which had so splendid an opening has seldom been recorded in any history. That was not the only example of the kind which we find in the records of Greece. The fact that the Grecian states were made up to a large extent of regions which had, from the dawn of their growth, no nationality or fellowship, but were brought into union by common dangers, or by common ambitions calling for combination at some particular moment, may account for some of the distressing incidents which we find recorded in the story of the race. Each of the allied forces had its own local sentiments and favouritisms and jealousies, and the failure of a leader in any one attempt was sure to make him the object of condemnation, and often of combined hostility, among the peoples or the clans who were not themselves in full sympathy with his leadership. Indeed, the invasion of Greece by the Persians was provoked, in the first instance, by one of the invading expeditions of the Greeks themselves.

Persian Invasion of Greece. In the opening of the Persian invasion Thrace and Macedonia were conquered by the invaders, and it was by the efforts of Athens and Sparta in the first instance that the Persians were wholly defeated. It may well have been that among the leaders of those who had failed to drive back the Persians there was a feeling of jealousy and rancour against him whom Athens had been mainly instrumental in placing at the head of a combined army, the more especially as Miltiades had come from a Thrasian colony.

The Persians were not so far discouraged by their defeat at Marathon as to give up all idea of restoring their warlike renown and their hopes of subduing Greece. The Persians were in those days an essentially warlike race, and seemed to be fired by an irrepressible desire to extend their conquests over as much of the world as was then known to them. The failure of one expedition only provoked the formation of another. Not many years after, Xerxes I., who succeeded his father Darius as King of Persia, prepared for another great expedition against Greece. He formed a large army drawn from all regions under his rule, and, what will interest the modern reader still more, he actually formed a great fleet.

The First Fleet. The formation of a regular fleet for war purposes was a marvellous achievement in those days. It is stated that Xerxes' fleet numbered at least 1,200 vessels, and that his invading army from first to last had more than a million of men. To make his way into Greece more easy he threw a bridge across the Dardanelles, and had a great canal dug in order to save his fleet the perilous necessity of sailing round the promontory of Athos. Fleets and armies made but slow progress in those days, and we are told that the passing of boats across the bridge occupied seven days and nights. Xerxes poured his forces into Thrace, Macedonia, and Thessaly, and these provinces or states made no effort to resist, but allowed themselves, for the time at least, to surrender to the invading power.

Sparta, however, acted in a very different spirit, and made for herself an unfading record in the history of the world. Leonidas, the King of Sparta, waited his time, and when the Persians were about to penetrate the narrow pass of Thermopylæ, in Northern Greece, Leonidas, with a force of 300 Spartans and 700 Thessalonians, resisted the whole army of the Persians for three days. Then Ephialtes, a traitor to the Greek cause, conducted the enemy, or at least a large part of their force, by a secret path through the mountains, and brought them to the rear of the Spartans, who thus, with enemies in front and enemies behind, had nothing left but to fight to the last. They met their death nobly amid slain masses of their enemies. Only one

Greek was able to escape and to return to his home, and he was received by his countrymen with reproach and contempt for having left his comrades and saved his own life. Simonides, the famous Greek lyric poet, wrote an elegy on the dead Greeks who perished at Thermopylæ in which, speaking, as it were, from the lips of one of the dying heroes, he used the thrilling words:

> Stranger, let Sparta know her sons could die
> Obedient to her laws; for here our bodies lie.

Themistocles. The next great struggle between the Greeks and the Persians was a sea fight in the Gulf of Salamis, near Athens, 480 B.C. Themistocles, a great Athenian statesman and soldier, who had already accomplished much by prevailing upon his countrymen to see that a powerful fleet was needed to maintain anything like a successful resistance to their invaders, won a brilliant victory over the Persians—a victory which has been celebrated and, indeed, consecrated by unnumbered poets, historians, and artists of all kinds from that day to this.

Themistocles was actually, although not nominally, in command of the Athenian squadron, that squadron making much the larger part of the combined fleets of Athens and Sparta. The Spartan commander had not been inclined to await the attack of the powerful Persians, and Themistocles had to use all his influence indeed to employ some stratagem in order that the struggle might take place at once.

Themistocles became after this victory one of the most powerful men in Greece, but his power over his countrymen did not last, and his story is one of the too numerous illustrations of the manner in which during those days of early Greece the hero of one season has been the outlaw of the next. Sparta was jealous of Themistocles and his success, and the Spartan faction was still strong in Athens. The Spartans did all they could to effect his ruin, and it must be owned that Themistocles sometimes endeavoured to maintain himself by plots and stratagems which do not seem to have been quite consistent with pure patriotism.

His enemies prevailed against him, and he was sent into exile—at least, he was banished from Athens. It was generally believed that the hostility of the Spartans had for its principal cause the fact that he had advised the rebuilding of the walls of Athens on a much larger scale, and with far stronger materials than before; and that leading Spartans had assumed that this must be a project undertaken with the object of preventing Sparta from ever becoming mistress of the Athenian capital.

End of Themistocles. Themistocles, after his ostracism, or banishment, was removed from one place to another, until at last he fled into Asia, and was received there with cordiality and protection by the then reigning Artaxerxes. He seems to have acquired much influence over the Persian sovereign, and his enemies in his own country did not hesitate to say that he was at one time engaged in concerting with Artaxerxes plans for the subjugation of Greece. He died in Persia some 450 years B.C. Even concerning the manner of his death there was much controversy, for there was a theory accepted by many in Greece that he died by his own hand. The great English historian George Grote describes Themistocles as "alike vast in his abilities and unscrupulous in his morality."

During all these struggles with Persia Athens was becoming stronger and stronger. She had risen to be the leading state in Greece. She had won the chief honours in the war. She had accepted the position of leader in the struggle against Persia, and in the greatest triumphs over the Persian invaders she had won the best of the fame.

Cimon of Athens. Besides the heroes mentioned, Athens had sent into the war Cimon, the son of Miltiades. Cimon was both soldier and sailor; he had encountered the Persians at sea and completely destroyed one of their great fleets, and he encountered them on land with equal success. His military career closed with splendid victory, and brought the Persian War to an end. His life was not without its troubles. During the internal quarrels going on between Athens and Sparta, quarrels which he sought to bring to an end by establishing a friendly and complete alliance between the two states, he was accused by some among his own people of being an accomplice in the projects of Sparta, and for a time he underwent ostracism. He was recalled, however, to his former place in the confidence of the Athenians, and helped in obtaining an armistice of five years, if he could not obtain an actual alliance, with Sparta. After his restoration to power, he was again put in command of a fleet, and he died while engaged in an attack upon a hostile city. It is believed that Cimon did not find the manner of death which he would himself have chosen. There can be no question that, if he could have dictated terms to destiny, he would have elected to die in a gallant fight by some hostile sword; but the accepted belief is that he perished by an ordinary illness.

The Power of Athens. Athens now began to be the leading power in Greece. The Persian invasion had found Sparta at the head of the Greek peoples, but she did not long maintain this position after the struggle with Persia had fairly begun. Athens appears to have acted throughout the whole of the war with a steady and patriotic regard to the common interests of the whole Greek race, while Sparta would seem to have ever had in mind the maintenance of her own superior position. The Athenian commanders, too, proved to be men of the highest military and naval capacity, and in this way drew upon themselves the admiration of all the Greek peoples. The most signal victories over the Persians were won by Athens, and thus she came to be, for the time, the queen among the Greek states.

It was not to be expected that under the conditions then prevailing this supremacy should be long allowed to remain unchallenged by Sparta. The rivalry had yet to be illustrated by a long and severe struggle. Sparta made every effort to persuade the other Greek peoples that Athens was deliberately planning to obtain

the sovereignty of the whole country, and appealed to the patriotism of other Greek states in order to secure their help towards the repression of Athenian ambition.

Influence of Pericles. The leading man among the Athenians at this time was the illustrious Pericles. Pericles was born of an eminent Athenian family during the earlier part of the fifth century B.C., and had risen rapidly in public life as a leader of the democracy. In the struggles between Athens and Sparta, Athens represented the democratic, and Sparta the aristocratic, element in the modern acceptation of these terms. Pericles looked with utter disapproval on the rivalries and jealousies among the Greek peoples, and he was ever striving to realise a project of his for the creation of a great federation in Greece which might bring the peoples into fraternity under some system of authority representing all the different states.

Sparta set herself resolutely against this project, and for the time it came to nothing. Athens and Sparta were already beginning to drift towards that great international struggle which made so deep an imprint on the history of Greece. The climax of the rivalry was postponed for a time by an arrangement of a thirty years' peace between Sparta and Athens, and in the meanwhile the influence of Pericles grew greater with every day.

The age of Pericles may be described as the greatest age of Athens, the greatest age of Greece, indeed, one of the greatest ages in the world's history. Pericles was statesman, soldier, commander of armies and fleets, a lover and patron of arts and letters, and to him Athens owes some of her noblest architectural monuments. The traveller from foreign countries still gazes with enthusiasm and with reverence on the majestic Parthenon, than which the genius of architecture, inspired by lofty ideas and pious emotion, has never bequeathed to the world a nobler or more lasting trophy.

Athens had then but lately lost Æschylus, one of the greatest dramatists of all time. She still had Sophocles and Euripides, tragic poets who stand in equal rank; Herodotus the historian; Aristophanes, unsurpassed as a comic and satiric dramatist; Phidias, its most renowned artist; and Socrates, who holds one of the highest places among the great thinkers and interpreters of thought in the ancient and modern world. It is not surprising that under such conditions men from all parts of Greece, and from all parts of the world then within touch of Greek civilisation, should have streamed into Athens as into a sacred city.

Macedon. We need not enter into a minute survey of the various struggles between Athens and the other Greek states. These struggles gave opportunity in one way or another for the development of the genius of such men as Alcibiades and Epaminondas and Pelopidas, and of Xenophon, at once soldier, historian, and essayist. Xenophon was the son of a distinguished Athenian officer, and during all his earlier years, up to his manhood, he had been under the close and enlightened influence of Socrates, the greatest of Greek philosophers. Xenophon became commander in the march of the famous Ten Thousand, the history of which he has left to the world in his "Anabasis." He wrote many other books, the most interesting among which tell us all that he knew of Socrates. But in the meanwhile troubles of the most serious kind were awaiting the Athenians and the Greeks in general by the rise of Philip of Macedon. Macedon was a kingdom in the north of Greece which had been at different times under the protection of Athens, of Thebes, and of Sparta, had been conquered by the Persians, and redeemed by the Greek victory of Platæa. Macedonia had kings of its own, and of these Philip II. was the first to make a permanent mark on history. Philip was the third son of Amyntas II., King of Macedonia, and seemed at one time to have no chance of ascending the throne. His eldest brother was assassinated, and his second brother was killed in battle. The death of his father left to him the guardianship of his eldest brother's infant son. Philip was a man of daring ambition, and in a short time he contrived to make himself sovereign of the kingdom.

Philip II. It was not unusual in those days, where a Royal Family existed, for the leading men of a state to select any one actually of the Royal Family to fill a vacancy in the throne. In this way Philip II. was able to make himself King of Macedon. His kingdom was threatened with many dangers from other states, but his energy and ability succeeded in making the frontiers of his realm secure against invasion, and his restless spirit then began to occupy itself in enterprises of conquest. He captured a city in Thrace to which he gave the name Philippi, a place afterwards famous in the history of Rome, and associated since the days of Christianity with the teachings of St. Paul. There were gold mines in the surrounding regions which gave Philip ample means of paying his military recruits and extending their numbers, also of buying up supporters and accomplices among the populations he designed to make his vassals. He built a navy and greatly strengthened his army.

A Prison and a Kingdom. Macedon had been a kingdom from the earliest days of which we know anything, but had played a poor figure in the progress of Greece. An event which at first seemed a calamity in the early life of Philip had given him a singular opportunity of cultivating his genius and seeing how great deeds were to be done. He had been sent to Thebes as a hostage, and while there had been received into the house of Epaminondas, and had learned from the example of that great soldier and statesman some lessons in the art of war and in statecraft which he afterwards turned to account. Thus it was that when he became King of Macedon he was already well prepared for the career of conquest and despotism on which he had determined to enter. He turned the noble

teachings of Epaminondas to his own advantage after a fashion illustrated in many other remarkable historical instances. He invaded Thrace, and was successful for the time. He then attacked Byzantium, but here Athens came to the rescue and prevented its conquest.

Demosthenes. The Athenians appear at that time to have been the only Greeks who regarded as a national interest the defence of all the Greek states against invasion. Their great orator, Demosthenes, saw from the first the selfish and ambitious purposes of Philip, and devoted all the power of his marvellous eloquence and argument to arouse his people to a sense of the danger which threatened them. His great orations, known as the "Philippics," were directed against the projects of the Macedonian sovereign. Philip, however, made some conquests which helped to remove certain of the practical difficulties in his way, and the Athenians had to sign a treaty of peace that even Demosthenes felt compelled to recommend, and helped to negotiate with Philip. The Athenians believed themselves safe under this treaty, and Philip succeeded in persuading them to give him a vote in the Amphictyonic Council. This celebrated council is described by tradition as having been the creation of Amphictyon, a lawmaker of somewhat mythical origin, and was intended to have the general direction of all the affairs of Greece. It was made up of twelve members, selected from among the best and most high-minded representatives of the various Greek cities and states, and was in fact a sort of Hague Tribunal devised at the opening of history.

A Wonderful Orator. Philip was able to impress the Greek states for a while with the belief that his policy was purely patriotic, and turned his aggressive projects towards regions outside the boundaries of Greece. Demosthenes, who now began to understand the designs of Philip, rose to a splendid height of eloquence and statesmanship in his efforts to prevail upon the Athenians not to risk their national independence. Demosthenes was unquestionably the greatest orator of the ancient world. His style is not florid, is never redundant, but its power of condensed expression is marvellous, and the reader feels that no other word was needed in any sentence to convey the full meaning of the orator. Argument directs the very passion of each oratorical outburst, and passion itself seems able to lend new force to each argument. Philip's attack on the Olynthian state occasioned some of the most powerful speeches delivered by Demosthenes, and they inspired Athens to take the field in defence.

Athens did not make any success from the beginning of her operations, and it may be that the heart of the Athenian state was not entirely with the policy of war. The Athenians were easily induced to come to terms of peace with Philip, terms which Philip made especially convenient for himself. Then ensued an interval of peace for about four years, so far as Athens was concerned, and during that time Demosthenes devoted himself with all his energy and perseverance to the task of creating an anti-Macedonian party in Athens. A defensive league was formed in which Thebes and other Greek states supported the cause of Athens. Philip was equally resolute in the pursuit of his own designs, and with the battle of Chæronea in Bœotia the independence of Greece came to an end during that part of the world's history.

A Great Soldier's Initiation. The victory at Chæronea was brought to its completion by a splendid cavalry charge, and that charge was led and directed by Philip's son Alexander, of whom the world was soon to hear much more. Philip behaved not ungenerously towards his conquered opponents. The Thebans were compelled to receive a Macedonian garrison, and to acknowledge themselves subjects of the Macedonian king, but they were not otherwise treated with severity. From the Athenians Philip exacted the recognition of his conquering rule, but he returned the prisoners he had taken, and he inflicted no cruelties on his defeated enemies. We must not extol the clemency of Philip too highly because of the course which he took after his great victory. His mind was filled with a project to make the Greeks his confederates in a scheme of conquest of a yet more venturous nature, which he could not hope to carry out without the assistance of the Grecian states. He convened a congress at Corinth, to be composed of delegates from the great cities of Greece, and when the congress assembled caused it to be made known that Greece was to have a constitution of her own, under which complete local freedom was to be given to each state, on condition that these states submitted to the sovereignty of Macedonia. Each state was to enter into a solemn treaty of alliance with Macedonia, some cities were to receive Macedonian garrisons, and Philip was to be commander-in-chief of the whole army.

The Close of a Great Reign. Then Philip announced his purpose to undertake the conquest of Asia, and his desire to make his great effort as the representative of the whole Greek federation, as well as of his own kingdom. The enterprise aroused much sympathy and even enthusiasm among the Greeks. But the career of Philip was brought to a sudden close before he had made any great advance towards the realisation of his most ambitious plan. He had many private enemies in and around his own household, and he was suddenly attacked and assassinated while taking part in his daughter's marriage procession. He was forty-seven when his life of conquest was thus brought to a close. His reign had lasted nearly twenty-five years, and during that time he had accomplished wonders for Macedonia. When he succeeded to the throne it was an unimportant stretch of territory, and he had made himself and his people the masters of all Greece. His fame in history does not, however, depend so much upon his own achievements as on the more marvellous exploits of his son, who will be known to all time as Alexander the Great.

THE BOOKS OF THE FIRM

Purposes of Books used in Business. Show-room Records. Double-entry Bookkeeping. The Sales Book

By A. J. WINDUS

The Books of the Firm. We approach at length the books used by Bevan & Kirk in their business, and it may be noted in this connection that the constant and minute registration of everything that takes place and the tremendous value put upon time are two of the distinguishing features of business life.

It will be convenient if we classify the books of Bevan & Kirk under two headings (as pertaining either to the show-room or to the counting-house), explaining their several purposes preparatory to resuming our study of the firm's system of bookkeeping.

Show-room Records

1. Price Book. Register of goods stocked or "carried," giving manufacturers' names and numbers, short description of the goods, their buying and selling prices, and the "Call" numbers.
2. Letter Book. Book with blank numbered leaves of specially thin paper, in which outgoing letters are copied by means of the copying-press.
3. Order Guard Book. Book with blank leaves of specially stout paper, into which are pasted, as they arrive, the orders received.
4. Telegram Book. Book of stamped telegraph forms, with blanks interleaved. When writing out a telegram, a carbon sheet is inserted between the stamped form and the blank underneath—a facsimile of the message being thereby obtained. The original telegram is torn out and despatched, whilst the duplicate remains for future reference.
5. Agency Order Books. These are constructed on the same principle as the Telegram Book, a separate book being kept for each manufacturer. Thus there is one for Jones & Co., one for Wm. Smith, and one for the Berlin Manufacturing Company. Suppose an order comes in from Manchester for goods of the Berlin Company's make. A copy of the order, with carbon duplicate, is written out in the appropriate Agency Order Book and transmitted to Berlin, and the original order is then pasted in the Guard Book, as explained.
6. Agency Commission Book. Register of dates, names, and amounts of invoices sent out by Berlin Manufacturing Company and others for whom Bevan & Kirk act as agents for goods supplied in execution of orders from Bevan & Kirk's customers—whether such orders come direct or through the agents.

   A certain number of pages in the book is allotted to each agency, and care must be exercised to ensure the invoices being entered under the proper headings—that is to say, under the names of the manufacturers from whom they come. In order that the Agency Commission Book shall contain *full* lists of invoices, it is customary when goods are sent direct from manufacturer to customer to advise the London representatives, Messrs. Bevan & Kirk, by sending them either a tissue copy of the invoice which has been despatched to the customer or the invoice itself. In the latter case, a copy is made and kept by Bevan & Kirk for their own use; this done, the original goes away again on its journey to the actual purchaser of the goods.
7. Address Book. Register of the names, addresses, telephone numbers, etc., of the firm's customers.
8. Stock Order Book. Similar in construction to No. 5, but only one book is kept. It contains a record of orders for stock given by the firm to manufacturers and others.
9. Box Files. By the use of these files, one for each agency, the correspondence with manufacturers is rendered easily accessible. Quotations, memoranda, and letters received are filed in datal order, copies of replies being attached thereto. If, moreover, instead of using the Stock Order Book, an order is given in a typewritten letter, carbon copy of same is placed on file.
10. Delivery Book. A book of printed forms with counterfoils, used in connection with the despatch of goods. The customer who takes delivery of the goods, or the carrier who receives them in trust to be forwarded to their destination, has to sign one of these forms as an acknowledgment of receipt of the goods therein referred to.

This summary list is complete so far as the show-room of Bevan & Kirk is concerned. That being the case, let us anticipate the question which may arise in the minds of students: "Why is it the show-room does not keep some sort of book in which to enter all goods coming in and going out (in other words, a *stock book*), so that it could always be ascertained what goods were on hand?"

In order to clear up this point, we must take the risk of trespassing a little on our next bookkeeping lesson. If we were to put the question to the firm, their answer would probably be somewhat as follows: "We can tell from the invoice book the quantity we have lately bought, and from the day book the quantity we have lately sold of any of the 'lines' in which we deal; and it is the duty of the stockkeeper to inform us when sizes or numbers in a particular stock are running low. We 'take stock' ourselves once a year, or oftener, when our accounts are made up, and

we should consider it a waste of time to keep a stock book such as you suggest.

Because Bevan & Kirk do not keep a stock book, we cannot be sure that Brown & Jones get along without one. On the contrary, business methods differ, not merely with different classes of business, but it may almost be said that no two businesses of similar character are run on quite the same lines.

Double-entry. At the same time, there could scarcely be a more perfect illustration of "unity in diversity" than is afforded by trade viewed as a whole. The one and only object of business is to make money, but this single object is pursued by innumerable methods and fostered by countless aids. Among the latter must be reckoned double-entry bookkeeping; and here, again, we have "unity in diversity," for there is unanimity in regard to the fundamental principles of double-entry existing side by side with the utmost diversity in applying those principles. That is why some authorities assert, wrongly as we believe, that bookkeeping is not an exact science. Certain it is that knowing how to keep the books of a brassfounder, for example, will not help us very much with theatre accounts until we grasp the truth that, although the principles of double-entry are essential and unchanging, we may apply them in any way we please to suit the special requirements of a business.

The "Day Book." We need not linger over this point, as we may have occasion to revert to it; but a simple illustration may be helpful. In double-entry it is necessary to keep a record of sales. Some business men call such record a *sales journal*, others a *day book*, but that does not alter the character of the transactions recorded therein—they are still sales, so that this is merely "a distinction without a difference." If we refer to what was said about the entering desk, we shall find that some houses copy their invoices in a press copy book, and that from thence the dates, names of customers, and amounts of the several sales are entered in a book which in form is a condensed day book, but in name is a sales journal. Other business houses, as explained, make full entries in the day book itself. But there is no real difference.

It will be remembered that in a previous chapter we considered the petty cash book kept by Bevan & Kirk's junior clerk. In our study of this book we had arrived at the point where—the expenditure for the month of September, 1905, having been analysed under various columnar headings—we desired to learn how the information thus given could be utilised. But there were "lions in the path." We were unable to go a step farther in this direction until we had grappled with the chief principles of double-entry. These have now been dealt with. It is too much to hope that they have been wholly mastered by the earnest student, but, at least, he need no longer fear them, and a careful scrutiny of the table of books used in the counting-house [see next page] will clear the way for a general advance.

Let us take courage from the thought that, being now in possession of the broad outlines of Bevan & Kirk's system of bookkeeping, all that remains is to fill in the outlines properly. This is chiefly a matter of learning how to interpret in terms of double-entry all or any of the firm's operations. To do this successfully we must not overlook the important distinction between books of original and books of final entry. What is meant by "original" and "final"? The answer to this will be found in the answer to another question. "What are the books of final entry?" Our list shows that they are *ledgers* of one sort or another. Ledgers are in a class by themselves, storing up information contained in other books.

The Use of the Ledger. Thus a ledger may be described as a storehouse of information which is gleaned from other books and classified under appropriate headings called Accounts. It follows that there should be no items in the ledger except such as have been "posted" thereto from the books in which they were originally entered. Transactions should be recorded in the ledger through the medium of the books of original entry only. There are eight of the latter in our list, and, with the exception of the journal proper, each book or sectional journal is devoted to a single class of transaction. The cash book is for monetary receipts and payments (with special columns for discount), the invoice book for credit purchases, the day book for credit sales, etc.

A Selection of Transactions. But practice is better than precept. With a view to testing our ability to express business operations in the language of double-entry bookkeeping, we will take the following selection from those which occurred during the period from 20th to 30th September last. The information contained therein has been collected from various books of original entry, and we are asked to indicate the books to which the items respectively belong.

September, 1905.

(*a*) 20th. Cheque, £5, drawn for petty cash.
(*b*) Stamps purchased, 5s.
(*c*) 21st. Invoice passed for goods received from Ord & Mackay, £57 10s. 0d.
(*d*) Mr. Allday purchased for cash goods value £1 5s. 9d.

Goods sold on credit as follows:
(*e*) Harold Springer, £2 12s. 0d.
(*f*) J. Bruce, £11 4s. 8d.
(*g*) Aird Bros., £44 9s. 10d.
(*h*) 22nd. Received from Brown & Co., Ltd., cheque, value £10 1s. 9d., in settlement of their a/c for £10 6s. 11d., less 2½ per cent. discount, 5s. 2d.
(*i*) Drew on J. Wake for £20 10s. 6d., at 3 months' date, in settlement of account to 19th September.
(*j*) 23rd. Paid from petty cash salaries and wages, as per salary book, £11 9s. 0d.
(*k*) Paid Rice and Sons cheque value £49 4s. 3d., in full of their account £50 9s. 6d., deducting 2½ per cent. discount, £1 5s. 3d.

A TYPICAL TABLE OF BOOKS USED IN THE COUNTING-HOUSE

No.	Posting Contraction.	Name.	Explanation.
			BOOKS OF *ORIGINAL* ENTRY
1	C.B.	Cash Book	Record of all moneys received and lodged in the bank and of all cheques drawn.
2	P.C.	Petty Cash Book ..	See definition *ante.*
3	P.B.	Postage Book	Ditto.
4	Jl.	Journal	The functions of this book and the modern system of subdividing it into invoice book, day book, etc., will be dealt with in a special paragraph.
5	I.B.	Invoice Book	Journal of goods bought on credit in which is entered (*a*) number and (*b*) date of each invoice, (*c*) name of creditor, (*d*) amount of the invoice.
6	R.O.	Outwards Returns Book.	Converse of No. 5, being a journal of goods returned, in whole or in part, by Bevan & Kirk to the persons from whom they were bought. Returned empties, shortages and allowances claimed by the firm are also entered herein.
7	D.B.	Day Book	Journal of goods sold on credit (see remarks on "Entering Desk" *ante*).
8	R.I.	Inwards Returns Book	Converse of No. 7, being a journal of goods returned, in whole or in part, to Bevan & Kirk by their customers. Shortages and allowances claimed by the latter are also entered herein.
			BOOKS OF *FINAL* ENTRY
9	B.L.	Bought Ledger.. ..	Book of accounts of those persons from whom Bevan & Kirk buy goods on credit.
10	S.L.	Sales Ledger (or Sold Ledger).	Book of accounts of those persons to whom Bevan & Kirk sell goods on credit.
11	P.L.	Private Ledger ..	Book of private accounts, such as partners' capital and current accounts, loan accounts, etc. Copies of the periodic Balance Sheets and P. and L. accounts also appear herein.
12	G.L.	General Ledger ..	Book containing (*a*) *real* or *property* accounts, such as cash, stock-in-trade, etc.; (*b*) *nominal* or *temporary* accounts, as trade expenses, salaries and wages; (*c*) accounts which do not find a home in any of the other ledgers.
			SUPPLEMENTAL
13		Paying-in Books ..	Two books supplied to Bevan & Kirk by the Commercial Banking Company—the firm's bankers—to facilitate the payment of money into the bank. One is a *town* paying-in book for cash, bank-notes, town cheques, etc.; the other, which has paper of a different colour, is a *country* paying-in book for country cheques, etc. These books will be described more fully hereafter.
14		Cheque Book	Book of forms, each bearing an impressed Revenue stamp value one penny, issued to the firm by their bankers. Whenever Bevan & Kirk desire to draw money from the bank, or to pay an account by cheque, they fill out one of these forms for the required sum and sign it with the firm-name. The amount is paid by the bankers on presentation to them of the form or cheque as it is now termed.
15		Bank Pass Book ..	Book issued by the Commercial Banking Company showing the state of Bevan & Kirk's banking account according to the bank ledger. The book derives its title from the fact that it *passes* between the firm and the bank. Its uses will be explained presently.
16		Ledger Indexes ..	A ledger index ought to reveal the folio of any and every account in the ledger. Therefore, immediately a new account is opened, the full name and ledger folio should be recorded in the index under the appropriate alphabetical heading. Some indexes are bound up with their ledgers, while others are bound up as separate books. It is entirely a matter of convenience which method is adopted. For the firm's Bought and Sold ledgers—collectively styled trading ledgers—there is one B.L. index and one S.L. index. These are bound up apart from their ledgers, and separately from each other. But the P.L. index forms the front part of the Private ledger itself, and so with the General ledger. To avoid continual borrowing of the show-room address book, the accountant is in the habit of adding full postal address after each name in the trading ledger indexes, but the rule is not to allow addresses to appear on the ledger accounts themselves.
17		Bill Book	The Bill Book actually consists of two books, which we may call P. and R. P. extends to about the middle of the whole book; R. does the same, but starts from the other end, the book having been turned right over so that P. and R. are upside down to one another. This seems cumbrous, but is, in reality, very simple. The one part of the book contains a record of bills of exchange payable (P), the other a record of bills of exchange receivable (R.). Bills payable are one thing, and bills receivable are another, but for various reasons it is convenient to have a compact record of them such as the double book affords us. Fuller explanation must be deferred until the subject of bills compels our close attention.
18		Salary Book	Memorandum book showing how the weekly total of £11 9s. (*vide* P.C. Book) is made up.
19		Letter Book	Book (similar to that described in the Show-room Records) in which are copied outgoing letters on counting-house matters only.

(*l*) 25th. Paid postage of parcel to Williams Bros., Cape Town, 5s.

(*m*) Accepted Henry Norgate's draft at 60 days' for £55 4s. 11d., payable at the Commercial Banking Co., in settlement of account to 19th September.

(*n*) 26th. Received and discounted J. Wake's acceptance for £20 10s. 6d., the bank's charge for discount being 3s., or at the rate of 3 per cent. p. a. (see Pass Book).

(*o*) 27th. Paid from petty cash cost of advertisement for town traveller, 3s ; and 1s. 9d. for brown paper..

(*p*) Mr. Bevan drew £5 and Mr. Kirk £3 on private account.

(*q*) 28th. J. Bruce paid cheque £11 4s. 8d. less discount of 3¾ per cent. for cash, 8s. 5d.

(*r*) 29th. One quarter's rent of business premises, £37 10s. 0d., paid by cheque.

(*s*) 30th. Received of Jones & Co., cheque for £29 8s. 2d., in payment of commission, £27 6s. 0d., and expenses, £2 2s. 2d., to 30th June, 1905.

(*t*) Invoice passed for goods received from Ord & Mackay, £46 15s. 3d.

(*u*) Goods returned by Aird Bros. (wrong pattern), £3 7s. 4d.

The best way to answer the question, "Where were the above transactions first recorded ?" is for the student to mark down in pencil opposite each item the name of the book whence he believes it was derived. Take (*e*) for example. Goods were sold on credit to Harold Springer, £2 12s. Opposite this transaction we should write down the words "Day Book," or the contraction D.B., to signify our belief that transaction (*e*) was entered first in the day book. The marking of all the items is recommended.

The majority of these transactions are of a simple character, but one or two may be described as compound, and almost all possess special features, so that we work through the entire list, beginning with :

(*a*) September 20th. Cheque for £5 drawn for petty cash. We must conclude that the cheque was presented for payment and cashed at the bank, because, otherwise, it would not have availed for the purpose for which it was drawn. Therefore, the junior clerk has *received* £5 *paid* to him by the bank. With folio 58 of the petty cash book, exhibited in a previous chapter, open before us, we see at once how the junior clerk treats the money thus received. He enters it in the "received" column, on the debit side of the petty cash book, thereby conforming to rule (*b*) given in Part IV. But for every debit there must be a corresponding credit, and, in the present instance, the credit will be found duly entered in the bank cash book under date of September 20th.

NOTE. On page 409, in the "coinage" column, under Egypt, the line £1 = £E ·0985 should read £1 = £E ·985.

DRAINAGE OF COUNTRY HOUSES

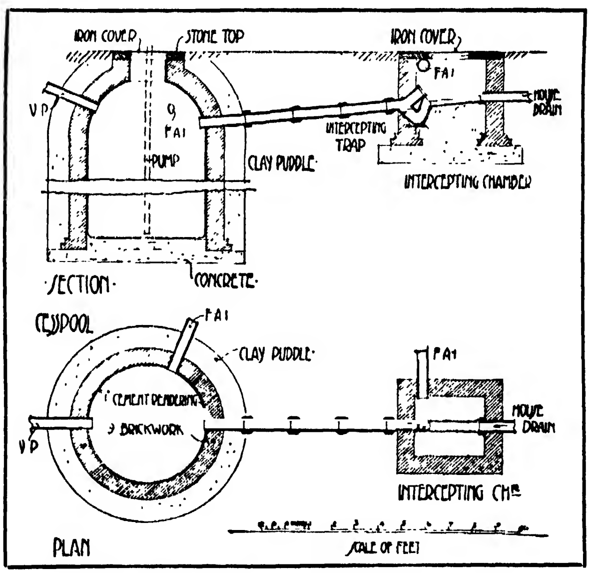
Its Special Requirements and Practice. The Failure of Traps. Drain Ventilation. Drain Testing and Cleansing

By Professor R. ELSEY SMITH

IN the drainage of country houses some features not met with in towns provided with sewerage systems are introduced. The first of these are *sumps*, or *soakaways*, for rain-water. They may be employed when it is not desired to store the rain-water. Such a sump consists of a pit which is sunk in the soil, and which should have a capacity of at least one cubic yard, and should be filled in with hard, dry, clean brick or stone rubbish; it should be at least 6 ft. from the building, and a drain is taken from the foot of the rain-water pipe, so as to deliver the water into the sump. A small chamber may be formed with bricks laid dry around the end of the pipe, to ensure that it is not choked up by the smaller material. Each pipe may have its own sump, or two or three may deliver into one. In dry, porous grounds the size may be kept small, as the water will rapidly disperse by percolation, but in moist and clayey soils the capacity should be large. The actual size will depend upon the amount of water delivered by the pipe; no sump should be formed for this purpose so deep as to reach the level at which water stands naturally in waterlogged ground. Wooden butts are often used to receive the rain-water delivered by a single pipe, but should have an overflow and a drain placed under the draw-off tap which is usually provided.

Cesspools. Cesspools are large receptacles sunk below the ground-level for the reception of sewage. They are of two classes, both generally circular in plan. Those usually required are made watertight, with the bottom of cement concrete, walls and domed top of brickwork set in cement; or the wall and dome may also be in concrete. The interior is rendered in cement and sand [see PLASTERER], and in damp situations the outside may be surrounded with *clay puddle* [see ENGINEERING FOR WATER SUPPLY]. The top has an opening closed with a manhole cover and a perforation for the suction-pipe of a pump, if one is used for pumping liquids only. [45]

The drain which delivers into the cesspool has an intercepting chamber close to it. The cesspool, which should be placed at least 100 ft. from any dwelling, has a F. A. I. and a V. P. carried up a tree or a tall post. Nothing should be led into it but the soil-drains from closets and the scullery sink. The size varies with circumstances; but even a large cesspool, if it has no outlet or overflow (and this is not as a rule permitted), will require pumping out at frequent intervals.



45. CESSPOOL AND INTERCEPTING CHAMBER

The second variety of cesspool is similar in form, but is built dry—*i.e.*, the bricks are laid without mortar. In chalk it may be excavated in the chalk, and remain unlined. Its construction allows the liquids to percolate into the soil, and is only suitable for dry, porous soils in situations where there is no danger of contamination of any source of water supply. Into such a cesspool all wastes, as well as soil-drains, may be taken, and if capacious it will require cleansing only at long intervals. The intercepting chamber and system of ventilation is required, and a small cesspool of this type is sometimes provided for bath and lavatory wastes where the soil-drains are taken to a watertight cesspool.

Storage Tanks for Rain-water. These are employed where separate rain-water drains are used. They are constructed underground in a manner similar to watertight cesspools, but

of much greater capacity. The actual size is regulated by the area from which rain-water is collected and the rainfall of the locality. For every square of 100 ft. of roof drained a provision of 8·3 cubic ft. must be made for each inch of rainfall to be stored, and about half this amount from paved yards. The average rainfall throughout England is about $2\frac{1}{2}$ in. per month but varies considerably in different districts and in different months. Where it forms the only source of supply the capacity for the tanks should be equal to storing four months' supply.

Storage Tanks. The tank [46] may be circular or rectangular, and is sometimes lined with asphalte. [See BRICKLAYER.] It may be provided with a small catchpit and strainer to receive the end of the drain, and to retain any solid matter It must have an overflow, which, if possible, should be taken to a ditch or pond; if taken to the soil-drainage system it must be efficiently disconnected. The tank must have a manhole cover for access, and a lift or force-pump for raising the water to the cisterns supplying the house. The pump must be connected to the well with a suction-pipe, taken down nearly to the bottom of the well, and to the cistern by a delivery pipe. Pipes and cisterns for rain-water should be of iron, not lead, as the rain-water attacks lead.

Subsoil Drainage. Subsoil drainage is required for draining off stagnant subsoil water due to general saturation or to a land spring. The drains are laid with the agricultural drains already described. Pipes of 3 in. diameter are usually employed; a series of parallel trenches are cut, the drains laid in the bottom, and the trenches filled in. The depth of the trench varies with the nature of the soil, from 2 ft. to about 4 ft. 6 in.; the distance apart of the trenches varies usually from 12 or 15 ft. in stiff ground, to from 30 to 40 ft. in loose, porous ground. The trenches when close are kept shallow, and increase in depth as they are spaced further apart.

The ends of the pipes are connected to a 6 in. or 9 in. socketed drain, and taken to a ditch or pond. The outfall should be open to inspection, but closed by a wire grating against vermin. Such drainage may be laid with very little fall, but any general inclination of the ground surface should be followed, where possible, the outlet of the main cross drain being at or near the lowest level of the land to be drained.

Failure of Traps. Conditions arise when the traps previously described may cease to be efficient. The arrangement of a good drainage system should be such as to minimise the effect of their failure. The principal causes of failure in traps are the following:

1. The water-seal may be *forced* by an accumulation of gas on the sewer side if the pressure is sufficient. This most frequently happens with the main intercepting trap from the collection of gases in a sewer. It should not happen with gullies if the ventilation of the drains is well arranged and kept efficient.

2. The water in the trap may be *evaporated* in dry weather to such an extent that the seal ceases to exist. This happens most often to gullies provided to receive surface drainage only from small areas. Such areas are often placed directly under basement windows, and, if a gully placed in one of these becomes inefficient, sewer gas is liable to enter the building through the window. A gully in such a position should have, if possible, a lavatory or sink waste taken into it. This will keep it charged if in frequent use. If this is impossible, the most certain method of protection is to take the drain from the gully, not directly into the main drain, but into another gully which does receive such a waste, and will not, therefore, be liable to dry up even in a prolonged drought. Gullies are not desirable, and, as a rule, are not permitted, in the interior of buildings. If used in any case, the drain from such a gully should on no account be connected with the general drains directly, but must be disconnected as already described.

3. The contents of a gully may be *syphoned out.* This is caused by the creation of a partial vacuum on the inner side of the seal, produced by a full-bore discharge in a neighbouring pipe. The pressure of the air on the upper side of the trap may then suffice to drive before it the water standing in the trap and force the seal, which remains open till the trap itself is recharged. This affects the small traps of sanitary fittings more seriously than gullies, and will be referred to again [see INTERNAL PLUMBER], but the condition may arise in gullies.

4. The contents of the trap may be carried out by the force of *momentum.* When a considerable full-bore discharge takes place the whole body of water may pass through the trap without leaving a sufficient quantity in the trap itself to complete the seal. This is very liable to happen in the discharge of a flushing tank or cistern, and most flushing rims are constructed so as to retain a sufficiency of water to recharge the trap after the main flush is completed.

The Placing of Gullies. It is necessary, therefore, to bear in mind the possibility of the failure of traps, and, in planning drainage, to avoid placing gullies in positions where, in the event of such failure, sewer gas will readily find its way into the building. One useful means of reducing the liability to this danger is to place the gully not directly under the pipe, but at a distance of about 18 in. from it. The pipe is arranged to discharge into an open channel, which may be formed in concrete and lined with cement, or with a half-round channel; but the most complete form is the *slipper gully* [30, page 571]. This is an ordinary gully fitted with a special form of top, including the channel, which is adapted at one end to receive the discharge of one or more pipes, and at the other to deliver the contents into the gully. When fixed, it should have a galvanised-iron grating or wire cover to prevent choking with dead leaves or rubbish.

Ventilation of Drains. An essential feature of a good drainage system is efficient ventilation, which is required to prevent the

accumulation of dangerous gases in the system and to ensure that any gas generated in it or entering it from the sewer may be discharged in such a manner as to be innocuous. Briefly stated, the system consists in providing an inlet for fresh air (F. A. I.) on the house side of the intercepting trap, the construction of which has been already described; and to provide at or near the head or highest part of the drainage system an outlet, which is carried up well above the highest window or other opening into the building, or, better still, to the ridge of the roof. It is not desirable to carry it up a chimney stack, and in no case should it terminate at the level of the top of a chimney flue. When there is no fire in the fireplace below, such flues often act as inlets to the building, and may suck in the gases that we have been at great trouble to exclude from the building. Between the inlet and outlet there must be nothing in the way of a trap or other obstruction to impede the circulation of the air.

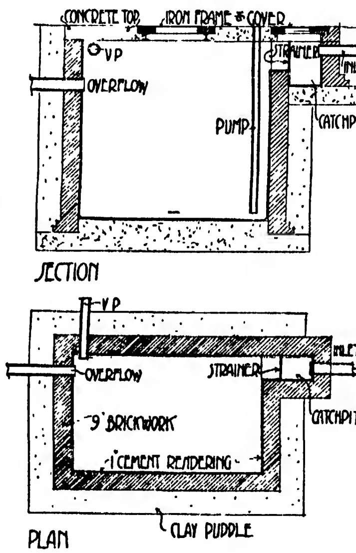
Ventilating Pipe. The ventilating pipe (V. P.) [see PLUMBER] may be a pipe of lead or iron specially erected, but if the soil-pipe from a w.c. occurs within 10 ft. of the head of the drain it may be *utilised*. Every soil-pipe ought to be treated as a ventilating pipe wherever it occurs in the system. The soil-pipe is cut off from the interior of the house by the traps of the w.c. apparatus [see INTERNAL PLUMBER]. The V. P. is connected at its bottom end to the drainage system, and is carried up, without any reduction of its diameter, as straight as possible. All unnecessary bends must be avoided, and the top finished with a fixed dome or globe formed of copper or galvanised iron wire to prevent birds having access and building in it nests, which would destroy its utility.

In some cases an exhaust cowl is added to the V. P. to assist in extracting the air. The pipe should be fixed against a sunny wall if possible, for in such a position the sun will heat the pipe and the column of air within it will be heated, rarefied, and tend to rise, setting up a natural current of air in the pipe, while cool air will be drawn in through the F. A. I. to replace it. But under some conditions this action may be reversed, and it is on this ground that the head of the F. A. I. is provided with a self-closing flap. Lest this should fail, the position selected for the inlet should be such that if for a time it forms an outlet no serious harm may be done. It is best placed as far as possible from any opening into the building.

So long as such a ventilation system operates, it is impossible for any serious pressure of gas to be created in any part of the drainage system, so that the danger of the seal of the gullies being forced is obviated, and if the interceptor is forced the sewer gas has a free road to escape above the roof level.

Testing Drains. The laying of the drain in straight lines and to true falls should be watched during its progress; it may be tested on completion by placing a small mirror in the invert of one manhole and a lamp or candle in the next; even a sheet of white paper will serve in place of the lamp if the manhole cover is open. When truly laid the orifice at the distant end will appear in the mirror truly centred in the near orifice.

Water Test. The test for soundness—that is, the capacity to retain without leakage liquids passing through or standing in the drain—is made by charging the drain with water. It is usual to test each length of drain separately as laid, and later to test the whole system or considerable sections of it, including the manholes.



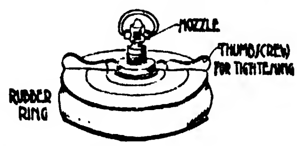
46. RAIN-WATER STORAGE TANK

Drain Plug. For each individual length the lower end of the drain where it enters a manhole is stopped by means of a *plug* or *stopper*. There are two principal classes of these. One consists of two metal plates, the edges arranged to form a V joint, and capable of being adjusted by means of a screw [47]. In the V is placed a thick ring of rubber circular in section. When the plates are separated the diameter is slightly less than that of the pipe to be tested, and it can be placed in the mouth of the pipe. On turning the screw the plates are drawn together, the width of the V joint reduced, and the rubber band, forced into contact with the surface of the drain at all parts, closes the drain completely. Where a considerable pressure of water is to be used, it is useful to strut this plug from the opposite side of the manhole, or it may be blown out bodily by the pressure. Through the centre of the plug an outlet of small diameter is formed, with a tap or screw cap by which it may be closed or opened. This is used for allowing the water to escape after the test is completed. There is also a loop or ring to which a cord or chain may be attached to prevent the plug being washed down the drain if accidentally displaced.

Air-Bag. The other form of plug consists of an *air-bag* [48]. This is placed in the mouth of the drain, and air is pumped into it with an inflator till it swells and closes the orifice. It is held in position solely by friction

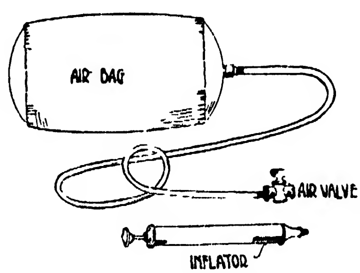
between the bladder and the pipe due to the air pressure within.

The outlet having been closed, the pipe is completely filled with water from its upper end. If the length of pipe is short and the fall slight, a bend may be inserted in the end and turned up so that the level of the water standing in the bend should be about 5 ft. above the level of the outlet. With long runs and fairly rapid falls the head of water in the pipe will be sufficient, and with very rapid falls the head of water may be excessive, but it should not be allowed to exceed 10 ft.



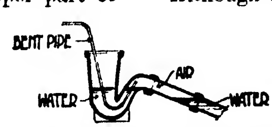
47. DRAIN-PLUG OR STOPPER

Filling the Drain. The filling is best done by a rubber hose, and care should be taken to prevent any water passing into the trench. When the pipe is fully charged the water-level is noted, which may be done by a 2-ft. rule. A convenient plan is to use a strip of white paper, which may be dipped into the water and then stuck against the side of the pipe or gully so that the lower edge just touches the water. If the water remains in contact with the paper without perceptible movement for 20 to 30 minutes the drain is sound. If the water is observed to fall very slightly in the pipe it may be due to absorption by the cement in the joints, and a fresh observation must be made. If the water sinks at all rapidly, or continuously, all the joints in the drain must be examined to find the joint or joints that are defective, and any defective joint must be made good and the test again applied.



48. AIR-BAG AND INFLATOR

Withdrawing the Air. If the upper end of the pipe is formed by a gully or by the pan of a water-closet it is necessary to see that the air is withdrawn from the upper part of the trap, or it will be impossible to fill the pipe. This may readily be done by passing a piece of bent lead pipe—½ in. will suffice—under the seal, so that the inner end penetrates to the upper part of the outlet [49], giving a communication with the air outside and allowing the air in the pipe between the stopper and the water-seal to escape as the water rises.



49. WITHDRAWING AIR FROM GULLY OR W.C. TRAP

When all the pipes converging into one manhole have been found sound, the plug is inserted in the outlet of the manhole, and the manhole and the pipes entering it can be tested together, and, if necessary, by stopping off the various inlets, the manhole can be tested alone, but it is difficult in this case to be sure that all the plugs are perfectly watertight.

This test may be relied upon to disclose any defect in the pipes, jointing, or manholes; such a condition may actually arise in any drainage system should the intercepting trap or the outlet become blocked through any temporary cause, so that it is not an unduly severe one.

Smoke Test. The smoke test is usually applied to new drainage systems to ascertain that the ventilation is in proper order. The test for this purpose may be made with a smoke rocket. This is simply a stout paper cartridge filled with a special preparation which, on being ignited, emits a dense and very pungent smoke. It may be lighted and placed in the intercepting chamber, the lid of which must be at once closed. After a very short interval the smoke should be seen to issue from the top of the ventilating pipe, while none should be seen or smelt at the fresh-air inlet.

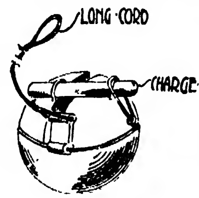
This test is also used for testing the soundness of the joints of the lead and iron pipes within the building [see PLUMBER], for if any of these are in the least defective, the very pungent smell of the smoke will be at once detected. In this case the observer should on no account personally light the rocket, as, if he does so, his nose may not, after smelling it in the manhole, be sufficiently sensitive to detect it in the building. Care must also be taken to see that all doors and windows are closed, and that the smoke, if any escape from the manhole, is not admitted directly to the building at any point. In making this test every room in which there is any fitting connected directly or indirectly with the drainage system should be visited.

This is a useful test to apply to drains and fittings that are not new, and the soundness of which is uncertain. For either purpose the smoke is sometimes generated in a special box, and forced into the drain under pressure by means of an air-pump. This ensures a slight pressure in the system, and adds to the utility of the test, but it is not necessary when the ventilation alone is to be tested.

Although the plumbers' work in fitting up w.c's and other apparatus will be dealt with later, another method of testing the soundness of internal joints may be here dealt with. It is used chiefly in connection with w.c's.

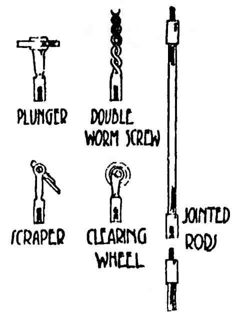
Ferrets. *Ferrets* are made of different varieties by different manufacturers, but the object of all is to introduce into the pipe behind the trap a charge producing a very strong pungent smell which cannot return through the trap, and which, if it is detected inside the building, can only find its way in through some defect in the pipes or workmanship. The form illustrated [50] consists of a ball of wood, with a deep slot cut into it. Across the top of this a thin sealed tube of glass filled with prepared

chemicals is placed through two eyes, and held in position by an elastic band. The cord attached to the ball when the ferret is to be used is placed in the slot below the tube, and the ferret can be inserted under the seal, and will float on the drain side of the trap. A sharp jerk of the cord will snap the tube and scatter the contents in the water, upon which the fumes will be generated; if any defect exists in the pipes or fittings the smell will be detected.



50. FERRET

The Cleansing of Drains. Even self-cleansing drains are liable to some fouling, and should have occasional attention. In case of an actual stoppage of the drain, notice will probably be given by the overflow of one or more gullies. If the stoppage is in the intercepting trap, and the cleansing eye is accessible by means of a chain, as recommended, this should be at once removed. This will allow most of the water held up in the system to escape; the remainder must be bailed out, unless the stoppage can be removed otherwise. If a stoppage occurs at some intermediate point, cleaning rods are used [51]. They are long rods made up of short lengths, which can be screwed together to make any required length. The point of stoppage is located from the manhole above or below it. If the rods can be worked from the manhole above, the *plunger* is fixed to the end of the rod, and the obstruction is pushed down the pipe to the next manhole, and removed. If the upper manhole is inaccessible from being charged with sewage, the *double wormscrew* is fixed to the top of the rod, passed up from below, and screwed into the obstruction, which may then be withdrawn.



51. APPARATUS FOR CLEANSING DRAINS

The *scraper* may be used for clearing partial obstructions in the invert of a drain, and the *wheel* for exploring a drain to locate an obstruction. All traps having containers for gravel or similar material require periodical cleansing, or the trap itself may be blocked. All traps with gratings require to be cleared of leaves or other obstructions regularly, especially in the autumn.

It is desirable to flush out drains from time to time, but it is useless to do this from a small hose, which will never fully charge the pipe. If there is no flushing-tank, a large tub, holding 50 gallons or more, should be filled and emptied rapidly into the top manhole. This will fully charge the outlet and flush out the drain.

Drainage of Complicated Buildings. It has been necessary in dealing with this subject to illustrate the work by plans of a not unusual though not very simple type, but it may happen that in the construction of a large building consisting, it may be, of several blocks more or less detached—for example, a thoroughly modern hospital on an open site—that the drainage of different parts must be dealt with as individual blocks, and that a main drain will take the place assigned to the sewer. But no new principle will be involved. Each block so dealt with, will be treated as if it were an entirely separate and detached building with its own intercepting chamber and trap and system of ventilation. The main drain receiving the sewage from these branches will in turn be provided with an intercepting chamber and trap to cut it off from the public sewer, and will have its separate system of ventilation.

Level of Sewers. The most serious difficulty in dealing with the drainage of any given site occurs when the sewer into which the drainage is to be taken is at such a level that there is difficulty in securing an adequate fall. The level of the invert of any sewer at any given point, or at least at every road manhole, can, as a rule, be ascertained by applying to the surveyor or engineer of the authority controlling the public sewer.

This should be done in all cases where a basement storey or storeys are intended to be introduced, or very great difficulties may result when the drainage comes to be dealt with. If this is done in good time, a little alteration in the floor levels may get over the difficulty. There are districts where the local authorities decline to connect any drain from a basement storey with the public sewer, on account of the occasional liability to flooding when the sewers are fully charged.

ARCHITECTS, CHEMISTS, & PRACTICAL EXPERTS

Architects as Public Servants. Public Analysts. Inspectors of Weights and Measures. Other Technical Appointments. Women Inspectors

Continued from page 701

By ERNEST A. CARR

CONSIDERING the vast number of town halls, schools, asylums, public baths, and other costly and extensive buildings erected and owned by local authorities, it is a little startling to discover how few chief architectural appointments are comprised in the municipal service. The explanation of this curious anomaly is twofold. In the first place, the leading county and borough surveyors are generally both willing and fully competent (as we saw when discussing those posts) to prepare complete plans, with specifications, for municipal buildings of moderate pretensions, at least; and their services are freely employed in the designing of libraries, baths, power stations, and similar public structures. When, however, a building of special importance is contemplated, or one whose planning involves peculiar difficulties, it is the very general practice of public authorities to organise a competition for a prize design amongst qualified architects. A practitioner of distinction is engaged to act as assessor, and substantial premiums are awarded for the plans of greatest merit. The scheme ultimately chosen is then carried into effect, under the supervision either of the local surveyor or of the architect who evolved it.

In the latter event, payment is usually fixed by scale, the terms being often 5 or 7½ per cent. of the total cost of erection. When we consider the enormous sums of money expended on the greater municipal buildings, it is evident that local councils are among the most lucrative clients of the architect. Such occasional commissions, however, limited as they are to the performance of individual contracts, cannot be said to constitute municipal employment.

Architects as Public Servants. Speaking generally, only the authorities for counties and leading county boroughs have sufficient work of building and reconstruction on their hands to justify them in adding the post of architect to their permanent staff, though many lesser bodies appoint architectural assistants to their surveyor or engineer. The London County Council, whose position with regard to building matters is of unique importance among local authorities, has a considerable staff of well-paid architectural experts, headed by a superintending architect at £2,000 a year. Edinburgh adopts the system of proportionate payment. Its architect's emoluments are a nominal retaining fee of £50 a year, 3 per cent. on all new work entrusted to him, and 5 per cent. on alterations. Among smaller authorities the mode of payment is usually by a fixed salary, which may be anything between £400 and £900. The Manchester Corporation pays its architect £700 a year, and this figure probably represents the average value of such posts.

The difficult question of an architect's training will be found fully considered in the course on ARCHITECTURE, and municipal differs so slightly from private work that nothing can usefully be added here on the matter. Within the service, as without, the diplomas of the Royal Institute of British Architects are of paramount value to candidates.

Assistantships. The great excess in numbers of architectural assistants over architects proper in the municipal service needs no explanation, in view of what has already been said on the practice of appointing assistants where no principal exists. The rate of pay is practically the same as for assistant surveyors. £120 to £150 is the average salary for junior architectural assistants, and £200 to £250 or £275 for senior and chief positions. To a young architect of student rank, or one who has but lately taken his A.R.I.B.A., these figures are perhaps sufficiently attractive; but in weighing the claims of public employment he should not lose sight of the unusual paucity of principal posts in this branch of the service.

London District Surveyors. Despite their official title, these officers perform architectural rather than surveying duties. They are, in fact, experienced architects, appointed by the London County Council after passing a special qualifying examination held by the Royal Institute of British Architects; and, although private practice is prohibited in respect of new appointments, a number of the older members are entitled to practise as architects in addition to their official work. Their duty consists in supervising new buildings and all alterations to existing buildings, and to see that these are carried out in accordance with the London Building Acts. They are remunerated by fees according to a statutory scale. The value of the position is shown by the latest yearly return of district surveyors' fees, which average £925 per officer.

Clerks of Works. Shrewd, practical men, with a sound working knowledge of the building trade in all its branches, are constantly in request among local authorities for the post of clerk of works on the architectural or surveying staff. As a rule, the appointment is temporary, in name at least, extending over a single contract only; but capable men are apt to find it so often renewed as to prove practically continuous, and authorities maintaining a Works department are able to offer posts of this class on the permanent staff. The salary paid varies from £3 to £5 5s. a week. A recent advertise-

ment of an urban district council offered £4 4s. weekly to "thoroughly experienced and practical men (between the ages of 35 and 50) able to put in levels, set out, and measure the work."

The qualifications needed to make a good clerk of works have been more carefully summarised by an expert in the following terms: "A man qualified for this position must have a knowledge of the different kinds of material, such as lime, cement, sand, gravel, stone, bricks, etc. He must also know the different kinds of earth work for foundations. He must be able to check bad workmanship at sight. Also, he should have some knowledge of engineering, such as the use of the level, and be able to set out work so as to check contractors as to lines and levels."

Salaries. The London County Council—an employer of building labour on a very large scale—pays clerks of works on the "unestablished staff" a starting salary of £3 3s. a week. A list of applicants is kept, from which appointments are made as occasion arises. Forms of application can be obtained of the Superintending Architect, County Hall, Spring Gardens, S.W. The official intimation further states that "there are also vacancies for temporary employment as clerks of works during the summer months to superintend the painting of the schools, and application for this class of employment should be made to the Architect, Education Offices, Victoria Embankment, W.C."

The system of keeping a list of applicants for such occasional posts as that of clerk of works, *instead of advertising the vacancies*, is followed by a good many authorities. Qualified candidates would therefore do well to forward to their local councils an application for employment, accompanied by copies of recent testimonials, without awaiting an invitation to do so.

Public Analysts. The Sale of Food and Drugs Acts, which are designed to protect consumers from fraud, impose upon local authorities the duty of procuring and analysing samples of food and medicine, and of prosecuting the sellers of those that prove to be adulterated. Samples taken by an inspector for this purpose are submitted by him to a specially appointed chemical expert for examination.

The public analyst, as the municipal chemist is officially styled, has a responsible and difficult duty to discharge. Against his professional skill is pitted every wile by which clever tricksters seek to mask their impostures and secure inflated profits. He must be able to detect the most cunning methods of admixture or dilution, the minutest traces of preservatives and colouring matter; and his methods must be as exact as they are subtle, for the result of his analysis determines entirely the action taken by the council employing him. His smallest mistake may have very serious consequences. Every day, in courts of law, men are convicted of adulteration charges on the evidence of the laboratory alone. It is clearly requisite, therefore, that he should be fully qualified for his task.

To ensure the appointment of none but properly trained chemists, every public analyst is required to satisfy the Local Government Board of his competency. Candidates must be specially qualified in analytical chemistry, therapeutics and microscopy; but registered medical men, their professional training having ensured a sufficient acquaintance with the last two subjects, need furnish evidence of their knowledge of analytical chemistry only.

Qualifications. The Local Government Board's regulations do not, in so many words, insist on any particular degree or diploma for public analysts. In practice, however, that body recognises only a single qualification as satisfactory, and rarely sanctions the appointment of any candidate who is not a Fellow or Associate of the Institute of Chemistry, and who does not possess the certificate of that Institute, granted after examination in therapeutics, pharmacology, and microscopy.

The diplomas of the Institute of Chemistry, and the training exacted of candidates, will be fully considered in the CHEMISTRY Course. We may note here, however, that the special test in the Analysis of Food, etc., which is essential for public analysts, may be taken either at the final examination for the Associateship (A.I.C.), of which it forms Branch *E*, or as a separate subject after the Associates' diploma has been obtained. In the official syllabus of the Institute of Chemistry (to whose very courteous secretary we are obliged for much useful information on the training of analysts) the test is thus defined:

"Analysis of Food and Drugs and of Water, including the Examination and Analysis of any food or drug within the meaning of the Sale of Food and Drugs Acts; the Assay of Alkaloids; the Recognition of Poisonous Chemicals and Crude Drugs ordinarily found in commerce and having well-marked physical characters; the Use of the Microscope in the detection of adulterations, substitutions, commonly occurring parasites, and impurities in Food, Drugs, and Water.

"Candidates in Section *E* are required to show a general knowledge of the Therapeutic Effects of Chemicals and Drugs, and of the quantities which, taken internally, would be injurious or fatal to man."

Although Associates of the Institute are strictly eligible for these posts, it will be found that, in fact, there is little chance of winning an appointment before completing the three years' "study and practice of applied chemistry," which qualify for the Fellowship. In the list of chemists practising as public analysts the initials "F.I.C." occur with almost unbroken regularity after each name; indeed, nearly 95 per cent. of the appointments as public analysts are held by Fellows of the Institute. Degrees in medicine and science are also very frequent.

Emoluments of Analysts. The earnings of public analysts vary widely, not only with the importance of the area for which they act, but also with their individual status in the profession. In some instances they are paid a fixed stipend; more generally they receive a fee (ranging from 7s. 6d. to £1 1s.,

and occasionaly £2 2s.) for each analysis made, a minimum number of analyses each year being assured. A typical instance of this method is afforded by a London borough which pays 10s. per sample, guaranteeing an annual supply which ensures for the analyst a *minimum* salary of about £420. The chemist in question acts also for another Metropolitan borough and a provincial district, public analysts being neither restricted to the service of a single local authority nor debarred from private practice; his income as a public officer may, therefore, fairly be estimated at £1,000 a year.

Manchester pays its analyst a salary of £150, and in addition fees averaging between £450 and £500 a year. This gentleman also holds several similar appointments elsewhere. Indeed, the same is true of practically every successful public analyst. As a result, the earnings of a few leading members of the calling are very large, probably from £1,500 to £2,000 a year; whilst those of less distinguished practitioners may range between £250 and £1,200. Where so small a stipend as the former figure is paid, the borough council often provides its analyst with a properly equipped laboratory without charge. Holders of more important appointments usually furnish their own laboratories, the fees or salary they receive being inclusive.

For a man of the requisite ability the best means of gaining an entry into this fairly lucrative and distinctly interesting branch of the municipal service is to undergo the training necessary to pass the intermediate examination of the Institute, and subsequently to enter the laboratory of a public analyst of some distinction. This will probably involve the payment of a premium, or, for a time, service, either without salary or at a merely nominal one. But this is the most economical and effective method of gaining the special experience needed in order to qualify for an appointment.

Other Posts for Chemists. Apart from the analysis of food and drugs, the most important municipal work available to chemical experts relates to the testing of water, gas, and sewage. Leading positions of this sort are well remunerated. The chemist to the London County Council, a distinguished expert in questions of water pollution and sewage filtration, receives £1,100 a year; and the leading water examiner employed by the Metropolitan Water Board is almost as highly paid. Chemists are necessarily employed at municipal works for the supply of gas or water or the disposal of sewage. The salaries of these officers vary from £150 or £200 to £700, according to their qualifications and the importance of the post. For all professional positions of this class the most useful diploma is the F.I.C. Candidates proposing to specialise in water and sewage analysis should take Branch *F* at their final examination or subsequently.

Where the supply of gas or water is not municipal the local authority protects the interests of consumers by frequent tests of quality. For this work an analytical chemist is often retained at a substantial fee. The gas examiner to the City Corporation receives £400 a year, and several of the Metropolitan boroughs pay almost as much.

The London County Council employs a non-professional staff of gas examiners, under the control of the chief chemist and his assistants. On passing an examination in practical gas testing, candidates are placed on the list of relieving gas examiners, and are paid 10s. a day when on duty. From this relief staff appointments are made as gas examiners on the permanent staff, rising by £5 annually from £120 to £150 a year. Applications for employment should be made to the Chemist, 40, Craven Street, W.C.

EXAMINATION FOR INSPECTOR OF WEIGHTS & MEASURES

Examining Body, Time and Place of Examination.	Subjects of Examination. NOTE.—Only persons already nominated for inspectorships are eligible for examination.	Fees and Age Limits.
BOARD OF TRADE. STANDARDS DEPARTMENT, 7, OLD PALACE YARD, WESTMINSTER, S.W. Examinations are arranged as required.	1. **Dictation.** 2. **Arithmetic** (SIMPLE). 3. **Mensuration** (PLANE RECTILINEAR FIGURES AND SOLIDS). 4. **Elementary Mechanics.** A knowledge of statics so far as relates to the composition of parallel forces, centre of gravity, and the principle of the lever. 5. **Elementary Physics.** (*a*) Units, standards, and physical constants. (*b*) Definition and application of terms and expressions used in elementary physics. (*c*) Effects of heat in the measurement ofelength, weight, volume, and capacity. (*d*) Determination of specific gravities. 6. **Inspection and Verification of Weights, Measures and Instruments.** The mode of testing weights, measures, and weighing and measuring instruments, and the various tests prescribed in the Board of Trade Regulations. Candidates are required to adjust and stamp weights, etc. They are also examined in the Acts of Parliament relating to an inspector's duties, particularly in respect of prosecutions.	£1 10s. 0d. 21 years and upwards.

Inspectors of Weights and Measures. These officers are appointed by county and borough authorities for the protection of consumers from loss arising through faulty or fraudulent weights and measures. Their chief duties comprise the stamping of such weights, measures, and weighing and measuring instruments as prove on inspection to be correct, the seizure of those that are seriously at fault, and the prosecution of vendors for carelessness and dishonesty. The work requires shrewd, keen, zealous men, willing to extend their hours of duty for the sake of paying surprise visits in suspected quarters, and alert enough to compass the outwitting of that wily and dexterous weight manipulator, the itinerant trader of the streets.

The Weights and Measures Act of 1904 requires that every officer appointed in the future, without exception, must be the holder of a certificate of qualification issued by the Board of Trade. This document is gained by passing a theoretical and practical examination, particulars of which are given in the schedule appearing on the previous page. The standard of knowledge exacted by that test is modest enough, save in Subject 6—the actual duties of an inspector's position—in respect of which the examiners' questions and practical tests are very properly strict and searching. Examples of the papers set in the Board of Trade's Examinations can be obtained from Messrs. Eyre & Spottiswoode, East Harding Street, E.C.

Board of Trade Examination. We are indebted to the courtesy of Mr. Howard Cunliffe, Secretary of the Incorporated Society of Inspectors of Weights and Measures, for the following valuable suggestions as to the character of the Board of Trade examination, and the best practical means of preparing for it and of entering this branch of municipal employment.

"The arithmetic and mensuration questions are rarely difficult, but in order that a candidate may successfully answer the physics and mechanics questions he should have a good knowledge of elementary mathematics (Euclid, Books I. to IV.; Algebra to the Binomial Theorem; and a general knowledge of the Trigonometrical Formulæ); in addition to a thorough knowledge of a good text book on general elementary science.

"The legal part of the work can, of course, be learned by a study of the statutes, and of the Board of Trade Regulations. The difficult part of the examination is that dealing with the candidate's practical knowledge of the verification of weights, measures, and weighing and measuring instruments. The most satisfactory manner in which this information can be obtained is by being personally employed in the administration of the Acts as an assistant to an inspector of weights and measures. This is all the more important, because the examination is not an open one, the Board of Trade only accepting those candidates who are appointed to act as inspectors, or such as are nominated by a local authority as possessing sufficient practical knowledge for the proper performance of the duties of an inspector. While it is not unusual for assistants in Weights and Measures Departments to receive appointment or nomination by their local authority, it is very rare that those outside Weights and Measures circles obtain such an advantage, because when local authorities have no candidates in their own employ, they invariably advertise for inspectors holding the Board of Trade certificate.

"At the present time there are upwards of 500 inspectors of weights and measures in Great Britain. In Ireland the duties are performed by inspectors under the Royal Irish Constabulary."

There is a good deal of diversity in the salaries paid to inspectors of weights and mesures. Provincial appointments usually commence at £100 or £120 and advance by annual increments to £150 or £180, with an additional £100 or so for chief positions. The greater authorities, however, are more liberal. The City Corporation, for instance, pays its chief inspector £325, and his subordinates £200 a year. Under the London County Council, verification inspectors receive £135, with yearly advances to £175; and £200 on promotion to the full grade of inspector, rising by £10 and then by £12 10s. yearly to £300. These posts are filled from the ranks of assistants, whose pay begins at 30s. and rises to 50s. a week. Assistants are appointed from the list of applicants kept by the Council, and must, of course, pass the Board of Trade's test before being advanced to inspectorships.

Inspectors Under Other Acts. There are a few further technical appointments about equal in value with those we have just considered, for which no qualifying examination is necessary. Such are inspectorships under the Shop Hours, Petroleum, and Explosives Acts. Candidates for these posts should possess a fair education and some knowledge of the particular statutes concerned. In many of the counties and county boroughs a separate appointment is not made for each class of duties. They are undertaken by an inspector already holding office, in return for an increased stipend. That officer is most frequently the inspector of weights and measures. In London, as in other counties proper, the work under each group of statutes is performed by a distinct staff of officials, however small. The London County Council rate of pay may be taken as typical of such appointments. It commences at £150 a year for men, and rises by yearly increments of £10 to £250.

For women inspectors under the Shop Hours and other Acts the initial salary is £100, and the maximum £150. Candidates seeking any of the inspectorships mentioned in the present paragraph should lay their claims before the county authority; but it must be remembered that in any one area the total number of such posts is small.

ELECTRIC MEASUREMENT

Units and Standards. Legal British Units. The One-Ohm Standard. Resistance Boxes. How to Measure Resistances. Wheatstone's Bridge

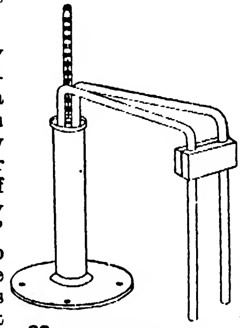
Continued from page 672

By Professor SILVANUS P. THOMPSON

IN a former section [page 291] it was told how the strength of a current is expressed in terms of a certain unit of current called *one ampere*, and measured by an instrument called an *amperemeter*. It was also told how the amount of an electrical effort, or electromotive force, is expressed in terms of another unit called *one volt*, and measured by an instrument called a *voltmeter* [page 292]. Subsequently [page 669] it was further explained how these two things, the electric effort which drives the current and the strength of the current thereby created, are related to a third thing—namely, the resistance of the circuit, resistance being expressed in terms of a unit called *one ohm*. The rule connecting together these three quantities, known as Ohm's law, is of vital importance in understanding the subject of the present chapter. It is to be found on page 670, to which the reader should turn before attempting to learn the principles of electric measurement.

Units and Standards. Every physical quantity needs for its expression the mention of a number and a unit. When you want to tell a man how long a piece of timber is, you may say "fourteen feet," or "thirty-four inches." Or, to describe the weight of anything, you may say "twenty tons," or "three-and-a-half ounces." Now, such expressions are all made up of two parts, the pure numeric and the name of a unit. The numeric tells how many times over the unit must be taken in order to arrive at the quantity in question. Everyone knows that you cannot express lengths in ounces, nor weights in feet. Each quantity must be expressed in terms of *a unit of its own kind*, lengths in terms of a unit of length, weights in terms of a unit of weight; and hence, to express the amount or strength of an electric current, it must be expressed in terms of the unit of current, as so many *amperes*. A unit of any of these physical quantities means a particular amount of that kind which has been agreed upon, or decided by law, to be taken as a basis for measurement. Thus, *one foot* is a unit of length—that is, a particular length, fixed by national consent in terms of which other lengths can be expressed. Again, *one second* is a unit of time, in terms of which other times can be expressed. In some cases a unit can be embodied in a concrete way in a *standard*. The wooden rod, one foot long, called a foot-rule, is a standard which embodies the unit called one foot. The lump of iron or brass called one pound is a standard in concrete form. It will be noted that a *unit* is a kind of legal definition or denomination of a measure, while a *standard* is an actual thing which embodies it. A gallon in this country is legally defined as the volume occupied by 10 pounds of water; the pot made to fit this definition is a standard embodying the unit.

Now, in matters electrical we have three chief units, the *ampere*, the unit of current; the *volt*, the unit of electromotive force; and the *ohm*, the unit of resistance. Now, unfortunately, we cannot have a standard ampere to carry about in our pockets like a foot-rule, but we can have a standard amperemeter, or ampere balance, such as that kept at the Board of Trade. But we can have a standard volt—that is, we can manufacture a standard cell which will have a constant voltage, against which other voltages can be checked. And we have a standard ohm—namely, a piece of wire such that it offers exactly that particular amount of resistance to an electric current that is denominated as *one ohm*.



32. STANDARD ONE-OHM COIL

Legal British Units. In the year 1894 the late Queen Victoria signed an Order in Council in which she approved and made legal certain new denominations of standard, which had been prepared and verified by the Board of Trade under the Weights and Measures Act of 1889. Amongst these were the *ohm*, the *ampere*, and the *volt*. It may be noted that these three words thus became legal British words, and that the word *ampere* is spelled without an accent and without a capital. The three legal British standards are as follows:

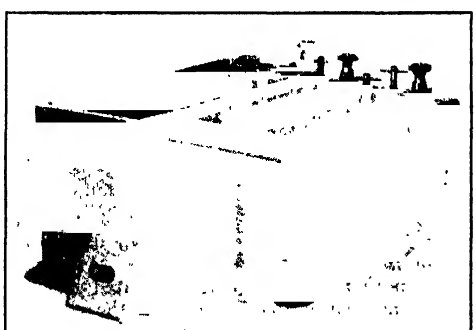
1. *The ohm.* A standard of electrical resistance denominated *one ohm*, being the resistance between the copper terminals of the instrument marked "Board of Trade Ohm Standard, Verified 1894," to the passage of an unvarying electrical current when the coil of insulated wire forming part of the aforesaid instrument, and connected to the aforesaid terminals, is in all parts at a temperature of 15·4° C.
2. *The ampere.* A standard of electrical current denominated *one ampere*, being the current which is passing in and through the coils of wire forming part of the instrument marked "Board of Trade Ampere Standard, Verified 1894," when, on reversing the current in the fixed coils, the change in the forces acting upon the suspended coil in its sighted position is exactly balanced by the forces exerted by gravity in Westminster upon the iridio-

platinum weight marked A, and forming part of the said instrument.

3. *The volt.* A standard of electrical pressure denominated *one volt*, being one-hundredth part of the pressure which, when applied between the terminals forming part of the instrument marked "Board of Trade Volt Standard, Verified 1894," causes that rotation of the suspended portion of the instrument which is exactly measured by the coincidence of the sighting wire with the image of the fiducial mark, etc.

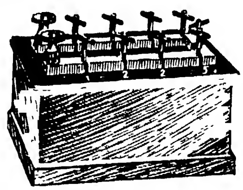
It will be noted that the standard ohm is a *particular coil of wire, while the* other two standards are balances which turn to special marks when the standard amount of current or of voltage has been reached. Fig. **32** depicts a *standard one-ohm coil,* a coil of platinum-silver alloy, wound in a flat double spiral, and enclosed in a thin, flat, watertight box, provided with stout copper electrodes.

Secondary Standards. From the primary standards copies can be made, just as our yard-sticks and foot-rules are made from the standard yard kept at the Board of Trade. Coils having their resistance adjusted to one ohm are sold by instrument makers; and coils that have definite multiples of one-ohm resistance, from $\frac{1}{1000}$ ohm up to 100,000 ohms, can also be purchased. Amperemeters can be calibrated by comparison with the ampere balance of the Board of Trade, or are more often calibrated by comparison between the deflection indicated on their dial and the amount of current passing through them, as computed by passing it for a given time through an electro-depositing cell where silver is being deposited. A current of one ampere will in one hour deposit 4·0248 grammes, or about 60 grains, of silver. As a secondary standard of voltage there is often employed a *standard cell* —that is, some kind of voltaic cell of which the voltage does not change with time. Of standard cells the best are those of Clark and of Weston. Clark's cell requires to be prepared with the utmost care under very precise conditions. It consists of an anode of pure zinc (or of zinc amalgam) in an excitant of a saturated solution of zinc sulphate, and a kathode of pure mercury in contact with mercurous sulphate to serve as depolariser. It has an electromotive force of 1·434 volts. The Weston standard cell has an anode of cadmium in an excitant of cadmium sulphate, while the kathode is mercury with mercurous sulphate as depolariser. Its electromotive force is 1 025 volts.



34. INTERNAL PARTS OF RESISTANCE BOX

Resistance Boxes. For the purpose of the commercial measurement and numerical comparison of the resistances of telegraph lines, circuits, coils, and conductors, copies of the standard resistance and of multiples of that resistance are made up in sets assembled in *resistance boxes.* A simple form of resistance box is shown in **33.** The top of the box is a slab of ebonite, upon which are mounted a number of brass pieces, separated from one another by narrow gaps, but between which brass pegs or conical plugs can be inserted, so as to connect them electrically together.



33. RESISTANCE BOX

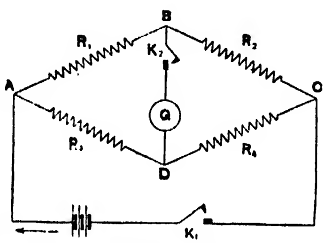
The resistance coils are inside. From each of the brass pieces there passes down into the box a stout brass rod, and between these rods the resistance coils are connected. Each brass plug when inserted in its place forms a bridge or short circuit to the coil below it; so that if all the plugs are in their places any current that may come to the apparatus by wires attached to the two terminal screws will simply pass from one brass piece, through the plug, to the next, and so will flow along the row of brass pieces without meeting with any appreciable resistance. But if any plug is withdrawn, then the current will have to descend into the box and traverse the coil that has thus been unplugged, and ascend again to the next brass piece.

All the coils inside the box need not be made of uniform resistance; and, in order that the experimenter may be able to introduce into the circuit any desired amount of resistance, it is expedient that the various resistances of the coils in the box should be arranged according to some methodical plan. In the cut [33], the coil below the first plug in the front row is 1 ohm, the second 2 ohms, the third 2 ohms, the fourth 5 ohms. If we were to unplug at the same time all four plugs the resistance thus introduced into the circuit would be $1 + 2 + 2 + 5 = 10$ ohms. To introduce eight ohms we must unplug only three of the plugs—namely, $1 + 2 + 5$. The remaining coils are 10, 20, 20, 50, and 100 ohms. So with this series we can introduce any number of ohms between 1 and 200. Thus, to introduce 86 ohms we should have to pull out the plugs corresponding to 50, 20, 10, 5 and 1 ohms, respectively. Some boxes contain more coils reading down to $\frac{1}{10}$ ohm and up to 100,000 ohms. The resistance of each coil is marked on the box.

The coils must be very carefully insulated, and each coil is wound back on itself, so that it exerts no magnetising effect. Fig. 34 gives a

view of the actual construction of a modern resistance box, dismounted to show the coils.

Finding an Unknown Resistance. If we want to find how many ohms of resistance there are in the wire of any particular piece of apparatus, we can do this with fair precision in the following simple way. Connect this unknown resistance into circuit with a suitable galvanometer and with a battery of a sufficient number of cells to produce a current that can be measured on the galvanometer. Then remove from the circuit this unknown resistance, and in its place substitute the resistance box. From the box then remove, by trial, some of the plugs until the galvanometer shows the same current as before, when it will at once be evident that the amount of resistance so unplugged (which can be seen by inspecting the numbers marked at the places where plugs have been taken out) is equal to the unknown resistance.



35. WHEATSTONE BRIDGE

Wheatstone's Bridge. It often occurs that the experimenter desires to know the resistance of some circuit or piece of apparatus, and it may be that this resistance is either larger or smaller than that of the coils in his resistance box; or he may wish to find the value of the unknown resistance with greater accuracy than is afforded by the method of substitution just described. To avoid the expense of a very large and cumbersome box of resistances, recourse is had to a very convenient instrument known as *Wheatstone's Bridge*. This is a device in which the value (in ohms) of an unknown resistance is ascertained by proportion. A diagram of this arrangement is shown in Fig. 35. In this instrument is adopted a grouping of several paths for the current; the grouping consisting essentially of four distinct resistances, which we will call R_1, R_2, R_3, and R_4, connected up in the manner shown. Thus, the current from the battery, entering the instrument at A, finds two routes, one through R_1 and R_2 to C, and the other through R_3 and R_4 to C, and so back to the battery. Now it can be shown that the following very simple proportion holds good between these four resistances. If the numbers of ohms in R_1, R_2, R_3, and R_4 respectively, are such that R_3 is to R_4 as R_1 is to R_2 (by simple rule-of-three calculation), then *no current* will flow from the point B to the point D on connecting these points by a galvanometer. On the other hand, if the resistances are not in proportion, we shall at once know it, for then when we connect the galvanometer across from B to D it will indicate some current. So, then, if R_3 be the unknown resistance, we can ascertain it in the following way. We must know the respective resistances of R_1 and R_2. Then we must adjust R_4 (by unplugging coils) until we get such an amount in R_4 that when we connect the galvanometer across as a bridge from B to D no current runs across the bridge. This process of adjusting till no current flows is called *getting balance*. Then we shall know that the proportion holds good, and since

$$\frac{R_1}{R_2} = \frac{R_3}{R_4},$$

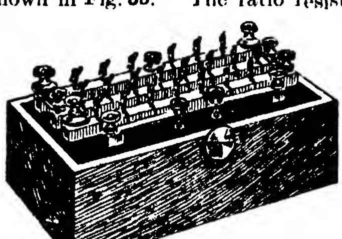
it follows that

$$R_3 \text{ (unknown resistance)} = \frac{R_1}{R_2} \times R_4.$$

Thus, if we had used 1 ohm for R_1 and 10 ohms for R_2, and had then found that to get balance we had to adjust R_4 to be 254 ohms, we should know that the unknown resistance was

$$R_3 = \tfrac{1}{10} \times 254 = 25{\cdot}4 \text{ ohms.}$$

Construction of Wheatstone's Bridge. The two coils R_1 and R_2 in the Wheatstone bridge arrangement are called the *ratio resistances*, or the *proportion coils*. They are kept constant during any one test, and are usually arranged so that their ratio has some convenient value, such as $\frac{1}{10}$, or 100, or 1,000, so as to save trouble in calculating. They are generally made up each of a short row of resistances of 1, 10, 100, and 1,000 ohms, set up at the back of the box, with the necessary plugs. By taking out the 10-ohm plug from R_1, and the 100-ohm plug from R_2, we can get the ratio of 10 : 100, which is the same as the ratio of 1 : 10. These four resistances (R_1, R_2, R_3, and R_4) are sometimes called the *arms* of the bridge. The ratio resistances are two of the arms, the unknown resistance to be measured is a third arm, while the fourth arm (R_4) consists simply of an ordinary set of resistance coils ready to be unplugged.



36. WHEATSTONE BRIDGE, POST OFFICE PATTERN

In practice the battery and the galvanometer are joined up all the time—one from A to C, the other from B to D; but these parts of the circuit are provided, as shown diagrammatically in 35, with keys (K_1 and K_2) to bring them into operation as required. The rule is that after any adjustment has been made by removing or inserting a plug, the battery key (K_1) is pressed down, and then the galvanometer key (K_2) is pressed down, while the galvanometer is observed to see whether balance has been attained.

Fig. 36 depicts a Wheatstone bridge of the Post Office pattern. The ratio resistances are the two sets of three coils each at the back of the box. The front two rows of coils are the adjustable resistance. The two keys are in front of all.

OBJECT DRAWING & PRACTICAL GEOMETRY

The Circle and Tangents. Representations of the Hexagonal and Octagonal Prisms, Showing Principles Involved

By WILLIAM R. COPE

PRACTICAL GEOMETRY

The definitions of a circle, diameter, radius, tangent, etc., have already been given in the Dictionary of Terms Used in Elementary Geometry (285), but the following facts should also be known :

i. The circumference of a circle is nearly $3\frac{1}{7}$, or, more accurately 3·14159 times its diameter. Archimedes discovered that the ratio lies between $\frac{22}{7}$ and $\frac{223}{71}$.

ii. A straight line which bisects a chord of a circle at right angles passes through the centre of the circle. [Euc. III. 1, Corollary.]

iii. The straight line which is drawn at right angles to the diameter of a circle, from its extremity, is a tangent. [Euc. III. 16, Corollary.]

iv. The angle in a semi-circle is a right angle. [Euc. III. 31.]

200. To Describe a Circle Passing Through Three Given Points, *A*, *B*, and *C*.. Join *AB* and *BC*. Bisect each by the perpendiculars intersecting at *D*. With *D* as centre, and *DA* or *DB* or *DC* as radius, describe the circle required.

This problem shows how the centre of a circle may be found by assuming any three points in its circumference, how to describe a circle about a given triangle, and how to describe an arc equal to a given arc with the same radius.

201. To Draw a Tangent to a Circle Through a Given Point, *A*, in its Circumference. Find the centre *B* and draw the radius *BA*, and produce it to *C*. Make *AC* equal to *AD* (any convenient distance). With centres *C* and *D*, and any radius, describe arcs intersecting at *E*. Draw *AE*, the required tangent.

202. To Draw a Tangent to a Circle Through a Given Point, *A*, Without it. Find the centre *B* of the circle, draw *BA*, and bisect it in *C*. With *C* as centre, and *CA* as radius, describe a semi-circle, cutting the circle in *D*. Draw *AD* the required tangent (Euc. III. 31). By describing a semi-circle on the other side of *AB*, another tangent may be drawn.

203. To Draw a Tangent to an Arc from a Given Point, *A*, in it, when the Centre of the Circle is Inaccessible. With *A* as centre and any convenient radius, describe a circle cutting the arc in *B* and *C*. With *B* and *C* as centres and any convenient radius, describe arcs intersecting in *D* and *E*. Draw *DE*. At *A* draw the tangent *AF* perpendicular to *DE*.

204. To Draw Two Tangents to a Circle to Meet at a Given Angle (say 66°). From the centre *A* draw any straight line *AB*. At any convenient point, *C* in *AB*, make an angle on each side of *AB* equal to *half* the given angle 66°. From *A* draw *AD* and *AE* perpendicular to *CD* and *CE* respectively, and cutting the circle in *F* and *G*. Through *F* and *G* draw *FH* parallel to *CD*, and *GH* parallel to *CE*.

205. To Draw a Tangent Common to Two Equal Circles. First, for *exterior* tangent. Join the centres *A* and *B*. At *A* and *B* erect perpendiculars *AC* and *BD* to the line *AB*. Draw the tangent through *C* and *D*.

Second, for *interior* tangent. Bisect *AB* in *E*. Upon *AE* describe a semi-circle, cutting one circle in *F*. Join *AF*, and through *B* draw *BG* parallel to *AF*. Draw the tangent through *FG*. Another interior and exterior tangent may be drawn, as indicated by dotted lines in **205**.

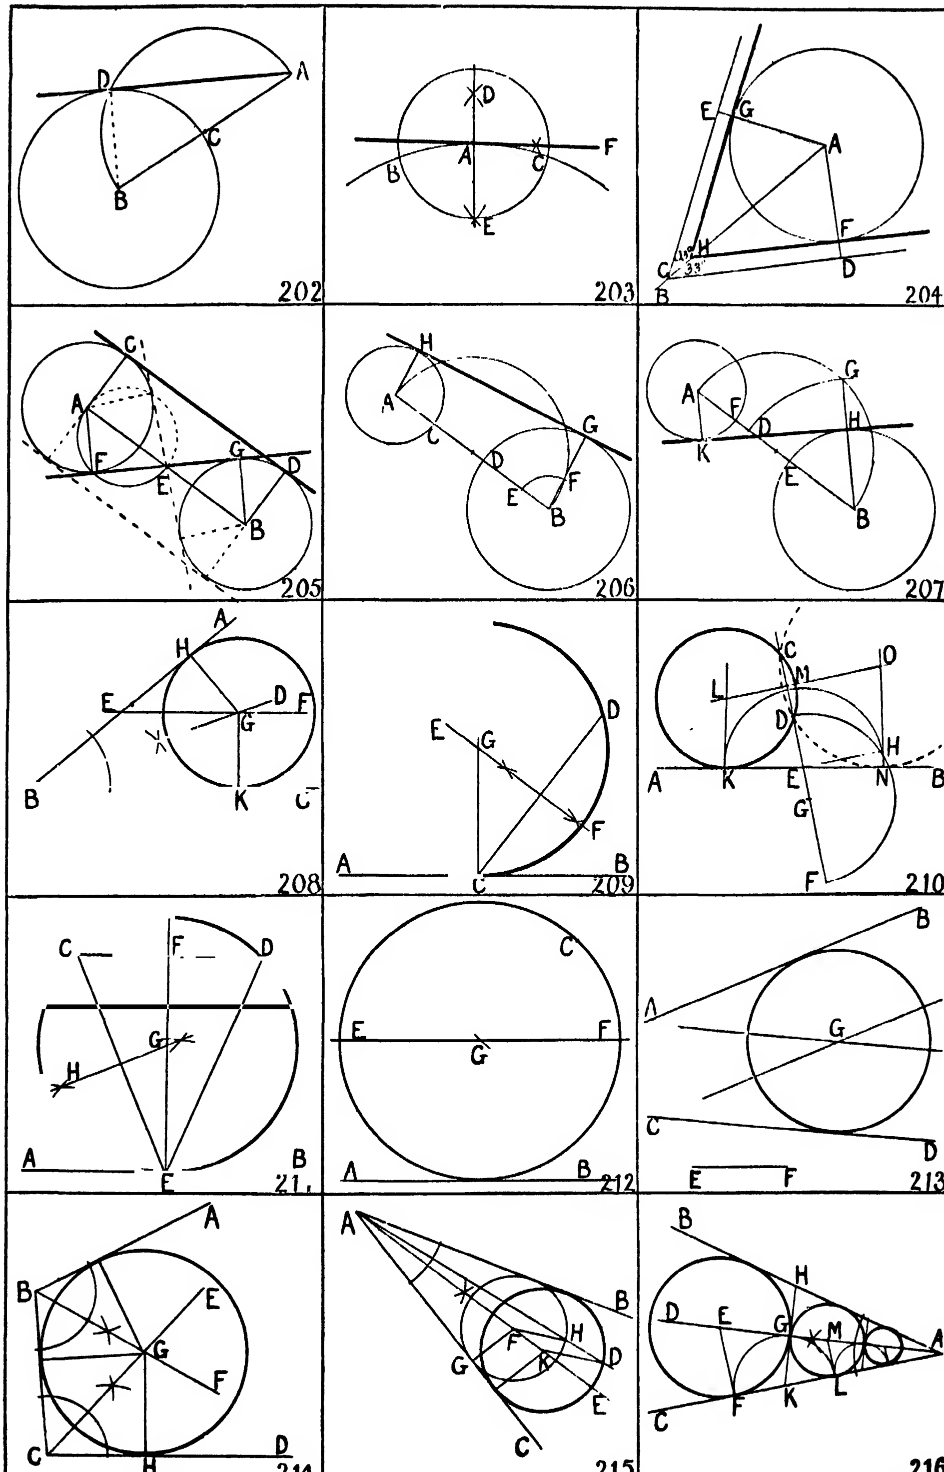
206. To Draw an Exterior Tangent to Two Unequal Circles. Join the centres *A* and *B*, and upon *AB* describe a semi-circle. Mark off *DE* equal to *AC*. With *B* as centre, and radius *BE* (the *difference* of the radii of the given circles), describe an arc cutting the semi-circle in *F* Through *F* draw *BG*, and through *A* draw *AH* parallel to *BG*. Draw the tangent *HG* through *H* and *G*.

207. To Draw an Interior Tangent to Two Unequal Circles. Join the centres *A* and *B*, and describe a semi-circle upon *AB*. Mark off *ED* equal to the radius *AF* of the small circle. With centre *B* and radius *BD* (the *sum* of the radii of the two given circles), describe an arc to cut the semi-circle in *G*. Draw *BG*, cutting the large circle's circumference in *H*, and through *A* draw *AK* (on the other side of *AB*) parallel to *BG*. Through *HK* draw the tangent required. Another could be drawn in this and problem **206** if the semi-circle is described on the other side of the line joining the centres, and proceeding as above.

208. To Inscribe in a Given Angle, *ABC*, a Circle of Given Radius (say ·4 in.). Bisect the angle *ABC* by the line *BD*, and draw *EF* parallel to *BC* and ·4 in. from it, intersecting *BD* in *G*. With *G* as centre and radius ·4 in., describe the circle touching the sides of the angle in *H* and *K*. The points of contact are found by drawing from *G*, *GK*, and *GH* perpendicular to *BC* and *BA* respectively.

209. To Describe a Circle Passing Through a Fixed Point *D*, and Touching a Given Straight Line *AB* in a Fixed Point *C*. Join *CD* and bisect it by the perpendicular *EF*. Through *C* draw *CG* perpendicular to *AB*, and cutting *EF* in *G*. With *G* as centre, and radius *GC*, describe the required circle.

210. To Describe a Circle Tangent to a Given Straight Line *AB* and Passing Through Two Fixed Points *C* and *D* without the Line. Join *CD*, and produce the line to cut *AB* in *E*, and make *EF* equal to *EC*. Bisect



PRACTICAL GEOMETRY: CIRCLES AND TANGENTS

DF in G and draw a semi-circle on DF with radius GF. At E erect a perpendicular to DF cutting the semicircle in H. Mark off EK from E on EA equal to EH. At K erect a perpendicular KL, and bisect CD in M by the perpendicular LM, which also cuts KL in L. With L as centre and radius LK draw the required circle. When the given line AB is not parallel to the line passing through the given points C and D, as in this case, *two circles* can be drawn, the centre of the second one being at O, the intersection of LM produced meeting the perpendicular from N through H.

211. TO DESCRIBE A CIRCLE TANGENT TO A GIVEN STRAIGHT LINE AB, AND PASSING THROUGH TWO FIXED POINTS C AND D, WHICH ARE EQUIDISTANT FROM THE GIVEN LINE. Join CD and bisect the line in F by the perpendicular FE cutting AB in E. Join CE or DE, and bisect it by the perpendicular GH cutting EF in G. With G as centre and radius GC describe the required circle.

212. TO DRAW A CIRCLE PASSING THROUGH A GIVEN POINT C, TOUCHING A GIVEN STRAIGHT LINE AB, AND HAVING A GIVEN RADIUS (SAY ¾ IN.). Draw a line EF parallel to AB and ¾ inch from it. With centre C and radius of ¾ inch intersect EF in G. With centre G and radius GC describe the circle.

213. TO DESCRIBE A CIRCLE OF A GIVEN RADIUS EF, TO TOUCH TWO CONVERGING LINES AB AND CD. At a distance equal to EF draw lines parallel to AB and CD intersecting at G. With G as centre and EF as radius describe the circle.

214. TO DESCRIBE A CIRCLE TOUCHING THREE GIVEN STRAIGHT LINES, AB, BC, AND CD, WHICH MAKE ANGLES WITH EACH OTHER. Bisect the angle DCB by the line CE, and the angle CBA by the line BF intersecting CE in G. From G draw perpendiculars to the three given lines, then either perpendicular (say GH), is the radius of the required circle, to be described with G as centre.

By this means a circle may be inscribed in a triangle.

215. TO DESCRIBE A CIRCLE WHICH SHALL TOUCH TWO GIVEN CONVERGING LINES AB AND AC, AND PASS THROUGH A FIXED POINT D BETWEEN THEM. Bisect the angle BAC by the line AE. Join D with A. From any point F in AE draw FG perpendicular to AC, and describe a circle touching AB and AC, and cutting AD in H. Join FH, and through D draw DK parallel to HF, cutting AE in K, which is the centre of the required circle, whose radius is KD.

216. TO DESCRIBE TWO OR MORE CIRCLES TOUCHING EACH OTHER AND TWO CONVERGING LINES AB AND AC. Bisect the angle BAC by the line AD. From any point E in AD draw a perpendicular to AB. With E as centre and EF as radius describe the circle touching AB and AC. Through G (the intersection of the circle with AD), draw HK tangential to the circle. Make KL equal to KF, and at L erect a perpendicular to AC, cutting AD in M, which is the centre of the next circle. Proceed in a similar manner for other circles as shown.

OBJECT DRAWING

For further practice in training the eye, and to show how to analyse an object to find a simple system of construction for drawing it correctly, we will explain the geometrical models called the hexagonal and octagonal prisms.

The Hexagonal Prism. This object has a regular hexagon for each of its ends, and oblongs for each of its other surfaces, but both shapes will, of course, vary infinitely *in appearance* according to the point of view from which they are seen. In **217** (which is the appearance of the prism when the student is directly opposite the end, but the object below the eye level), a system of construction lines (dotted), will be noticed—viz., AD, which is parallel to BC and EF; also BF and CE, *vertical* lines through B, F, and C, E, respectively. If GH is bisected in K, it will be seen that there are *four equal parts* along AD—viz., AG, GK, KH, and HD. These, of course, will not appear equal when the object is placed in such positions as represented in **218–224**.

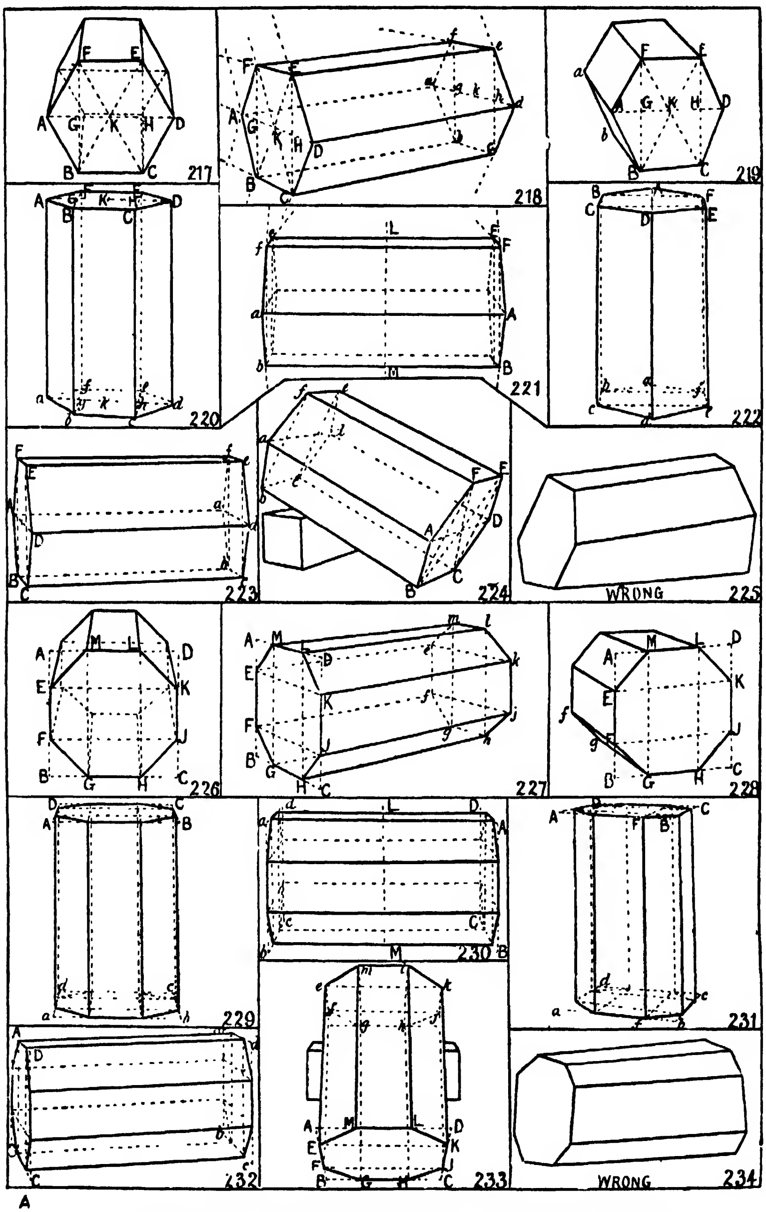
A view as shown in **218** is a good one from which to learn the method of drawing this object. Begin by determining the position of the corner C with relation to surrounding objects, then the direction of apparent slant of the edges BC and Cc and their respective apparent lengths. From B, C, and c draw vertical lines BF, CE, and ce, and determine the relative height of CE. Through E draw Ee converging with Cc, and EF with CB. Bisect CE in H, and BF in G. Through G and H draw AD converging with both CB and EF. Fix the position of K by drawing the diagonal BE. Make HD slightly—very slightly—longer than KH, and AG very slightly shorter than GK. The student should consider carefully why these are apparently different lengths, although in the object really the same.

Join AB, CD, DE, and FA, which will complete the apparent shape of the nearer end of the prism. Through D, E, and F draw lines converging with Cc. The line Ee intersecting with ce determines the height of ce. Through c draw dc converging *downwards* with DC, and through e draw de converging *upwards* with DE, and ef converging with EF, thus completing the drawing. The dotted lines at the further end are put in to show the full construction, and that again we have an instance of the further end being *apparently* slightly wider from a to d than from A to D at nearer end, but of course (owing to the convergence of Ee with Cc) the length of ce is shorter than CE. The foregoing method is somewhat mechanical, but if the student will make careful observation from the model, he will find the method an excellent proof of the accuracy, or otherwise, of his capacity of judging apparent lengths, etc., or of guiding or even compelling him to see the true apparent sizes, etc., of the object.

In **218** it should be observed that there are *four* directions of convergence: first Cc, Dd, Ee, and Ff converging to the right; second, CB, DA, EF and ef to the left; third, DC, FA,

and *dc* downwards to the left; and fourth, *DE*, *BA*, and *de* upwards to the left. Compare **218** with **225**, which is an incorrect drawing of the same view, showing the many usual errors made by beginners. Intelligent consideration should be given to ***why*** **225** is wrong in so many respects. The student should place the object as indicated in **218**, and make careful tests.

In **220** and **222** notice how *BA*, *DE*, and *ab* converge with one another; also *AF* with *CD* and *cd*; and *CB* with *EF* and *cb*. Fig. **221** shows the representation when the observer is directly opposite the dotted line *LM* and the object below the eye level. Notice the ***three*** sets of converging lines, and that *AB* is apparently smaller than *AF*, and *FE* much smaller still. In **219** observe the peculiar apparent shape of the face *ABba*. A view like that shown in **223** often gives considerable difficulty to beginners owing to very much foreshortening of the visible end, but it is constructed just like **218**. Fig. **224** is also rather difficult because of the tilting of the object, but keen observation of the model will enable the student to overcome such difficulties. Notice that the corners *E* and *F* are not *vertically* above *B* and *C* respectively, and that the construction lines *FB*, *EC*, *fb*, and *ec*, converge *downwards*. There are also, as in **218**, *four* directions of convergence.



A LESSON IN THE HEXAGONAL AND OCTAGONAL PRISMS

The Octagonal Prism. This model has a regular octagon at each end, but oblongs for each of its other surfaces, and both shapes may have an infinite number of appearances from different points of view. Fig. **226** is an end view, and shows how the regular octagon may be enclosed in a square *ABCD*. Then, if the relative sizes of *BG* and *GH* are determined the construction is easily made, for *AE*, *AM*, *BF*, *BG*, *CH*, *CJ*, *DK*, and *DL* are all equal in this view. Draw the construction lines as indicated.

Fig. **227** gives the usual system of guide lines. First determine the position and distance apart of the vertical lines *AB* and *CD*, and obtain the apparent height of *CD*. Draw *CB* and *DA* converging at the correct angle towards the left, thus completing the *apparent shape* of the skeleton square *ABCD*. Then by

careful comparison fix the positions of the points G, H, J, and K, and through each draw the respective construction lines, which at certain intersections give the positions of the corners of the octagon's *apparent shape*. Join these corners by the lines as shown. The completion of the drawing needs only care in observation as regards proportion and convergence of certain edges. Fig. **227** should be compared with the *incorrect* drawing shown in **234**, which contains very many errors usually made by careless observers. By intelligently criticising a bad drawing, and finding out why it is wrong, a student may sometimes learn more about the correct way it should be drawn than if he merely looked at a true representation of it; and, moreover, certain principles will be more deeply impressed upon his mind.

There is no need to give detailed explanations of the other representations of the octagonal prism as shown in **228-233**, as the drawings, with the dotted construction lines, speak for themselves as regards the method to be used in obtaining the various apparent shapes. The student must place the prism as indicated and *draw from the object*. Fig. **229** is the appearance when the student is opposite the front face but the object below the eye level. Fig. **230** gives the representation when viewed from a point opposite the line LM. Fig. **231** shows how the drawing should be made when seen from a point practically opposite the edge Ff. Fig. **232** shows the drawing of the difficult view when the near end is much foreshortened, while **233** is perhaps more difficult still, as the object is tilted upwards directly away from the observer, and particular attention should be given to the foreshortening of the near end, as well as the correct direction of convergence of certain edges.

OBJECTS DRAWN ON THE SAME PRINCIPLES AS THE HEXAGONAL AND OCTAGONAL PRISMS

Application of the Principles in this Lesson. It is sometimes difficult to obtain objects which are hexagonal or octagonal in shape, but drawings are given in **235-237**, **239**, and **240**. The objects should, in some cases, be placed lying over on their sides, so as to give further practice in drawing difficult views, and to give opportunities for improving the powers of observation to a higher level of excellence.

FORCE OF GRAVITY & ITS PHENOMENA

Specific Gravity and the Methods of its Determination. The Hydrometer and Specific Gravity Bottle. Equilibrium

Continued from page 664

By Dr. C. W. SALEEBY

The Force of Gravity. Before we consider the importance of gravitation in relation to the world as a whole we must pay some attention to the facts of gravitation as they are witnessed at the surface of the earth. The first thing to determine, if possible, is the intensity of the force of gravity at the earth's surface. We may measure this by measuring the acceleration which gravity produces on any body free to move under its action alone. The size of the body which we choose for observation is of no importance ; the same acceleration will be produced, as we saw in the first chapter, whether we choose a feather or a piece of lead. We have already stipulated that we are to observe the force of gravity alone, and therefore the resistance of the air must be excluded.

The student is sometimes puzzled to understand how it is that the acceleration is the same whether we choose a massive body or a "light" one. He argues that the force of gravity is proportional to the mass of the mutually attracting bodies ; if, therefore (he says), the mass of the body we study be increased, surely the resulting force will be greater, and therefore the body will fall with greater rapidity ? Now, until the last clause the student is quite right ; certainly, when we increase the mass of the body we examine, the force of gravity will be increased, but it is increased exactly in proportion to the work it has to do. In the case of the small body, it has to move only a small amount of matter ; in the case of the more massive body it has to move a much greater amount of matter, and its force is exactly proportional to the mass of matter in question ; hence the velocity which is imparted to the two bodies is precisely the same in both cases.

Now, it is possible to determine the intensity of gravity by allowing a body to fall and observing the velocity which it has gained in a second, but this method is exceedingly difficult, unless we are to be contented with a very rough estimate.

The method usually chosen depends upon the fact that the period of vibration or oscillation of a pendulum depends strictly upon the dimensions of the pendulum and the intensity of gravitation. Experiments with a pendulum are capable of great delicacy of observation.

The Value of Gravitation. The intensity of the force of gravitation—that is to say, of the earth's gravitation—is symbolised in physics by the letter "g." The value of "g" varies in different parts of the world, for the earth is not a true sphere, and thus different parts of its surface are at different distances from the centre. In the British Isles the value of "g," as determined by the direct method, by pendulum experiment, and by other means, is about 32·2 ft. per second per second. This phrase is somewhat confusing at first, the repetition of the phrase "per second" seems stupid, but in point of fact it is quite sensible. The assertion is that gravity produces during every second of its action an acceleration of 32·2 ft. per second—that is to say, its force is equal to an acceleration of 32·2 ft. per second per second. It need hardly be said that gravity does not act intermittently, but continuously ; we use the period of a second merely for convenience. The value of "g" at the Equator is less than 32·1 ; at the Poles it is about 32·25. This is equivalent to saying that a body is heavier at the Poles than at the Equator. The value of "g" at the Equator (more precisely represented by the figures 32·091) is less than the figure at the Poles in the first place because, owing to the shape of the earth (which is a sphere flattened at the Poles, or an oblate spheroid), a body at the Equator is more distant from the earth's centre than the same body at the Poles ; and, secondly, becau e of the centrifugal force at the Equator, due to the earth's rotation, which tends to hurl the body outwards, and so diminishes the apparent force of the earth's gravitation.

Specific Gravity. More for the sake of convenience than because the subject has a logical place here, we must now discuss the question of specific gravity. The word gravity is here used in a slightly different sense to that which has preceded. The word specific in this phrase is used in a sense frequently employed in physics, as for instance, in the phrase *specific heat*. This specific gravity is the representation of the amount of stuff contained in any substance in proportion to the volume of the substance taken ; hence it is merely a measurement of the massiveness of the substance. Most of us, in our day, have been puzzled by the question: Which is the heavier, a pound of feathers or a pound of lead ? Of course, by the definition, they are both of the same weight, but their density is very different ; and this gives us the key to the meaning of specific gravity, though of course no one would attempt to determine the specific gravity of feathers. For convenience, it is necessary to have some standard by which to compare all substances, and this standard is furnished us by water.

Distilled water is taken at the temperature of 4° C., which is its temperature of maximum density. If, now, we compare the weight of a given volume of any substance with the weight of an equal volume of water at this

temperature, we obtain a figure or ratio which is known as the specific gravity of the substance we are examining.

Density. Let us now consider *density*. The *absolute* density of a substance means the amount of matter contained in a unit volume of that substance. Hence, if "m" be the mass, and "v" the volume of the substance, then its density will be equal to $\frac{m}{v}$: but when we determine specific gravities, we are determining *relative* densities. But it is sufficient for our purpose to make only relative measurements, though what we really want to get at is an absolute measurement of the actual amount of stuff the substance contains in a given space or volume. The reason why the relative measurement suffices is that, as Newton proved, the mass of a substance, or the quantity of matter in it, is proportional to its weight; hence, if we take the weight of a unit mass of water at its maximum density (*viz.*, when it has the temperature above stated) as unit density, then the specific gravity of the substance will be identical with its density. This proposition may be stated in abstract terms thus. The relative specific gravity of any substance is an accurate measure of its absolute specific gravity, and thus of its density. All these propositions depend upon the Newtonian proof that weight is proportional to mass.

Determination of Specific Gravity. This offers no difficulties in the case of regularly-shaped bodies which we can weigh by the usual means—the balance or the spring. But this method will not suffice unless the body is of such a shape that we are also able accurately to determine its volume. When a body is of an irregular shape, it is impossible by direct measurement to ascertain its volume—that is, the amount of space it occupies. It was the great discovery of Archimedes that enabled us to ascertain without difficulty the volume of an irregular body by immersing it in water, and observing the degree to which the water rises. This is what he did with Hiero's crown. Not only so, a body which is wholly immersed in water loses a part of its weight, which is exactly equal to the weight of the water which it displaces; hence, by weighing the amount of displaced water we readily ascertain the weight of water equal in volume to any body.

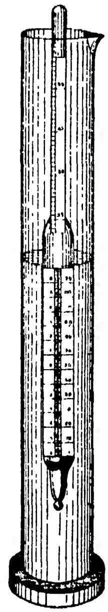
The Hydrometer. The instrument for obtaining the specific gravity of a liquid is the *hydrometer*. The principle of this instrument is known as "Archimedes' principle," which may be thus stated. *When a body is wholly or partly immersed in a fluid, it loses in weight an amount equal to the weight of the displaced fluid.* The common hydrometer consists of a weighted and graduated glass tube, which is suspended in the liquid to be tested, and the depth to which it sinks or the level at which it floats indicates the specific gravity of the liquid. Upon the stem of the hydrometer there is marked the point to which it would sink in distilled water at 4° C. If the liquid be heavier than water, the hydrometer will float at a higher level, and *vice versâ*. A great improvement is now effected in the common hydrometer by adding to it a thermometer in the stem. Thus the reading which it affords is a reading of the specific gravity of the liquid at the temperature simultaneously indicated by the thermometer. This is an important matter, since the specific gravity of a liquid varies with its temperature. As a rule, the addition of heat to a liquid increases its volume, or rather, the ratio of its volume to its mass—that is to say, it lowers its specific gravity.

Density of Water. A remarkable exception to this rule is furnished by water. When heat is added to water, at, say, 1° C. (just above freezing-point), the water does not expand, but contracts; it goes on contracting until the temperature of 4° C. is reached. If the temperature be raised beyond this point, the water starts to expand again, thus behaving like all other liquids beyond this point. This peculiar property of water—in virtue of which ice is lighter than water of 1, 2, 3, or 4° C.—is one of the most important physical properties of this exceedingly important substance. If water behaved according to the ordinary rule, ice would naturally be heavier than liquid water of any temperature, and would therefore sink, whereas, as we know, it floats. This is very fortunate, for otherwise the ice formed in cold weather would sink to the bottom of lakes or seas, which would thus be gradually piled up winter after winter by successive layers of ice; but in virtue of the fact that ice, in defiance of the general rule, has a lower specific gravity than water of a higher temperature than its own, it floats, and thus the sun's rays—when their strength returns—are able to melt it. Human life would be impossible were it not for this one property of water alone.

The hydrometer is very widely used in various forms. It is constantly employed by the brewer and the exciseman, who usually call it an alcoholometer, since their purpose is to ascertain the strength of a spirit. When it is used to ascertain the quality of milk, it is called a lactometer. The greater the amount of solid matter dissolved in the milk, the greater is its specific gravity. Similarly, the physician desires to test, by means of the hydrometer, the specific gravity of many of the bodily fluids.

Specific Gravity Bottle. But there are other cases where other means of ascertaining the specific gravity of a substance have to be employed. There is, for instance, what is called the *specific gravity bottle*, sometimes used for liquids, sometimes for solids. The bottle is constructed to hold precisely a thousand grains of water at the temperature now familiar; and the stopper of the bottle has a hole through which the contents can ooze when the stopper is driven home. Supposing, now, we wish to ascertain the specific gravity of small shot, we take a given weight of the shot and insert it in such a bottle already filled with water. The amount of water that escapes from the bottle in order to

make room for the shot is equal in volume to the shot inserted. We have already weighed the shot, and we now weigh the water displaced by it. The ratio of the first weight to the second is the specific gravity of the shot. Similarly, we may ascertain the specific gravity of a fluid which is lighter than water. If, for instance, we find that we can squeeze only 715 grains of ether into a bottle which will hold 1,000 grains of water at the same temperature, we are able to state that the specific gravity of ether is ·715, the specific gravity of water being taken as 1. For convenience we usually use 1,000 instead of 1, and adapt our other measurements to this figure; thus, the specific gravity of human blood is 1055, of ether 715, and so forth. [See below.]



HYDRO-METER

In order to obtain perfect results it would be obviously necessary to have constant temperature, and to have the pressure of the various gases within the globe always the same.

Here follows a list of some important specific gravities:

Solids.

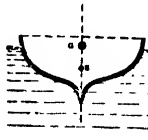
Platinum (rolled)	22·1	Diamonds ..	3·5
Gold	19·3	Marble ..	2·8
Lead	11·4	Aluminium	2·7
Silver	10·5	Ice	0·9
Iron (wrought)	7·8	Potassium ..	0·9
„ (cast) ..	7·2	Lithium ..	0·6
Tin	7·3	Cork ..	0·2

Liquids.

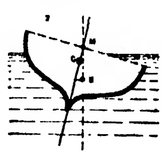
Mercury ..	13·59	Sea water ..	1·03
Sulphuric acid	1·84	Petroleum ..	0·84
Blood	1·05	Alcohol ..	0·79
Milk	1·03	Ether ..	0·71

In the "Encyclopædia Britannica," Vol. 12, page 541, the reader will find several hundreds of precise measurements of the densities of various bodies.

Specific Gravity of Gases. Lastly, as to specific gravity of gases. The ascertaining of this is a matter of more difficulty, but it follows the same principles. Our business is to determine the relative weight of the gas in question and of air; much better, however, is to take the lightest known gas—*viz.*, hydrogen—instead of air as our standard of comparison for gases. Relatively to hydrogen, the specific gravity of air is about 14·4, and of oxygen 16. One method of finding the specific gravity of a gas may be quoted. It consists in successive weighings of a brass globe to which an air pump can be attached. The globe is weighed when all the air has been extracted from it; it is weighed when full of air, and when full of the gas we are examining. Thus we ascertain the weight of the air and the weight of the gas, and thus the specific gravity. If we are using hydrogen as our unit, we will fill the globe, not with air, but with hydrogen.



1



2

Centre of Gravity. This is another term which must be dealt with here, though its treatment involves an interruption in our study of gravitation in general. The term *centre of gravity* is itself open to criticism. A much more correct term is centre of mass or centre of inertia. It may be defined as that point about which two or more particles are in equilibrium. We have already discussed the question of equilibrium, and seen that it depends upon an equality in the moments of the forces. Now in every body there is a point about which it will balance, and this point we call its centre of gravity. Some bodies are such that their centre of gravity is really central, and these are called *centrobaric* bodies. In the case of a sphere, for instance, whether solid or hollow, the force of the earth's gravity acts upon it, no matter in what position the sphere be placed, just as if all the matter of the sphere were condensed at its centre; and that centre is its centre of gravity. A rectangular plate, again, will be balanced by a thread supporting it at the point where its two diagonals intersect one another; but in the case of irregular bodies the position of the centre of gravity cannot be so readily ascertained.

Now, we have said that the centre of gravity is the point where the whole weight of the substance may be considered as massed; the body will be in equilibrium if this point is supported. Let us, then, pick up an irregularly shaped plate of which we desire to ascertain the centre of gravity. We hang it up by a string attached to it at one corner, and we find that it assumes a certain position. If we prolong downwards to the earth the line of the string, we may be certain that the centre of gravity will lie in that line, for we have said that the centre of gravity is the point around which the whole substance of the body might be supposed to be massed, and upon which the earth's attraction acts; hence, the centre of gravity must lie immediately under the supporting string since then we will have the earth's attraction acting downwards and the tension of the string acting upwards in the same straight line, the two forces neutralising one another so that the plate hangs steadily or in equilibrium. If, now, the plate be hung up at another point and a line be drawn upon it in continuance of the line of string, the centre of gravity must correspond to the only point which this line and the previous one have in common—*viz.*, the point where they cut one another.

Equilibrium. We are now in a position to add somewhat to the remarks already made on the subject of equilibrium. We said that a body is in a state of stable equilibrium when it tends to return to its original position after the temporary application of a disturbing force, whereas it is in a state of unstable equilibrium when the temporary application of any new

force causes a permanent change in its position. We also said that the conditions of stable equilibrium are satisfied when a vertical line dropped from the centre of gravity of the body in question falls within the area of ground formed by joining all the points at which the body is supported. But having considered the question of gravity at further length, we are now in a position to state the law which determines the difference between unstable and stable equilibrium, and which also brings the fact of neutral equilibrium into relation with them.

We may say that a body is in stable equilibrium when any displacing force tends to raise the centre of gravity. It is in unstable equilibrium when a disturbing force tends to lower it. This law is intelligible now, but it would not have been so before, for we have come to regard the centre of gravity as that point at which the whole weight of the body may be supposed to be concentrated. Hence the force that tends to raise the centre of gravity is doing work against gravitation, and, when the force ceases to act, gravitation (which never ceases to act) pulls the body back to its original position; hence its equilibrium is stable. On the contrary, the displacement which lowers the centre of gravity is a displacement which gravitation favours; and when the displacing force is removed the body shows no tendency to return to its former position; there is no force to make it do so.

The Illustration of the Egg. Let us take the illustration of the egg. The egg may be balanced for a moment on its point, but its equilibrium is unstable because any displacement involves a lowering of its centre of gravity. If, now, the egg be rested on its side we may consider the case of displacing forces applied to it in two directions. The egg may be rolled along the table by a push applied to it at one side. When friction and the resistance of the air have arrested its movement, the egg will come to rest. It is in a state of neutral equilibrium, for, assuming that the yolk of the egg is centrally situated, the centre of gravity of the egg has neither been raised nor lowered by this displacing force. If, however, we attempt to tilt up the egg by applying the finger at one end, we find that so far as such a force is concerned the egg is in a state of stable equilibrium, for now we are attempting to raise its centre of gravity, and as soon as the displacing force is removed the egg returns, after a few oscillations, to that position of stable equilibrium in which its centre of gravity is as low as possible—that is to say, the position the retention of which is favoured by the whole force of gravitation.

Equilibrium in Boats and Ships. This principle is not infrequently a matter of life and death. Let us take, for instance, the case of accidents in a rowing boat. Why should the stability of a boat be affected when one of its occupants rises? Why should fatal accidents often occur when two of them rise at once? The answer is that the centre of gravity of the whole system, boat and contents, is raised, and it is of course raised higher when two of the occupants are standing than when one only is standing. The higher the centre of gravity of the system, the more likely is a slight oscillation or displacement to swamp it.

Let us now take the case of a floating ship. It has its centre of gravity; it also has what is known as the centre of buoyancy*, which is the centre of gravity of the water which is displaced by the ship. The weight of this displaced water is one of the forces acting upon the ship, and it acts upon the ship at the centre of buoyancy. Now, when the ship is floating on an even keel, its centre of gravity is above its centre of buoyancy, but the two are in the same vertical line, which is the middle line of the ship [1].

Now, when the ship is tilted [2] its centre of buoyancy is shifted to one side of the centre of gravity. The weight of the ship acts still through the centre of gravity [G], whilst the re-active pressure or buoyancy of the displaced water acts vertically upwards through the new centre of buoyancy [B], in a line which cuts the middle line of the ship at the point M; this point is called the *metacentre*. The essential for the stability of the vessel is that the metacentre be above the centre of gravity; so long as this is so the weight of the ship and the buoyancy form what is called a *couple*, which tends to right the vessel. If the metacentre were below the centre of gravity, the couple would tend still further to roll the vessel over Hence, a ship must be so constructed that when she is displaced the centre of buoyancy comes to be at some distance from the middle line, and the metacentre well above the centre of gravity. The object of putting ballast in a vessel is to lower the centre of gravity. The removal of the ballast is thus equivalent in result to standing up in a rowing boat.

* This is situated, of course, nowhere in the displaced water, but at some point in the ship.

RAILWAY AND MINE SURVEYING

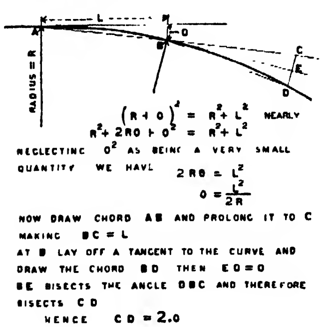
Setting out Curves and Sidewidths. Explanation of the Use of the Clinometer and Circumferentor

Continued from page 712

By Professor HENRY ROBINSON

IT is now proposed to explain a few methods of surveying more or less applicable to particular branches of work.

Railway Surveying. The details necessary for preparing plans and sections of a proposed railway line in this country are dealt with in another course, on PARLIAMENTARY SURVEYING. The subject of railway surveying is itself a large one, embracing as it does the preliminary survey, or reconnaissance, for a railway in unexplored countries, where the maps, if any exist, are inferior, to making the final survey and setting out the line. The positions of the centre lines with regard to one another, and taking the levels in order to fix the gradients of the line, are carried out by the methods already explained. It must be assumed for the purposes of this course that the general route is determined, and that it is necessary only to fix the position of the centre line of the railway, to fill in the curves, and to peg out the positions where the banks and cuttings will appear on the surface of the ground.



50. CHAIN AND OFFSET METHOD

In this country, where the Ordnance maps are good, and contour lines are shown, a sufficient approximation as to the general route can very often be made from them, with perhaps a few levels at the most important points, care being taken to interfere as little as possible with existing works. The main point is to get the most direct route with as little cutting, embankment or tunnelling as possible, without sacrificing directness from point to point. If cutting be necessary it should as nearly as possible equalise the stuff required for embankment. The steepness of the gradients and the sharpness of the curves must depend to a great extent on the purposes for which the line is to be employed.

In the event of the ends of two lines having to be joined by curves, one of the three following methods may be employed:

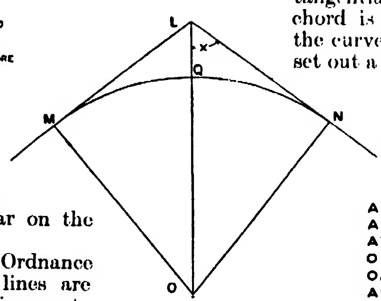
1. With chains and offsets
2. With theodolite and chain.
3. With two theodolites.

Chain and Offset Method. One method with chain and offsets is sufficient, and is shown by **50**. The point at which the curve commences is called the *tangent point*, and is shown at A. A length, L, is set off along the tangent line, and an offset O (calculated as shown in the illustration), is measured, meeting the line AB at B. AB is made equal to L. The method of fixing the point B is to pin down one end of the chain at A, and one end of the offset at the end of L. The chain is then swung away until the other end of the offset and the chain, when quite tight, coincide, which fixes the point B, or the first point on the curve.

The bottom part of the figure shows how all succeeding offsets are taken, and that the second and all following offsets are twice the first one.

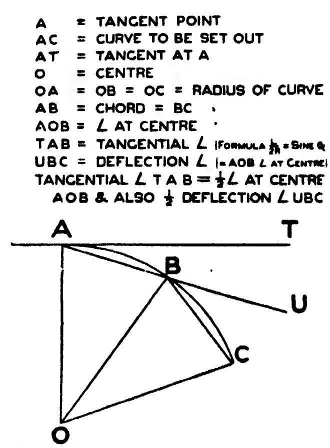
Theodolite and Chain Method. The simple method of ranging railway curves by means of *tangential angles*, set out by the theodolite and chain, will now be treated.

The illustration [**52**] gives the relations between the various factors in calculating the tangential angle. The length of the chord is called L and the radius of the curve R. When it is required to set out a curve of any particular radius between two straight lines it is necessary to find first the two tangent points at which the curve starts. The production of these two straight lines results in their intersecting at a point where the *angle of intersection* may be observed.



51. SECOND METHOD

Referring to **51**, LM and LN are the tangent lines which intersect at



52. TRIGONOMETRICAL RELATIONS

LENGTH OF TANGENT

$\angle MLN = \angle$ OF INTERSECTION

$\angle MLO = \frac{1}{2}\angle$ „ „ $= x$

$\frac{OM}{ML} = \text{TAN.}\,x \qquad OM = r$

$ML = $ TAN.

$\therefore$ LENGTH OF TAN. $ML = \frac{r}{\text{TAN.}\,x}$ OR $r \cot x$

DISTANCE FROM POINT OF INTERSECTION TO MIDDLE OF CURVE = LQ

$LQ = LO - OQ \qquad \frac{LO}{OM} = \text{CO-SEC}\ x$

$\therefore LO = OM \operatorname{cosec} x$

$= r \operatorname{cosec} x$

HENCE $LQ = r \operatorname{cosec} x - r$

$= r(\operatorname{cosec} x - 1)$

53. LENGTH OF TANGENT, ETC.

the point L. M and N are the tangent points, and MLN the angle of intersection. MQN is the curve to be set out. OM = ON = radius of the curve. The method of calculating the lengths of the lines LM and LN is shown in 53.

The calculated length of the tangent line is set out each way from the point of intersection L [51], and stakes are driven in at the tangent points M and N. Next we must find Q [51]. The method of calculating this is shown on the lower part of 53. This point is set out with the theodolite by bisecting the intersection angle, and ranging it in with the instrument. It is usual to set out part of the curve from each tangent point to minimise errors of lateral deviation, pegs being put in at equal intervals all along the curve or centre line of the railway, say at every chain. If these pegs are kept at the even chains it follows naturally that the tangent point rarely coincides with one of the chain pegs, and therefore the *first peg* at each end is only a fraction of a chain from the tangent point. It therefore becomes necessary to calculate the length of the curve in order to make the pegging out from both ends coincide in closing in the curve. The method of doing this is shown in 54, and serves as an excellent check on the work.

It now remains to be seen how these various factors are set out. The theodolite, after being used at L for finding the intersection angle, and the middle point of the curve, is removed to M or N, and after being set up, is sighted on to L, and the first tangential angle is taken. One end of the chain is then fixed at the tangent point, and the other end is moved until the cross hairs of the theodolite cut the peg held at the end, which gives the first point on the curve. The next angle is then set out equal to twice the first, one end of the chain is held at the peg just fixed, and the second point is found.

It often happens that some obstacle, such as a wood or hill, prevents the whole of a curve being set out from the tangent points. Fig. 55 shows how to range a new tangent point from any point on the curve.

LENGTH OF CURVE MQN = l

RADIUS = R

$\angle$ OF INTERSECTION $= 2x$

CIRCUMFERENCE OF A CIRCLE $= 2\pi r$

„ „ QUADRANT $= \frac{1}{4} \times 2\pi r = \frac{\pi r}{2}$

i.e. LENGTH OF CURVE SUBTENDING $\angle$ OF $90° = \frac{\pi r}{2}$

$\angle MON$ SUBTENDED BY CURVE $MQN = 180° - MLN$

„ „ „ „ $= 180° - 2x$

THEN

$l : \frac{\pi r}{2} :: (180° - 2x) : 90°$

$l = \frac{\pi r}{2} \times \left(\frac{180° - 2x}{90°}\right)$

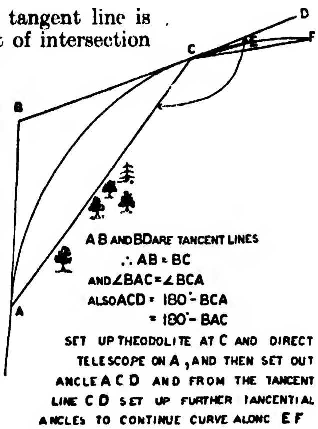
$l = \pi r \times \left(\frac{90° - x}{90°}\right)$ AND $90° = 5400'$

$\therefore l = \frac{\pi r\,(5400' - x)}{5400'}$ BUT $\frac{\pi}{5400} = \cdot 000582$

HENCE $l = \cdot 000582 \times r\,(5400 - x)$

x BEING IN MINUTES

54. LENGTH OF CURVE

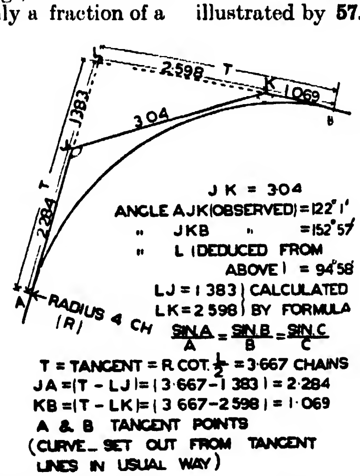


55. PASSING OBSTACLES

The point of intersection is frequently not accessible, so that its position has to be calculated trigonometrically, and the tangents determined in the same manner. Fig. 56 shows how this may be done.

The directions of the tangent lines are known. Any two points, J and K, are chosen, and the distance chained. The distances JA and KB are calculated, as shown in the illustration. They are then chained, and the tangent points A and B fixed. The curve is then set out as explained previously.

Method by Two Theodolites. The third method of setting out curves by two theodolites, one set up at each tangent point, is illustrated by 57.



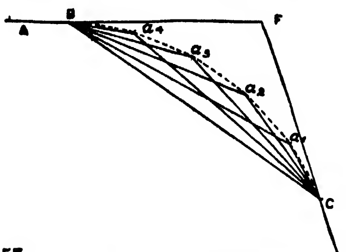
56. INTERSECTION POINT INACCESSIBLE

B and C are the tangent points. The telescope of the theodolite at B is directed to C, and the tangential angles set out from BC, while the tangential angles are set out from CF by the theodolite at C. The intersection of these angles fixes the various points on the curve, as A_1, A_2, etc.

After pegging-out the centre line of a railway, the "side widths," as they are termed, have to be set out to indicate the ground that will be occupied by banks or cuttings when the line has been constructed, which will depend on the depth of the cutting, or the height of the bank, and the ratio of slopes of the sides.

Fig. 58 shows a practical method of doing this. The point C is the centre of this particular section. It is required to find out where the side slopes of the cutting will cut

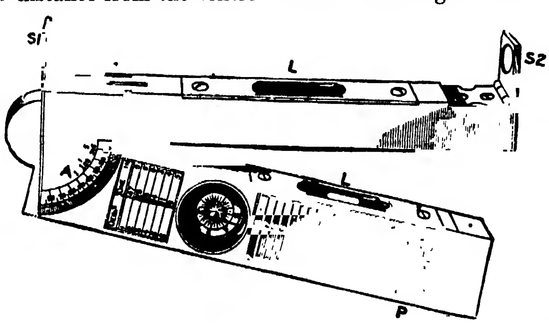
the surface of the ground. First assume the ground to be horizontal as HC, and compute the half width. In the illustration this would be 18 ft. for the half formation width (AB), and 40 ft. for the slopes (for a depth of 20 ft. with slopes of two to one), making altogether 58 ft. It is obvious that, for sloping ground, this width will be greater on one side than on the other. Taking the lower side, an approximate point is chosen and fixed by measuring down the slope some distance less than 58 ft. The difference of level of this point and the centre point C is found. This difference of level multiplied by the ratio of slopes (2 to 1) will give a figure to be subtracted from the calculated 58 ft. to give another trial point. One or two trials will generally suffice. In the case of the uphill side, the amount found by the difference of level of C and some chosen point greater than 58, multiplied by the ratio of the slopes, must be added to 58.



57. TWO THEODOLITE METHOD

As an example, let us suppose that the staff had been held at E, the correct point, and that the distance measured was 54 ft; then the difference of level between C and E was 2 ft. This multiplied by the ratio of slopes (2 to 1) = 4 and 58 − 4 = 54, the point already chosen. In the case of embankments the exact opposite would occur, as the toe of the bank would cut the uphill side at a less distance from the centre line than the downhill side. An instrument which is useful for determining the slope of the ground is the Clinometer.

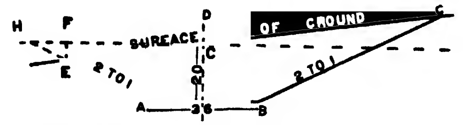
Clinometer. This useful hand instrument [59] is for determining the slope of the ground or the angle it makes with the horizon. From the illustration it will be seen to consist of two arms jointed at one end and provided with spirit-levels (L), the top arm having "sights" (S1 and S2), through which the inclination is observed. The value of the inclination in degrees is taken from the graduated scale (A), and the gradient is directly obtained from a table (P) marked on the side of the lower arm.*



59. CLINOMETER

* For example, a reading on the scale A = 6° the gradient will be found from the table (P) to be 1 in 9·5. On the reverse side of the lower arm is a table giving the rise in inches per yard for angles up to 45°.

Mine Surveying. In carrying out surveys underground a few special arrangements have to be adopted to ensure that accuracy which is of the greatest importance. The survey is necessary, not only as a record of existing works, but also to enable extensions of the headings and workings to be planned with regard to the minerals to be mined. In mines in this country the chain of 66 ft. is usually employed for measuring the survey lines, which are fixed by means of traversing. In making underground surveys by traversing with the magnetic needle, care must be taken that no disturbance of the needle is caused by the proximity of metalliferous substances, either the ore to be extracted, or rails, trolley lines, etc., in the workings. Where such causes of disturbance exist, the lines have to be set out by angular observation rather than by magnetic bearings. An instrument that has been employed largely for underground traversing is the circumferentor, or miner's dial.



58. SETTING OUT ON SIDELONG GROUND

Circumferentor. Fig. 60 is an illustration of a circumferentor, or miner's dial, manufactured by Messrs. Troughton and Simms. In the simplest forms the telescope and the vertical limb are omitted, and two vertical vanes, similar to the prismatic compass, are employed instead. The instrument illustrated is capable of being levelled by the screws (L), and the bearings of the lines are read by means of a vernier in the dial (D), which has also a magnetic needle enclosed in it. Vertical angles are read on the limb by raising or depressing the telescope.

Lighting the Lines. Owing to the surveys having to be carried out in the dark, various arrangements have to be adopted for lighting the lines. For long survey lines, a candle flame is the best object to sight, but care must be taken to shield it from draughts. When, however, the lines are short, sights are taken to a plumb-line suspended from the station point. In collieries where the risk of explosion from fire-damp has to be considered, the safety-lamp is employed, and should be supported on a tripod, which can be levelled in order to get it horizontal. In many cases the traffic of trolleys to and from the faces in tunnelling renders it desirable to mark

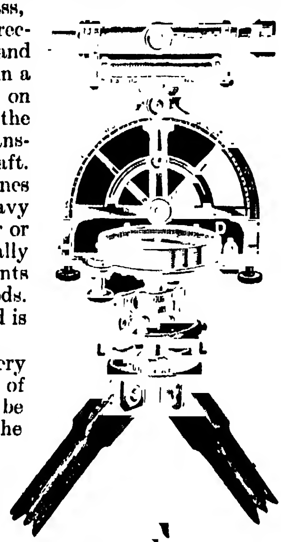
all station points used for the alignment on the roof or overhead timbering, and to suspend plumb-lines therefrom, so that a line can be produced or a sight taken with a theodolite or circumferentor.

61.

FIXING STATIONS UNDERGROUND

Garforth's Method. Fig. 61 shows a device for rapidly suspending a line and adjusting its position precisely under the station point, and was the invention of Mr. Garforth. The plumb-bob is suspended from a terminal carried on gimbals, like a ship's compass, and arranged to move in two directions when operated by rack and pinion gear. The terminal ends in a point, which is directed upwards on to the station mark. One of the most difficult operations is the transference of a base-line down a shaft. The method of using two plumb-lines of steel or brass wire, with heavy weights hanging into tubs of water or oil to retard vibration, is usually adopted. The vertical measurements are made with steel tapes or rods. In inclined shafts the rod method is preferable.

When using a steel tape for very accurate work, the temperature of the surrounding air should be observed, and also the tension of the tape. A spring tension dynamometer attached to one end of the tape affords an easy way of ensuring the same tension at each measurement.



60. CIRCUMFERENTOR

Transferring Stations Below Ground. Fig. 62 shows one method of getting a station from the surface, below ground. By this method a board is firmly nailed to the shaft, and is provided with an iron plate and clips, which are clamped to the board. The plate can be gently moved under the clips by tapping with a hammer. The plumb-line is suspended over the plate, as shown, and its position fixed by ranging it in line by means of a theodolite set behind it, and adjusted on to a point on the line above ground, which it is required to produce below ground. A similar arrangement is fixed on the other side of the shaft, and the line thus set out can be produced below ground. Great care is necessary in producing these lines, on account of the shortness of the base available. In the event of there being two shafts connected together, a plumb-line can be taken down each, and the station at the bottom fixed. They can then be connected together by traversing both below and above ground. When taking sights to a suspended plumb-line, it is necessary that all vibration should have ceased. The sight must be kept on the wire for some length of time, in order to be certain that the point is the correct one and not some other than the vertical taken up by the very slow vibration of the wire that is nearly imperceptible except by long observation. Iron plumb-bobs have been known to be drawn by induced magnetism in iron in the vicinity, and to make the line leave its vertical position. This can be prevented by using brass bobs.

As an instance showing how errors may occur through the transference of lines down deep shafts, the following is an extract from an article in the "Engineering and Mining Journal" of April, 1902, on the divergence of long plumb-lines. "The plumb-lines were used to transfer an azimuth from the surface to an underground level, and were 4,250 feet in length. They consisted of No. 24 piano wire, and the bobs were of cast iron and weighed 50 lb. each, the latter being immersed in pails of cylinder oil for the purpose of retarding vibration. Measurements between their upper and lower extremities showed a divergence of 11 ft. After a very thorough investigation, it was found that this displacement was simply due to air-currents. For the above reasons some engineers prefer to employ a form of transit theodolite specially made for this purpose."

The scales adopted for plotting mine surveys will depend to some extent on the size of the property. A very useful map can be prepared with a scale of two chains to the inch for small mines, and for large properties it will be found that 3 or 4 chains to the inch may have to be the scale adopted

All the underground observations should be carefully recorded on the plan of the workings as the work proceeds. If this precaution be neglected, difficulties may arise later on, when such records would have been of great service.

TONIC SOL-FA SYSTEM

Various Musical Notations. Principles on which the Tonic Sol-fa System is based. Use of the Standard Scale. The Modulator

Continued from page 634

By J. CUTHBERT HADDEN

THE Staff notation of music is the universal notation, the notation of the whole musical world. As such, it can never be superseded. Like the doctor's Latin prescription, it may be read with equal facility in England or Italy, in Germany or Spain. But other musical notations have been devised, just as "universal languages" have been evolved in alleviation of the confusion of Babel. Rousseau, the French author and critic, suggested, but afterwards discarded, a notation in which the notes of the scale were indicated by Arabic numerals. The same principle is the leading feature of the Chevé system, now largely used in France; and in certain essentials the Tonic Sol-fa notation of letters, the subject of the present lessons, corresponds with both. It is practically the only notation (apart from the Staff, of course) which demands to be considered seriously as a real and live factor in musical education, though its use is confined almost solely to England and English-speaking countries. It has a great and growing "literature" of its own; more than a million and a half of children are learning to sing from it in British primary schools, and choral societies and church choirs all over the country owe to it almost their very existence.

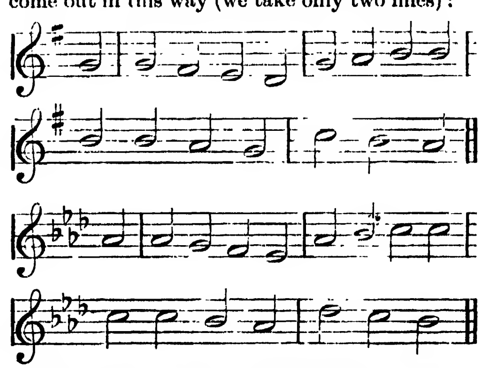
The Founder of Tonic Sol-fa. From his interest in school and congregational singing the Rev. John Curwen was led to take up the subject of teaching to sing at sight. Miss Glover, a teacher at Norwich, had already succeeded in removing from music something of the mystery of sharps and flats, minims and crotchets, and had formed out of her *Do, Re, Mi* diagram a kind of primitive letter notation which the charity children among whom she laboured found no difficulty in reading. Her method of sol-faing differed entirely from that which Mainzer and Hullah taught in their popular classes. These masters adopted the common French system of making the sol-fa syllables only substitute names for the fixed notes C, D, E, F, G, A, B. Miss Glover, on the other hand, followed the scientific usage of England, which makes *Doh* always the key-note, whatever the absolute pitch of that note may be.

Her plan, briefly stated, was to teach the thing music, apart from its signs and names, and to delay the introduction to the accepted mode of writing it until the pupil had obtained a mastery of the thing itself. Mr. Curwen had already come to see the shallowness of the parrot method of teaching to sing, and had been trying unsuccessfully to give permanence to his Sunday-school work by imparting to the children a knowledge of crotchets and quavers, clefs, flats, and sharps, etc. These things, he speedily discovered, were too abstruse for young minds—too abstruse even for the great majority of those who desired to sing yet could not be brought to do the thinking necessary to secure their object in the ordinary way. What was needed was a notation which a child might understand—a notation which a child could sing from as readily as he might read his school primer. Mr. Curwen had been looking for just such a notation, and when Miss Glover's method was brought under his notice he hailed it with delight as being the very thing he desired—easy to teach and easy to learn. As yet, however, it was only a crude idea. It required many modifications and additions—required, above all, to be systematised—in order to perfect it as a notation, as a method of teaching music. Mr. Curwen set himself enthusiastically to the work. He devoted, in fact, the remainder of his life to it, and the result was the Tonic Sol-fa notation and method as we know them to-day.

In proceeding to a study of the Sol-fa notation, we are brought at once face to face with its essential principle. That principle is that there is in reality but one scale in music; that to singers "one key is the same as another." Singers, let it be insisted, were Mr. Curwen's first consideration. His notation was specially devised for them, and although those who learn it can readily play from it, the interests of the player have never been put by the heads of the system alongside the interests of the singer.

Well, to the Tonic Sol-fa singer all keys, we repeat, are alike. Whether he is singing in the key of F or in the key of E, his scale is the same. It is always: Doh, Ray, Me, Fah, Soh, Lah, Te.

Doh always represents the key-note, no matter what may be the key of the music. To emphasise this fact, let us borrow for once an illustration from the Staff notation. Suppose we wanted to write the "Old Hundredth," first in the key of G and then in the key of A flat. It would come out in this way (we take only two lines):



Here, though the tune is identically the same in both examples, the notes have in each case

an entirely different position on the stave; moreover, they re affected, in the one case by a single sharp (look at the key signature), in the other case by four flats. To the eye the difference is considerable, to the ear it is practically nothing—merely the difference of half a tone in the pitch. Why, then, says the Tonic Sol-faist, should the singer be distracted by a new set of symbols? This is the great point of the letter notation. It recognises but one scale, so that the two lines of the "Old Hundredth," as shown, would come out respectively as follows:

KEY G. etc.

:d |d :t_1 |l_1 :s_1 |d :r |m :m |m :m |r :d |f :m |r ||

KEY A♭. etc.

:d |d :t_1 |l_1 :s_1 |d :r |m :m |m :m |r :d |f :m |r ||

There is absolutely no difference, it will be observed, except for the one f ct, not tionally unimportant to the singer, of a different key-name.

For this purpose of naming the key the Sol-faist has, like the Staff notationist, to depend upon what is called the Standard Scale of C, with its letter names in their ascending order:

C, D, E, F, G, A, B.

These names represent fixed sounds — that is to say, C is always C, D is always D, and so on, as on the keyboard of a piano. In Sol-fa their sole use is to determine the pitch of the particular *Doh* of a particular tune. Thus, when the indication "Key F" or "Key E" appears, it means that the *Doh* is at the pitch of the F or E of the Standard Scale. In pitching tunes, a tuning-fork is generally used. It sounds the upper C (there are pitch-forks in A), which the singer imitates, and then runs down the scale to the required note. For instance, if the indication is "Key D," you sound the fork, sing C, B, A, G, F, E, D, and repeat the sound of D to the name *Doh*. A speedier method is suggested in the following directions, which we copy from the "Companion for Teachers of the Tonic Sol-fa Method":

B♭	Sound C,	call it	Ray,	then sing	r d.
A♭	,,	,,	Me	,,	m d.
G	,,	,,	Fah	,,	f m r d.
F	,,	,,	Soh	,,	s m d.
E	,,	then sing C B A G F E.			
E♭	,,	call it Lah, then sing l t d'—s m d.			
D	,,	,,	Doh'	,,	r' d—s m d.

At present the student will not quite understand this, but it is best in place here, and may stand for after reference.

Such is the Sol-faist's use of the Standard Scale. For all other purposes he employs his one scale of *Doh*. The names of this scale are an Anglicised form of the old Italian solfeggio syllables:

Si = Te		Mi = Me
Lah = Lah		Re = Ray
Sol = Soh		Do = Doh
Fa = Fah		

The name *Soh* was preferred to *Sol* as being more open, while *Si* was changed to *Te* to avoid having the same initial letter twice in the scale. For purposes of teaching, and for the student's own practice, the scale is laid out on a sort of diagram called the Modulator. This Modulator, reproduced at the side, is, with its various evolutionary forms, to be subsequently explained, the foundation element in all Tonic Sol-fa teaching. To quote Mr. Curwen himself, it "takes the place of the Staff in the common notation. It stands behind every note in the book. From habitual use of it, the mind's eye always sees it there." It is frequently objected to the letter notation that the notes are "all on a dead level," and do not represent to the eye, as does the Staff, the rising and falling pitch of the notes. But the inventor of the notation was undoubtedly within the mark in saying that by early training the pictorial Modulator is fixed in the mind's eye of each pupil, and the notes start into their places in the scale as he looks at them.

THE MODULATOR

$f^{\prime}$
$m^{\prime}$
$r^{\prime}$
DOH'
TE
LAH
SOH
FAH
ME
RAY
DOH
t_1
l_1
s_1

The Modulator represents pictorially the exact intervals of the major scale. Such a scale is formed of an ordered succession of tones and semitones, or, as the Sol-faist calls them, whole tones and half tones. On the Staff there is nothing to show which are the tones and which are the semitones of a scale. On the Modulator the differences are represented by the differing vertical space. Thus, between *Me* and *Fah* and *Te* and *Doh* we see only half the space that is given to other notes. Hence, *Me* and *Fah* and *Te* and *Doh* are the semitonic intervals of the scale; the others, with the wider space between, are the full tones. "The order and succession of the scale is so natural to us," says Mr. Curwen, "that we do not at first feel this discrepancy; but when the attention is called to the point it will generally be perceived." A most important point it is, for the scale tones derive their individuality from the position of these "little steps," as we shall see when we come to speak of the minor mode.

In the accepted method of teaching the pupil to sing from the Modulator, the scale is taken in sections, as it were, these sections representing the consonantal and foundational chords of the scale. There is no running up and running down of the scale in the stepwise order of its notes, a method which indeed is quite useless for all practical purposes. Instead, the pupil first learns to sing the notes of the Tonic chord—*Doh, Me, Soh*—in the various positions in which these notes may be arranged, the octave of *Doh* (the "high *Doh*") being added last. The same process follows with the notes of the Dominant chord, *Soh, Te, Ray*; and the five notes of the scale thus learnt in two sections

are then combined in one section. After that, the seven sounds are completed by exercises on the Subdominant chord of *Fah, Lah, Doh*. Thus is the pupil gradually made familiar with the diatonic scale in all possible positions in which its intervals can be disposed—in fact, just as he will meet with them in his ordinary vocal routine.

But now we have to see how this Modulator scale is expressed in the notation. It is done in the very simplest way, by merely writing the initial letters of the syllable names, as here:

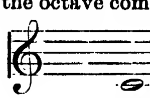
d r m f s l t

Leaving out of consideration the so-called "chromatics," to be dealt with in next lesson, nothing more is notationally required, so far as tune is concerned, but some means of indicating the higher and lower octaves of these scale notes. As the diatonic scale consists of only seven notes, it is obvious that when we have exhausted these we must begin again—must go on in a higher or in a lower direction, as the case may be. The term "octave" means eighth; and when we begin again we begin with the eighth of the original note. Thus, every *Doh*, every *Me*, every *Soh*—every note of the scale—has its octave or eighth above or below. The question, then, is, how to differentiate these octave notes from the others. This, again, is managed very simply. The upper octaves are represented by figures above the scale letters; the lower octaves by figures below, as thus:

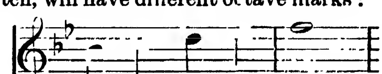
d^1 d^2

d_1 d_2

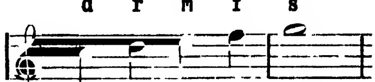
It must be understood, of course, that all the scale notes within the key are left unmarked, and that the marking begins only when the octave above or the octave below the key *Doh* is called into use. To put it in Mr. Curwen's own words, the octave commencing on middle C



is taken as a standard. The notes of that octave bear no mark above or below, and every *Doh* chosen as a key-note within that octave is unmarked also. Thus (to borrow once more from the Staff) these passages, so nearly alike in pitch, will have different octave marks:



d r m f s



d^1 r^1 m^1 f^1 s^1

because in the first case the *Doh* is within the Standard octave; in the second it is above it.

Notation of Time. The Tonic Sol-fa has this advantage over that of the Staff notation, that it indicates clearly each individual beat or pulse of the measure. In teaching time the Tonic Sol-fa instructor begins by pointing out how in speaking and in singing we accent certain words or syllables, and do not accent others. Thus, in the line "Tell me not, in mournful numbers," a strong accent comes on every alternate syllable. In "Take her up tenderly, lift her with care," again, the accent comes on every third syllable.

Now, to mark these accents, a musical composition, long or short, is cut up exactly in the same way. First it is divided by bars into measures, then in Tonic Sol-fa the measures are divided visibly into beats or pulses. The strong accent comes in every case at the beginning of the measure, and to mark it a vertical line is used exactly like the bar-line of the Staff. The sign for the weak accent is a colon (:); and when a subordinate accent—technically the medium accent—has to be shown, a short upright line is employed. Thus, "Tell me not in mournful numbers" would be set out in this way:

| : | : | : | : ||

Tell me not, in mourn-ful num - bers,

while "Take her up tenderly, lift her with care" would appear so:

| : : | : : | : : |

Take her up ten - der - ly, lift her with care.

In the first example the measure contains two pulses, and is thus said to be in two-pulse measure; while the second example, with three pulses to the measure, is similarly described as in three-pulse measure. In naming a measure the pulses are always counted from one strong accent to the next. Altogether there are six kinds of measure in common use. After three-pulse measure comes four-pulse measure, where the order of the accents is strong, weak, medium, weak, as here:

| : | : |

Then we have six-pulse measure, written thus:

| : : | : : |

Nine-pulse measure:

| : : | : : | : : |

And twelve-pulse measure:

| : : | : : | : : | : : |

These, as we have said, are all the measures in general use. We meet now and again with:

| : | : | : | : |

called eight-pulse measure, but it is only used when a four-pulse measure is to be so slow that each beat is divided into two. The six, nine, and twelve-pulse measures are made up of two, three, and four measures of three-pulse time, the medium accent being used instead of the strong. They are therefore called compound measures. It is obvious that a composition cannot always begin on the strong accent. If a composer had to "set" the words, "They grew in beauty, side by side," he would begin with a weak accent, the strong accent following on "grew."

GUMS & OTHER SUBSTANCES

Including India-rubber and Gutta-percha, Gums and Glues, Bone, Ivory, Camphor, Asbestos, Glass, and Emery

By Professor HENRY ADAMS

India-rubber. *India-rubber*, or *Caoutchouc*, consists of the dried coagulated milky juice of various trees and shrubs belonging chiefly to the natural order *Euphorbiaceæ.* The caoutchouc appears to be kept in suspension in the juice by means of ammonia; at least, in some cases the fresh milk exhales an ammoniacal odour. Probably it is on this account that the addition of liquid ammonia prevents the juice from coagulating for a considerable time, and ammonia is added, in certain districts, when the milk has to be carried some distance from the place of collection. Of all varieties the most important is Pará rubber.

Pará Rubber. *Pará rubber* is obtained from *Hevea Brasiliensis*, a large tree 60 ft. high. The caoutchouc is collected in the so-called dry season between August and February; the trees are tapped in the evening, and the juice is collected on the following morning. A deep horizontal incision is made near the base of the tree, and then from it a vertical one extending up the trunk, with others at short distances in an oblique direction. Small shallow cups, made from clay and dried in the sun, are placed below the incisions to receive the milk, each cup being attached by sticking a piece of soft clay to the tree and pressing the cup against it. Each tree yields only about 6 oz. of juice in three days.

To produce the rubber the juice is heated in the following manner. A piece of wood about 3 ft. long, with a flattened clay mould at one end of it, is dipped in the milk, or this is poured over it as evenly as possible. The milk is then carefully dried by turning the mould round and round in a white vapour obtained by heating certain oily palm-nuts, the vapour being confined within certain limits by the narrowness of the neck of the pot in which the nuts are heated. Each layer of rubber is allowed to become firm before adding another. A practised hand can make 5 or 6 lb. an hour. The cakes when completed are, in order to remove them from the mould, slit open with a sharp knife, which is kept wet, and are hung up to dry. The flat, rounded cakes of rubber made in this manner are known in the London market as "biscuits."

Ceara Rubber. *Ceara rubber* is considered next to the Pará in value. It is obtained by brushing away the loose stones and dirt from the root of the tree by means of a handful of twigs, after which the collector lays down large leaves upon which the milk may fall. He then slices off the outer layer of the bark to a height of 4 or 5 ft. The milk—which exudes in many tortuous courses, some of it ultimately falling on the ground—is allowed to remain on the tree for several days, until it becomes dry and solid, when it is pulled off in strings, which are either rolled up into balls or put into bags in loose masses, in which form it enters commerce under the name of *Ceara scrap.*

Composition of India-rubber. India-rubber is composed of carbon and hydrogen alone, but its exact chemical nature is not by any means known with certainty. When pure it is odourless and nearly white, and possesses a specific gravity of ·915. It is porous and cellular in texture, and absorbs from 10 to 25 per cent. by weight of water when soaked in it for a long period.

Industrial Preparation. In the preparation of india-rubber for industrial purposes the first matter to be attended to is the removal of the various impurities present in the crude material. This is done in the following manner. The lumps of crude caoutchouc are first softened by the prolonged action of hot water, and then cut into slices by means of a sharp knife. The softened slices are now repeatedly passed between grooved rollers, known as the washing rollers, a supply of hot or cold water being made to flow over them. Solid impurities speedily become crushed, and are carried away by the water, while the rubber takes the form of an irregular sheet perforated by numerous holes. The washed product contains in its pores a notable proportion of water, which is removed by hanging the rubber for some days in a warm room. It is now ready either for incorporation with sulphur and other solid bodies, or for agglomeration into solid masses by means of the masticating machine. Sheet rubber is largely used in the fabrication of certain classes of rubber goods, these being made by cementing the sheets together with a solution of rubber in coal-naphtha or benzol. Most articles made of cut sheet-rubber would, however, be of very limited utility were they not hardened or vulcanised.

Waterproof Cloth. The ordinary macintosh or waterproof cloth is prepared by spreading on the fabric layers of india-rubber paste or solution made with benzol or coal-naphtha. If cotton or linen is used, it is usual to incorporate sulphur with the paste, and to effect vulcanisation by steam heat; but when silk or wool is employed no sulphur is added to the paste, the dried coating of rubber being merely brought into momentary contact with the mixture of chloride of sulphur and carbon

disulphide. Double texture goods are made by uniting the rubber surfaces of two pieces of the coated material. Air goods such as cushions, beds, gas-bags, etc., are made of textile fabrics which have been coated with rubber, either by the spreading process already described, or by means of heated rollers, the vulcanisation, or "curing," as it is called, being then effected by steam heat.

Other uses to which vulcanised rubber is put are packing for stuffing boxes of steam engines, stereotypes, rubber stamps, over-shoes, fishing-boots, etc. Springs, valves, and washers are manufactured out of mixed rubber, and vulcanised either in moulds or in powdered French chalk.

Vulcanised Rubber. *Vulcanised rubber* consists of the chemical combination of sulphur with india-rubber, and not merely the admixture of the two substances. If an article of cut sheet-rubber is immersed for a few minutes in a bath of melted sulphur maintained at a temperature of 120° C., the rubber absorbs about one-tenth of its weight of that element, and, although somewhat yellowish in colour from the presence of free sulphur, it is still unvulcanised and unaltered as regards general properties. If, however, it be now subjected for an hour or so to a temperature of 140° C., true combination sets in, and vulcanised caoutchouc is the result.

Another method of vulcanising articles from cut sheet rubber consists in exposing them to the action of chloride of sulphur. Either they are placed in a leaden cupboard, into which the vapour is introduced, or they are dipped for a few seconds in a mixture of one part of chloride of sulphur and 40 parts of carbon disulphide, or purified light petroleum. Vulcanisation takes place in this instance without the action of heat, but it is usual to subject the goods for a short time to a temperature of 40° C., after their removal from the solution, in order to drive off the liquid which has been absorbed and to ensure a sufficient action of the chloride of sulphur. Treatment with a warm alkaline solution is afterwards advisable, in order to remove traces of hydrochloric acid generated during the process. Most of the rubber now manufactured is not combined with sulphur when in the form of sheets, but is mechanically incorporated with about one-tenth of its weight of that substance by means of mixing rollers, any required pigments for colouring being added. The mixed rubber thus obtained can be very easily worked into any desired form or rolled into sheets by means of the calendering machine.

Vulcanite. Vulcanite is the harder of the two forms of vulcanised india-rubber, the other form being known as soft rubber. Vulcanite differs from soft rubber in that it contains more sulphur, and is cured or vulcanised at a higher temperature. A kind of vulcanite which contains a very large proportion of vermilion is used, under the name of dental rubber, for making artificial gums.

Ebonite. *Ebonite* is a black, hardened compound of caoutchouc or gutta-percha and sulphur in different proportions, to which other ingredients may be added. It is properly black vulcanite. Ebonite takes a fine polish, and is valuable to the electrician on account of its insulating properties, and to the chemist and photographer because vessels made of it are unaffected by most chemical reagents.

Gutta-percha. The name *gutta-percha* is applied to the concreted or inspissated juice of various plants belonging to the natural order *Sapotaceæ*, growing in the Malay Peninsula. To what particular tree the name "gutta-percha" properly belongs there is no evidence to show, but it has been generally given to *Dichopsis gutta*, which usually attains a height of 60 to 80 ft., with a diameter of 2 to 4 ft. The wood is soft, fibrous, spongy, of a pale colour, and marked with black lines, these being reservoirs of gutta-percha. The collection of gutta-percha generally takes place directly after the rainy season, as in the dry season the gutta does not flow so readily. The yield of a well-grown tree of the best variety is from 2 to 3 lb. of gutta-percha, such a tree being about 30 years old, 30 to 40 ft. high, and 1½ to 3 ft. in circumference. A full-grown tree sometimes measures 100 to 140 ft. to its first branches, and may yield 50 to 60 lb. of gutta-percha, which loses in six months about 35 per cent. of its weight in drying.

The methods of extracting the gutta-percha are much the same amongst the Malays, Chinese, and Dyaks. The trees are cut down just above the buttresses, or *banees*, as they are called, and for this purpose a staging about 14 to 16 ft. high is erected. When the tree is felled, the branches are speedily lopped off, to prevent the ascent of the gutta to the leaves. Narrow strips of bark, about 1 in. broad and 6 in. apart, are then removed; but not all round the tree, as its under part, in its fall, becomes buried in the soft earth, much sap being thus lost. Some natives beat the bark with mallets to accelerate the flow of milk or gutta, which flows slowly and rapidly concretes. The gutta is received into hollow bamboos, doubled-up leaves, pieces of bark, cocoanut-shells, or in holes scraped in the ground. If the quantity obtained is small, it is prepared on the spot by rubbing it together in the hands into a block, in one end of which a hole is made to carry it by; in this state, it is known in the market as *raw gutta* or *gutta muntah*.

Preparation. Gutta-percha, as received in England, is in irregular clumps or blocks, and is frequently adulterated with massive stones, sawdust, bark, sago-flour, etc., and the first step in its manufacture is to cleanse it thoroughly. The blocks are first sliced by means of a powerful circular wheel, driven by machinery, and having fixed to it two or three strong chisel-like knives. These slices are placed in wooden troughs, filled with water and heated by steam. As soon as the gutta-percha becomes soft, it is taken out in baskets and placed in a toothed iron cylinder, called a

"devilling" machine, which tears it into fragments. These fall into a trough of water, and the impurities sink to the bottom, leaving the purified gutta floating in the form of a spongy mass. This mass is then taken out, thoroughly washed in cold water, and dried in baskets. It is then placed in jacketed iron chests, heated by steam, and left till it becomes soft, when it is at once removed and placed in a machine called a *masticator*, which kneads or masticates it, the result being a homogeneous dough-like, reddish-brown mass. While still hot this mass is placed between two steel cylinders and thoroughly rolled. By means of an endless band of felt the gutta is returned again to the cylinders, the distance between which is gradually diminished, so as to compress and completely drive out any contained air from the gutta-percha.

Uses of Gutta-percha. In telegraphy gutta-percha is of the very highest importance, being a cheap, lasting, and powerful insulator, easily applied to telegraphic wires. The value of gutta-percha piping is very great; it does not contaminate water as lead piping does; it withstands insects, damp, etc., and is easily manipulated, being shortened, lengthened, or repaired with little trouble or expense; and its acoustic properties have led to its employment in the manufacture of aural, stethoscopical, and other instruments. Gutta-percha speaking-tubes are now widely used. The substance is also largely employed for funnels, syphons, and other chemical apparatus, from the fact that few acids and alkalies affect it. It is also used for golf balls, and may be moulded into any shape by simply softening it in hot water and pressing it into the mould.

Gum. Gum exists in the juices of almost all plants, but is produced in its purest form by various species of *acacia*. The name is applied to those exudations from plants, stems, branches, or fruits which are entirely soluble or soften in water, and form with it a thick glutinous liquid. In structure, gum is quite amorphous, being neither organised, like starch, nor crystallised, like sugar. According to Trecul, the acacias yield their gums more abundantly when sickly and in an abnormal state, caused by a fulness of sap in the young tissues, whereby the new cells are softened and finally disorganised; the cavities thus formed fill with liquid, which exudes, dries, and constitutes the gum.

Gum-arabic. Gum-arabic may be taken as the type of the gums entirely soluble in water. The principal kinds are distinguished as Turkey picked gum, Gedda, Amrad, Gheziri, Senegal, Talca, Australian, Barbary, Cape, and East Indian (from Bombay and Aden). It occurs in pieces of varying size, and some kinds are full of minute cracks. The specific gravity of Turkey picked gum (the purest variety) is 1·487, or when dried 1·525. The finer varieties are used as an emollient and demulcent in medicine, and in the manufacture of confectionery. The commoner qualities are used as an adhesive paste, for giving lustre to crêpe, silk, etc. For labels it is usual to mix sugar or glycerine with it to prevent it from cracking.

Gum-tragacanth. Gum-tragacanth called also *gum dragon*, exudes from the stem, the lower part especially, of the various species of *astragalus*, and is collected in Asia Minor and shipped from Smyrna. It has a dull white colour, and occurs in horny, flexible, and tough, thin, twisted flakes. It is used in calico-printing as a thickener of colours and mordants; in medicine as a demulcent and vehicle for insoluble powders, and as an incipient in pills.

Gum-benjamin. *Gum-benjamin*, *benjamin*, or *benzoin*, together with other resins, such as copal, mastic, shellac, kawrie, or cowdie, or Australian copal, etc., are often improperly called gums.

Mastic. *Mastic* is a resinous exudation obtained from the *Pistacia Lentiscus*, or mastic plant, an evergreen shrub found in the Mediterranean coast region from Syria to Spain, but growing also in Portugal, Morocco, and the Canaries. The resin is not contained in the wood, but in the bark, and to obtain it numerous vertical incisions are made in the stem and chief branches. Besides that obtained from the incisions, mastic of very fine quality spontaneously exudes from the small branches. Mastic occurs in English commerce in the form of roundish tears about the size of peas, some, however, being oblong or pear-shaped. They are transparent, with a glassy fracture, of a pale yellow or greenish tinge, which darkens slowly by age. Its solution in turpentine constitutes a varnish much used in oil-painting.

Gelatine. The gelatine derived from bones enters very largely into human food, in the stock for soups, etc., and as prepared gelatine, calves-foot jelly, and isinglass. It is employed as a sizing agent in paper-making, and by painters it is also used for sizing or priming. It is further used in the preparation of elastic moulds of undercut work, and in the manufacture of inking-rollers for printing.

Glue. Glue is a form of gelatine, which, on account of its impure condition, is employed only as an adhesive medium for wood, leather, paper, and like substances. In the preparation of ordinary glue the materials used are the parings and cuttings of hides from tanyards, the ears of oxen and sheep, the skins of rabbits, hares, cats, dogs, and other animals, the parings of *tawed* leather, and many other scraps of animal matter. Taking tanyard refuse to be the principal material, it is first steeped for some weeks in a pit with lime-water, and afterwards carefully dried and stored. The object of the lime steeping is to remove any blood and flesh which may be attached to the skin, and to form a lime soap with the fatty matter it contains. When thus prepared, the glue pieces, or *scrows*, as they are termed, are thoroughly washed before boiling. They are then placed in hemp nets and introduced into an open boiler, which has a false bottom, and a tap by which liquid may be run off. As the boiling proceeds, test quantities of liquid are from time to time examined, and when a sample is found on cooling to form a stiff

jelly, it is ready to draw off. From the boiler the solution is run to a tank or *setting back*, in which a temperature is maintained sufficient to keep it fluid, and in this way any impurity is permitted to subside. The solution is then run into wooden troughs or coolers, in which it sets to a firm jelly. When set, a little water is run over the surface, and with knives of suitable form it is detached from the troughs, cut into slices about an inch thick, and these are placed on nets stretched between upright wooden frames for drying, an operation which requires special care.

Isinglass. *Isinglass*, or *fish-glue*, in its raw state is the swimming-bladder, or sound, of various species of fish. Russian isinglass, which is the finest made, is obtained from several species of sturgeon found in the Volga, Caspian and Black Seas, and in the Arctic Ocean. It is prepared by cutting open the sounds, steeping them in water till the outer membrane separates from the inner, then washing the latter and exposing it to dry in the air. The principal uses to which isinglass is applied are for jellies and confections, and as a clarifying or filtering medium for wine, beer, and other liquids. When dissolved in strong acetic acid it forms a powerful cement, much used for repairing glass, pottery, and similar small objects.

Marine Glue. Various adhesive but non-gelatinous substances are, on account of their properties, known commercially as glue, and are used as substitutes for ordinary glue. Thus marine glue, employed in shipbuilding and for other purposes, is a compound of india-rubber and shellac dissolved in coal-tar naphtha.

Bone. Bones of cattle and other animals are extensively used in the arts in forming knife-handles, buttons, combs, etc., in making size, gelatine, lampblack, and animal charcoal, and for various other purposes. They are also extensively used as a manure for dry soils, with the very best effect, being ground to dust, bruised, or broken into small fragments in mills, or dissolved in sulphuric acid.

Horn. The weapons which project from the heads of various species of animals, constituting what are known as horns, embrace substances which are, in their anatomical structure and chemical composition, quite distinct from each other, and although in commerce also they are known indiscriminately as horn, their uses are altogether dissimilar. Their differences are thus indicated by Professor Owen: "The horns of deer consist of bone, and are processes of the frontal bone; those of the giraffe are independent bones covered by hairy skin; those of oxen, sheep, and antelopes are projections of the frontal bone, covered with a sheath of true horny material. Only the horns of the rhinoceros are composed wholly of horny matter, and this is disposed in longitudinal fibres, so that the horns seem rather to consist of coarse bristles compactly matted together in the form of a more or less elongated sub-compressed cone." True horny matter is really a modified form of epidermic tissue, and consists of an albuminoid principle termed *keratin*. It forms not only the horns of the ox tribe, but also the hoofs, claws, or nails of animals generally, the shell of the tortoise, porcupine quills, and birds' feathers, etc.

The principal application of horns is for the manufacture of combs; and other uses to which the substance is put are pressing of buttons, handles for walking-sticks, umbrellas and knives, manufacture of drinking-cups, spoons, snuff-boxes, etc. The parings and refuse of horn are valuable for the manufacture of prussiate of potash and as manure, and the ash of the cores of horn makes excellent cupels for the assay of precious metals. Deer-horn is used almost exclusively for handles by cutlers and walking-stick and umbrella makers.

Ivory. Ivory is essentially equivalent to dentine, that hard substance of which most teeth are principally composed. By usage, however, its application has become almost restricted to the dentine of those teeth which are large enough to be available for industrial purposes—*viz.*, the tusks of the elephant, hippopotamus, walrus, narwhal, and sperm whales.

The best ivory is the African, and the first quality of that comes from near the Equator. The tusks are sold by weight, and stones and iron are sometimes thrust down into the hollow pulp cavity to increase the weight, so that dealers generally feel the hollow with an iron rod to detect foreign matter.

The tusks of the extinct mammoth from Northern Siberia furnish almost the whole of the ivory used by Russian ivory workers. They come principally from the neighbourhood of the Lena and other large rivers discharging themselves into the Arctic Ocean, and are abundantly found in the Liakhoff Islands. Mammoth tusks are slender, much more curved, and in proportion to the size of the animal much larger than those of our elephants. In England this ivory is not very highly esteemed, being considered too dry and brittle for elaborate work, and very liable to turn yellow.

The great canine teeth of the hippopotamus furnish an ivory which is harder and whiter than that of the elephant and less prone to turn yellow. No large piece can be obtained from a hippopotamus tusk, and the incisors and upper canine teeth yield even smaller pieces than the lower canines.

The tusks of the walrus have long been used as a source of ivory among the northern nations. The upper canines are oval in section, solid, and their axis is made up of secondary dentine, which makes up a considerable part of the whole tooth, the quantity far exceeding that in the hippopotamus. The spirally-twisted tusk of the narwhal, the teeth of sperm whales, the ear bones of whales, and the molar teeth of elephants, are also all made use of as sources of ivory, though they are far less valuable than the larger tusks.

Uses of Ivory. In former times ivory was frequently used for the manufacture of artificial teeth, but it has been superseded by more durable and more manageable materials. The principal demand for ivory arises in

connection with the cutlery trade, very large quantities being used for the handles of pocket and table knives. It is also extensively used for the handles of walking-sticks and umbrellas, combs, paper-knives, ladies' fans, and for measuring-rules, and mathematical scales. It is in considerable demand for the manufacture of chess and draughts men, for statuettes, caskets, and many minor objects of furniture and ornament, and for inlaying. All ivory dust and chips are utilised by being converted into gelatine—which they may be made to yield by prolonged boiling—or by being calcined into ivory black.

Vegetable Ivory. The plant yielding the vegetable ivory of commerce is known to botanists as *Phytelephas macrocarpa*, and is a native of South America. The fruit consists of a conglomerated head, composed of six or seven drupes, each containing from six to nine seeds, and the whole being enclosed in a walled woody covering, forming altogether a globular head as large as that of a man. A single plant sometimes bears at the same time from six to eight of these large heads of fruit, each weighing from 20 to 25 lb. In its very young state the seed contains a clear, insipid fluid. As it gets older the fluid becomes milky and sweet to the taste, and gradually continues to change, both in taste and consistence, until it becomes so hard as to make it valuable as a substitute for animal ivory. The seeds, or nuts, as they are generally called, when fully ripe and hard, are used by the American Indians for making small ornamental articles and toys. They are imported into Britain, frequently under the name of Corozo nuts, and are used chiefly for small articles of turnery.

Xylonite. *Xylonite, Zylonite,* or *Celluloid*, is a substance made of guncotton, camphor, and ivory dust, imitating ivory, or, when coloured, tortoise-shell, coral, amber, etc. Celluloid has recently been introduced for stereotypes instead of metal, and it is found that many thousands more impressions can be printed from them than from stereotypes without showing perceptible signs of wear. It is used in the manufacture of billiard balls, combs, small mirror backs, pocket-book covers, and other small objects. It is also used in the manufacture of collars and cuffs, but its fiercely combustible character renders it somewhat dangerous.

Camphor. *Camphor* is a translucent substance, of cooling taste and penetrating odour, distilled from the wood of the camphor-tree (*Cinnamomum camphora*), which flourishes in the Island of Formosa, and also in Japan and parts of China. It is produced from the branches, trunk, and roots of the tree by cutting them into chips, which are placed in closed vessels and exposed to the vapour of boiling water, the steam volatilises the camphor, which comes to the top of the vessel. Camphor is largely used in the production of celluloid goods, and in the manufacture of smokeless powder and cordite. It is also employed in the making of medicaments, and in keeping moths away from furs and woollen goods.

Mica. *Mica* is one of a group of minerals, all of which are characterised by their perfect basal cleavage, in consequence of which they can be separated easily into extremely thin, tough, and usually elastic laminæ. The micas are silicates of aluminium with other bases, as iron, calcium, magnesium, potassium, sodium, and in some kinds fluorine is present in small quantities. The micas, of which there are several varieties, enter into the composition of many rocks, including the crystalline rocks, both metamorphic and volcanic (as granite, gneiss, mica-schist, etc.), and sedimentary rocks (as shales and sandstones), sometimes giving them a laminated structure. Mica (*muscovite*) is often used in thin transparent plates for spectacles to protect the eye, in reflectors, instead of glass, in places exposed to heat, for unbreakable lamp chimneys, deflectors over gas-jets, and, in Russia, even for windows. When ground to powder, mica is combined with varnish to make a glittering coating for wall-papers, and is used also in preparing a covering for roofs, and as a packing and lubricant for machinery. *Talc* is a similar material and is a magnesian silicate.

Asbestos. *Asbestos* is a variety of the hornblende family of minerals. It consists of fine crystalline elastic fibres, with a silky lustre, varying in colour from white to grey and green, and derives its name from being specially indestructible by fire. A single fibre of it fuses to a white enamel, but in the mass it is capable of resisting ordinary flame. There are several varieties of asbestos: (1) *Amianthus* is the rarest kind, its fibres being white, flexible, long, and regularly laid. It is found in the centre of the older crystalline rocks in the Pyrenees, North America, Sweden, New South Wales, etc., but the most beautiful specimens come from Tarantaise, in Savoy, and from Corsica, where it is somewhat abundant. (2) *Common asbestos* is not so light, either in colour or weight, as amianthus, and is more inflexible, splintery, and irregular in structure. It is found in serpentine rocks in Anglesea, in Cornwall, and in several parts of Scotland, as Glenelg in Inverness. (3) *Mountain leather and mountain cork* are other varieties where the fibres are less flexible and regular than either of the above, while their colour is brown or dirty white. Mountain leather is in thin flexible sheets, and mountain cork is so named from being not unlike common cork, and so light as to float on water. It is found in Lanarkshire. (4) *Mountain wool* is a soft, tough, opaque brownish-coloured variety of asbestos, much heavier than the last, and melting to a black slag before the blow-pipe. It is found in Tyrol, in Dauphiny, and in Scotland at Glen Tilt, Portsoy, and Kildrummy. Paper has been manufactured from asbestos, and would prove invaluable, in case of fire, for charters and other important documents were it not that the paper is rather tender for use, and that the writing disappears after a red heat. More success has attended its employment for fireproof roofing and flooring, for non-conducting envelopes of steam-pipes, and for the packing of fireproof

safes; it is also prepared as a cement for protecting heated surfaces, roofs and floors, and for various fireproofing purposes.

Uralite. The main ingredient of this substance is asbestos, obtained from Canada, the United States, and Russia. This is cleansed, and afterwards mixed, with water and chalk as a binding agent, into a pulp similar to that of paper pulp. The pulp is rolled into sheets, and, for the purpose of securing stability, a small quantity of silicate of soda is added to it. The sheets thus formed are cut into the sizes required, pressed, and dried, leaving boards of fibrous asbestos. These boards are steeped in a solution of silicate of soda, the water is driven off by drying, and they are then dipped in a solution of bicarbonate of soda and again dried. The technical application consists of the impregnation of the asbestos board by silicate of soda, and its subsequent decomposition by bicarbonate of soda. This is accomplished by regulating the strength of the two solutions so as to ensure the complete impregnation of the whole of the board by the two chemicals, which are of mineral character. In this way the time of deposition is determined, and, after a sufficiency of the colloid silica is deposited over the fibres of the asbestos, it is gradually dried until the 75 per cent. of water, natural to freshly formed colloid silica, is driven off, leaving a hard, dense substance which attaches itself as a cement to the asbestos, and thus forms a homogeneous mass incapable of lamination, with no planes of cleavage, and fire-resisting to a high degree. When made in sheets it is used for roof covering, ceilings, floors, and partitions, and can be veneered, varnished, and worked with carpenters' tools like ordinary timber. It will stand 2,000° F. without destruction, and is coming largely into use.

Slag-wool. *Slag-wool* or *silicate cotton* is made from the slag of blast furnaces, by allowing a jet of steam to blow through a stream of molten slag while falling, converting it into a glassy substance with the texture of cotton-wool. Owing to its fire-resisting properties, it is used as a substitute for asbestos in the manufacture of several fire-resisting plasters. It is extensively used as a sound-proof packing, which is not subject to decay, and does not harbour vermin. It is a favourite substance for use as a non-conductor in refrigerating chambers, as it is impervious to damp, and unaffected by temperature.

Fossil Meal. *Fossil meal*, or fossil flour, is a variety of infusorial earth found in abundance in Tuscany and elsewhere beneath peat beds. It is a white flour-like powder used in the manufacture of *floating bricks*, and for non-conducting boiler coverings.

Glass. *Glass*, in its ordinary signification, is a brittle, transparent compound produced by the fusion, at a very high temperature, of silica (*silicic acid* or *oxide of silicon*) with one or more basic substances, one of which, in all cases, must be an alkaline metal. The substances which form the essential basis of all varieties of common glass are (1) silica as the acid element; (2) soda or potash as the alkaline base, and (3) lime and oxide of lead as the alkaline earths. To the alkaline earths commercially employed there ought also to be added baryta and alumina, the former being used in the place of lead, and the latter a common ingredient in certain kinds of glass. The properties on which the great value and utility of glass principally depend are (1) its well-known prevailing transparency, combined with a brilliant lustre and great hardness; (2) its fusibility at a high temperature; and (3) its softness and viscosity at a red heat, whereby it can be worked with facility into any desired shape. Of great value also is its resistance to the influence of common solvents. Properly made, glass is not sensibly acted upon by any of the acids except hydrofluoric acid, which attacks it powerfully, combining with and removing its silica. Of the many varieties of glass manufactured may be mentioned: crown, sheet, plate, flint or crystal, pressed, baryta, bottle, massive, spun, etc., but of these, only the first three are in common use in connection with the building trade.

Emery. *Emery* is an impure variety of the mineral corundum, bluish-grey to brownish, granular and rough in fracture, with a specific gravity varying between 3·7 and 4·3. Much of the emery of commerce is artificially coloured to a rich reddish brown. It occurs in amorphous masses in schists, gneiss, granular limestone, and other crystalline rocks, and in rolled and detached pieces and in granules in soils. The principal European source of emery is the island of Naxos, but it occurs also near Smyrna, and in Sweden, Saxony, Spain, and other localities. When broken by hammer, or crushed by stamps, it is used as a polishing material for plate glass, crystal, lapidaries' work, and metals, and in cutting granite and marble. Emery-powder is mixed with other substances and formed into grinding wheels, hones, and similar instruments. Emery, more especially that used for emery-paper and emery-cloth, is commonly adulterated with garnet, zircon, iron-slag, and other substances harder than quartz sand.

Carborundum. *Carborundum*, which on account of its great hardness has assumed an important place among abrasives used for polishing, is a silicate of carbon, formed by the action of carbon on sand (*silica*) at high temperatures in the electric furnace. When taken from the furnace it is crystalline, green, blue, or brownish in colour, sometimes opaque, but often translucent, resisting the action of even the strongest acids, and the action of air or sulphur at high temperatures. The crude product can, therefore, be treated with hot sulphuric acid to purify it. In hardness it nearly equals the diamond, and it is used for tool-grinding in the form of vitrified wheels. Carborundum-paper—made like emery-paper—is now largely used in place of garnet-paper in American shoe factories.

LADY'S-MAID, FOOTMAN, & COACHMAN

Duties of the Lady's-maid. Hairdressing. Needlework. The Footman's Duties. General Manservant. Page and Houseboy

By A. EUNICE T. BIGGS

THE LADY'S-MAID

The lady's-maid ranks with the valet, and she takes her meals with him, together with the butler, in the housekeeper's room. Her duties bring her into personal contact with her mistress, and it is important that she should possess certain mental and moral qualities to fit her for the work. She should have both tact and patience, and be able to exercise forbearance and self-control should her mistress be unreasonable and capricious. She will do well to maintain a respectful manner, and to be very considerate with her mistress. She should never repeat to the other servants anything that may come to her ears, and she should take care that information of a private character, which may accidentally become known to her, is not repeated.

Duties of the Lady's-maid. The lady's-maid's first duty will be to make preparations for her mistress's toilet. She should put everything in order in the dressing-room, lighting the fire if the weather is cold. The bath should be prepared, with plenty of hot and cold water in readiness, and an early cup of tea made for her mistress, if she wishes for it. She should then, at the appointed time, call her mistress, give her her tea, pull up the blinds, and close the windows. She should put out all clean linen to be aired, and put away every garment that has been left out from the evening before. The lady's-maid then goes downstairs to her own breakfast, and her mistress will ring when she is ready for her.

Hairdressing. It is of the utmost importance that the lady's-maid should be skilful in dressing hair. If she can obtain some lessons from a good hairdresser she will find them invaluable. Many ladies who find their maids satisfactory in all other respects will occasionally send them to have a few lessons, in order to acquire the latest styles.

Having helped her mistress to dress the [illegible] the [illegible] all [illegible] the bedroom and dressing-room. The visits of the housemaid to these apartments will, in this case, be confined to the occasions on which the rooms are thoroughly turned out.

The Daily Routine. As soon as her mistress has gone down to breakfast, the lady's-maid should throw back the bed and open the bedroom windows, and in about half an hour the room will be thoroughly ventilated. She can then return to the room and begin its rearrangement. The whole process of cleaning and dusting must be carried out with great care. Every particle of dust must be removed, the ornaments dusted, glass and silver ornaments polished, and the dressing-mirror and handglass cleaned.

The silver will need particular attention, especially in a town where the fog and smoke will quickly blacken it. The hairbrushes should also be cleaned. All hair is first drawn out of the bristles with the comb. Some very hot water is placed in a basin, and some soda added. The brush is then cleaned by dipping the bristles in and out of the hot solution, care being taken to keep the handle and back of the brush quite dry. When the bristles are clean, they should be rinsed in cold water, and then shaken, to dry them as much as possible. The final drying may be effected by the sun, which will whiten the bristles, or by the fire, which will make them rather stiffer. In any case, the bristles must not be rubbed with a cloth, as such treatment makes them soft. A little ammonia may be added to the washing water, but no soap should be used. The comb should but seldom be washed. It can be effectively cleaned with a small brush, or by rubbing on a clean cloth.

Duties in the Bedroom. The housemaid will probably help the lady's-maid with the process of bedmaking and the other details of the bedroom arrangement. She should study her mistress's personal likes in all these details, and do her best to please her in every way. In putting away her mistress's dresses, the maid should see that they are well brushed, and that any little attention in the way of mending or renovating is not neglected. She should then examine the dresses that her mistress will wear later in the day, and put them out in readiness for use. She should also notice carefully that nothing is wanting in the rooms under her charge. Should anything be missing, she should tell her mistress before she goes out, so that she may give orders for its purchase. She should see that her mistress's apartments [illegible] dresses, after a short [illegible] replaced in the wardrobe.

The Maid's Wardrobe Duty. The greater part of the day will be devoted to needlework—making, mending, renovating, altering; which duties will keep her busy day after day. In a thousand little ways the lady's-maid who is skilful with her needle can make herself invaluable. In the matter of mending, she should take charge of everything except stockings and woollen underwear before it goes to the laundry. A small rent will become larger if not mended before the garment is washed.

When the linen has been carefully overhauled, the maid should make a list of all that is sent to the laundry, and check the articles when they are returned to see that none are missing. In spite of the mending previous to the sending to the laundry, many little repairs may be necessary after their return. Buttons will doubtless be missing, tapes torn off or allowed to "run out"; these defects must always be remedied. Then, if the mistress prefers narrow, coloured ribbons to tapes in her underwear, the lady's-maid should remove these, and also fragile lace, before sending the article to the laundry; wash them carefully herself, and replace them afterwards.

Dresses of soft, crushable material, such as washing silk or muslin, will need attention every time after wear. They will become crushed, and need smoothing with an iron, although they are not dirty enough to send to the laundry.

Travelling. Many ladies take their maids with them when paying visits. In any case, it is the maid's duty to pack the travelling trunks. The maid should lay out all that is necessary for her mistress's visit, and ascertain exactly what her wishes are with regard to which dresses shall be taken, etc. The dress-trunk should then be carefully dusted and packed.

Heavy articles, boots and shoes, should be placed near the bottom of the box, and the linen spread flat to form the next layer. Above this should come skirts, etc., and lastly, bodices, blouses, and dainty articles that are likely to crush. Between the various layers plenty of tissue paper should be placed, and care should be taken to protect by an intermediate layer all light coloured articles from those of darker tint. Special covers of linen or white calico may be used for very delicate articles, and the greatest care must be taken that bottles containing perfume, toilet lotions, etc., are securely packed in corners where they are not likely to upset.

During the journey the maid will probably travel in an adjoining compartment, and should be in readiness to wait on her mistress should there be any changes or long waits at intermediate stations. Arrived at their destination, the lady's-maid will be shown her mistress's room, where she should unpack, and try in every way to make all as comfortable as possible. During the visit her duties will be much the same as those which devolve upon her at home. She will be responsible for personal attendance on her mistress, and should always be in readiness to wait on her when summoned by the bed-bell. She will take her meals in the housekeeper's room, where the need for reticence on her mistress's concerns is, of course, even greater than at home.

THE FOOTMAN

The duties of the footman vary considerably, according to whether he works single-handed or whether there are other footmen working under him. Where others are kept the head footman works in conjunction with the butler. He helps in, or supervises, the laying of the table for meals, and in the serving of afternoon tea and coffee after dinner. During meals he waits at table, under the butler, taking precedence of the other footmen. In the afternoon he should be in readiness to answer the front-door bell. If a valet is not kept, he will doubtless be required to give a certain amount of personal attendance on his master, looking after the brushing and putting away of his clothes, and preparing his room for the morning's toilet.

If there are visitors in the house who have not brought their own valets, he will probably be called upon to give them similar personal attendance. He will have no responsibility with regard to the washing of glass and the polishing of plate beyond that of seeing that the under-footmen carry out their duties in this direction efficiently.

Duties of the Second and Third Footmen. The second footman has more onerous duties than those of the head footman, whom, in every way possible, he is called upon to assist. He may occasionally wait in the hall if many visitors are expected. His table duties include assistance in waiting, and in the washing of the glass and silver used in the dining-room. In the afternoon he may be called upon to go out with the carriage if the ladies of the house wish to pay calls. In this case he should see that they are seated comfortably, and the rugs and wraps adjusted satisfactorily. He should place the umbrellas or sunshades in the carriage, and take from his mistress her order to the coachman as to the direction of the drive. He will then close the carriage door, and mount to his seat beside the coachman. When the house at which the mistress intends to call is reached he should descend from his seat, ring, and find out if the ladies are at home, telling his mistress and awaiting her orders.

The third footman is responsible for the heavier dirty work, such as cleaning the knives and boots, filling the coalscuttles, etc.—in fact, carrying out the duties of a houseboy, if one is not kept.

GENERAL MANSERVANT

The single manservant does not wear livery, but his duties combine the most important items of the work of a butler, footman, and valet. He should rise early, and get such work as boot and knife cleaning finished before breakfast. He should see that his master's clothes are brushed, and that hot water is in readiness in the dressing-room. He should then take his own breakfast, and afterwards set that of the household. After he has put the hot dishes on the table, he will probably not be required to wait at table, but may withdraw and begin to busy himself with the morning's task. This may be plate-cleaning, etc.; and he will also have to answer the front door.

He will then set the luncheon, and attend at that meal until he is dismissed from the room, when he may retire and take his own dinner. After luncheon he will clear the tables, clean and wash the plate and glass used, and

in the afternoon he will generally answer the front-door bell, or go out with the carriage. In the evening his duties will include the laying of the dinner-table. He may be assisted by the parlourmaid, and also in the waiting at table during this meal. After dinner he will clear away, either unaided or assisted as before, and a little later bring in the coffee.

Characteristics of a Good Footman. Certain physical characteristics are generally required in a good footman, such as fair height and good carriage. He should be invariably attentive and polite. He may often be sent on messages, or with notes, and should restrain his curiosity as to their purport, and take only such time as is necessary for their delivery. In bringing a note or a card to his mistress he should offer it on a salver. In answering the door he should announce visitors distinctly by name, being careful to listen attentively when the visitor answers his query, "What name, please?" Then in opening the front door for departing guests he should close the carriage door, unless they are accompanied by a footman. The front door should not be closed until the visitors are a short distance from the house.

Coachman-gardener. The single manservant sometimes confines his attention to outdoor work. The garden may fall to his share, and the rest of his time be devoted to boots, knives, window-cleaning, and the carrying of coal and the trimming of lamps. In such households the outdoor manservant may also be required to act occasionally as coachman, should a carriage of any description be kept. In this case, his time will be fully occupied with his outdoor duties and those enumerated above, which include the rougher housework.

He will not be required to do any other indoor work, or to wear livery, except perhaps when out driving. The outdoor manservant will probably be required to arrive about seven in the morning. Before breakfast he will probably clean the boots and bring in the coal. Then he will go home to his breakfast, unless by arrangement he takes it with the other servants of the household. He will busy himself in the garden until after dinner, when he will probably be required to drive his mistress. On his return he will have the carriage to clean and the horse to look after, and about 6 p.m. he will be free to leave. He will doubtless be required to call at the house for any particular orders, or to take letters to the post.

PAGE AND HOUSEBOY

The page wears a livery, and his duties vary considerably in every household. In some, where he is kept as a concession to appearance, he will be expected to be neat, and ready always to answer the front door. He may also have to wait at table and carry messages. In the case of professional men, it is almost a necessity for a page to be kept whose almost exclusive duty it is to answer the front-door bell. In other cases a boy is kept who does not wear livery, nor appear beyond the kitchen precincts. Such a boy is a useful adjunct in a house where no other manservant, either indoor or outdoor, is kept.

The chief work of the houseboy is to perform tasks which are too heavy for the maidservants. For example, he will bring in coal, clean the knives and boots, and in general make himself useful to the cook and housemaid. Both page and houseboy may, by making good use of their opportunities, fit themselves to perform more important duties as they grow older. The most capable butler is generally the result of many years' training in a gentleman's house. By beginning when young at the bottom of the scale he may gradually work his way upwards, learning in turn the duties of each indoor manservant from page to butler. In this way, by the time he is old enough to undertake the onerous and responsible duties of butler, he has gained a thorough knowledge of the duties of each servant he will have to supervise. His knowledge of their duties will be thorough, and will enable him to so direct the work of those under his control that he will ensure the most efficient service for his master.

THE COACHMAN

The coachman is the head of the stables, and should have a wide experience in dealing with horses. He should be skilful in driving, and able to decide wisely in matters concerning the exercise and feeding of the horses entrusted to him. Experience should have taught him how to deal with the minor ills which affect horses, and he should be able to discriminate between unimportant trifles and the symptoms of more serious disease. The coachman's chief duty is to drive, and to drive well. Incidentally, he will have other duties connected with the care of the horses, the stable arrangements, and the cleaning of the carriage, but his chief work is the management of the horses. He will probably be required to assist in their choice, and so should be a judge of horseflesh. In selecting a pair he should endeavour, if his master allows him to assist in the choice, to select two that are well-matched, not only as regards colour and height, but also in habits and pace. Should they differ widely, he must use his discretion in making them work together as harmoniously as possible.

He should see, before driving up to the front door to fetch his mistress, that everything connected with both carriage and horses is well-arranged and in order. He is not expected to descend from the box, even should no other manservant accompany the carriage, for the ladies can open the door from the inside themselves. During the drive the coachman should confine his attention to the horses, and avoid any distraction which might lead to an accident. He should avoid letting his horses get into lazy habits, but at the same time he must not overdrive them. [See DRIVING.]

MINOR FIBRES & STRUCTURE OF FIBRES

Conclusion of the Survey of the Raw Materials of the Textile Trades.
The Microscopic Structure of Fibres in Relation to Commercial Value

Continued from page 731

By W. S. MURPHY

Rivals of Cotton. Sometimes the merits of neglected fibres are re-discovered and brought before the world by ardent enthusiasts. *Madar, Mudar*, or *Yercum*, is one of those fibre plants about which extravagant hopes have been raised, with disappointment and consequent reaction. About the middle of the nineteenth-century textile manufacturers were informed that this tree was the universal provider of textile fibres. It was, in itself, a producer of wool, cotton, and flax. These extravagances had a basis in fact. From the large pods of the fruit a fine silky cotton floss is derived, and the inner bark of the tree contains a fibre admitted to be one of the finest of all vegetable fibres. When it is further understood that the plant will grow abundantly, without care or culture, in any tropical climate, on soils otherwise barren, the hopes excited by its discovery may be appreciated. The floss could be spun, but it lacked the mobility and tensile strength of the fibres already in use, and no further trouble was taken with it. The bast, or stem fibre, too, offered difficulties when subjected to commercial tests. Bark-stripping by hand was costly, and no machine had been invented to do the work. Other objections, more or less unreal, were raised, and the discouraged friends of the fibre deserted the cause. We think renewed attention ought to be given to this plant. The French now utilise it in the manufacture of fans.

Another plant of great possibilities is the *Paper Mulberry*, found growing wild, and extensively cultivated throughout Eastern Asia and Polynesia. It is a small tree, and the fibre is found in the bark. The Japanese already use the bark for making fine papers of wonderful strength; they also prepare the fibre for spinning and weave it with silk, while the yarn by itself is made into a strong cloth resembling corduroy. Expert opinion favours the paper mulberry above ramie, though the fibre is chiefly known in this country as a paper-making material.

Rivals of Ramie. Among these the *Ban*, or *Bon Rhea*, of Assam may be mentioned. It is a nettle, closely related to its better-known rival, and produces a fibre of great strength and fineness, which possesses the power of resisting moisture. The Assamese use it for fishing-lines and nets. We understand that it has been favourably reported on to the Indian Government, and successful cultivation in Assam would greatly enhance the reputation of the fibre; but the labour difficulty in that region presents a serious obstacle to immediate experiment.

19. KAPOK
Which yields a valuable stuffing material

A Fine Floss. *Kapok* [19] is a silky white floss developed in the fruit pods of the white silk cotton - tree, which grows largely in India, Ceylon, Africa, and the West Indies. The pod varies from 3 to 4 in. in length, and measures 2½ in. in diameter at the centre, tapering to blunt points at both ends. Of a yellowish buff colour when ripe, it splits open lengthwise, and a heavy tress of fine floss springs out. Originally started from Java by Dutch merchants, the trade in this material has attained considerable dimensions, and it deserves close attention. As a vegetable stuffing material, kapok has no superior. As "vegetable down," it commands a good price on the London market.

The Basis of a Colonial Industry. *New Zealand Flax* [20] has been misnamed; it is not a flax, and belongs to the lily family. When properly dressed, the fibre can be used for most of the purposes for which flax is used; but

careless gathering and dressing have greatly reduced the market reputation of the fibre. Perhaps the fact most important in connection with this fibre is the establishment of an important industry in New Zealand on the basis of "Phormium tenax," as the plant is named. Alone in Australasia, New Zealand has flax manufactures, the industry employing, in 1903, 2,637 male workers.

Allies of Flax. *Ban Ochra*, or *Toja*, grows in the tropics of both hemispheres. The fibre, which can be easily treated, is said to be a good substitute for flax.

Red Sorrel grows in the West Indies, and is widely cultivated throughout India and Ceylon for the sake of its fleshy calyx, from which an excellent jelly is made. The fibre from the stem is strong and of silky quality, largely used by the natives for cordage.

20. NEW ZEALAND FLAX

The *Pineapple* is well known as a fruit, but it may be made to yield also a very good fibre, capable of being woven into fine fabrics. A native of tropical America, the pineapple has been successfully cultivated in South Africa, and all over Australia, the crop being specially cultivated in Queensland. The fibre is derived from the leaves of the plant, and as growers, for the most part, cultivate for the fruit, the best quality of fibre is derived from the wild plants. If the fibre were to come greatly into favour, as it might very well do, growers would pay more attention to the development of the leaf. Fibre has been taken from the pineapple leaf 6 ft. long.

Hempen Fibres. The *Abrome* abounds in the hotter parts of India, and is cultivated by the natives for its fibre, used for cordage. This little bush should be better known than it is, because its fibre is fine, white, lustrous, and strong, and might be used as a substitute for silk. So quickly does the plant grow that three crops can be reaped in one year. It responds to cultivation more gratefully than either jute or Sunn hemp.

The *Ko Hemp* plant is a native of China and Japan, where the prepared fibre has long been woven into summer under-garments. The cloth keeps free from the skin under conditions when all other fibres cling.

Dunchi has been cultivated for many centuries by the natives of the marshy districts of India, and it is found all over the tropical regions of the Old World. The plant is a hardy annual, and the fibre is a good substitute for hemp.

Sisal plant [21] is grown extensively in the Bahamas, and is second only to Manilla hemp in value as a rope fibre. It is an attractive plant, with a thick bush of spike-pointed, fleshy leaves, and a straight, flowering stem rising from the centre. Sisal hemp is easily grown, and the fibre [22] is separated by a very simple process.

The fibre of the *Ochro*, or *Gombo*, is very white, strong and pliable, but the plant is grown for its fruit, which is used as a food, and the fibre is not much considered. It will grow almost anywhere in a hot climate, and should be a valuable source of fibre.

The plant known as the *Bola*, in Bengal, is one of those vegetable products which flourish best in conditions fatal to all others. On the sandy tracts of Northern India it grows profusely, and the fibre—a strong, useful substance, suitable for cordage and ropes—parts from the outer bark with little trouble.

21. SISAL PLANT
[Bahamas]

Varieties of Jute Substitutes. *Musk Mallow*, the seeds of which are useful to perfumery manufacturers, is a tropical plant of luxuriant growth, yielding a fibre of a quality resembling jute at the rate of about 800 lb. to the acre.

Bolobolo is a handsome flowering shrub, native to Sierra Leone, Senegambia, the Cameroons River, and the Congo. Closely allied to the jute plant, it yields a stronger, finer fibre, and would command a higher price on the market.

Sahadebi is a wild plant of the mallow family, growing abundantly all over India, and distributed all over the tropics. Closely related to jute, according to Dr. Watt, editor of the

"Dictionary of Economic Products of India," "its claims to superiority over jute are very considerable. The fibre is not half so coarse as jute, and it is of a much purer quality, and can, therefore, be spun into finer yarns."

Another rival to jute, of the mallow tribe, is the *Ran*, or *Banohendi*, generally supposed to be a native of the tropical zone of West Africa and tropical America, but found abundant in the damp lands of Bombay. It yields a fibre almost as soft as silk, 8 ft. to 9 ft. long.

Other Rope-making Fibres. The *Kanghi*, of Hindostan, a small mallow, distributed throughout the tropics, yields a strong fibre suitable for ropemaking. Its relative, better known as the *Indian Mallow* or *American Jute*, has a softer fibre, and is regarded as a jute by the Chinese, who produce large quantities of it. The plant flourishes over a wide area, both in Asia and North America, having become a troublesome weed in the middle States of the latter continent.

22. SISAL HEMP

Nilgherry Nettle. Belonging to the order *Urticaceæ*, and a near relative of the common stinging nettle, this plant grows in great profusion throughout the forests of the hilly districts of India, Burmah, and Ceylon. The stem is from 5 to 7 ft. long, and yields a fine fibre of great strength and high spinning value. Natives of the districts where it grows weave it into a cloth which strongly resembles silk. The season for cutting is between August and September. After being cut, the stems are stripped of leaves and dried in the sun. Dried hard, the stalks are boiled for twenty-four hours with wood ashes, and then washed with water. This preparation separates the fibres from the rest of the stem, and the long tresses are dried again in the sun. When dried, the fibres are spun into yarn or made into cordage. The yarn is woven into a fine cloth of wonderful texture and durability. Like most plants which seem to be candidates for textile honours, the Nilgherry nettle has had its day of "booming." Of the excellent spinning quality of the fibre there never has been much question; but it has one defect which repels. Being a large and powerful nettle, it is covered with stinging hairs filled with a virulent irritant extremely annoying to the gatherers of the stems. Nor does the preparatory process altogether destroy this stinging property. From all accounts, it seems that the cloth would make a very good modern substitute for the shirt of Nessus, the stinging filaments passing into the body of the fabric. Perhaps some means might be devised for destroying the noxious quality, which, for the present, is sufficient to exclude the fibre from the European market.

Scarcely so well known as the Nilgherry nettle, and free from its main defect, though of the nettle family, is the shrub known to botanists as the *Debregeasia hypoleuca*, abounding in the western Himalayas, Afghanistan, and Abyssinia. Growing to a height of 9 ft., the stalk about the thickness of a man's finger, the shrub has potent claims upon the attention of users of bast fibres. When subjected to the same treatment as flax or hemp, the stem yields a strong fibre, white, clean, and delicately fine. Its textile qualities have never been thoroughly examined. Because it does not rot in water, the people of the lands where it grows use the fibre for fishing-nets.

Coir. Coir is one of the best known rope and mat fibres. It is derived from the unripe nut of the coco palm. Emptied of its succulent contents, the nut is immersed in water and retted for a period of six months. When taken from the pits, the nuts are denuded of fibre by beating with sticks. While yet soft, the coir is spun into yarn by the natives, and comes to this country in huge coils of hard, crinkled fibre. Being very light and strong, coir was used in the making of the earlier deep-sea telegraph cables. Lacking the flexibility of hemp, coir is best suited for ropes having a straight pull, and does great service on docks and quays. In many departments of industry coir has been displaced by wire ropes. Coir has found another outlet in mats, and for this the fibre has many good qualities. It may claim, indeed, to be the most serviceable of the mat fibres, combining durability with flexibility.

Of fibres which may be utilised in the production of ropes and cordage there is an almost endless variety, both wild and cultivated; but, in the majority of cases, the fibres are consumed in the localities where they are grown, and therefore can only be considered as remotely potential, not actual, sources of fibre supply. In the list given, we have kept within the limits of the practical. Many experienced manufacturers will accuse us of having far exceeded that limit; but the present is a time of rapid progress, and the resources of the world are being swiftly developed. The purely scientific abstraction of yesterday becomes to-day a powerful factor in industry.

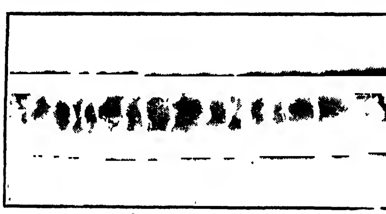
THE MICROSCOPIC STRUCTURE OF TEXTILE FIBRES

By William I. Hannan, Lecturer on Fibre Technology

EXAMINATION of the fibres of commerce under the microscope reveals distinctive features and explains in great measure the peculiar fitness of respective fibres for certain purposes. A glance at the properties of fibres revealed under great magnification will have an interest both practical and academic. The microscope is being called into service more and more as science is taking the guiding reins in modifying and developing modern industry. In the textile trades it has not yet attained the importance it possesses in the metallurgical and other manufacturing industries, but the tendency is all in the direction of greater knowledge through its instrumentality.

Wool. The illustration [25] shows wool fibres under a high state of magnification. The centre fibre has well-developed scales, that are almost closed and overlapping on the surface of the fibre when the yolk or suint has been removed. But here and there, on the left-hand side of the picture, are a few dot-like interruptions, which are evidently particles of natural yolk. The centre fibre is a fine specimen of a well-grown wool fibre, and the next fibre to it shows a graceful bend which extends over the greater part of the field. The third fibre has a stouter appearance, with a dense structure, and, as it is crossed by the fourth fibre, it is fairly well bedded underneath. The fifth fibre is crossed by two others of nearly similar thickness; and on the plate there is a translucent crossing of two fibres resembling a Maltese cross, which is always an object of interest when viewed with an objective with a clear penetration, such as the one used on this occasion. In the more highly magnified illustration [23], the photographer has brought into notice the typical structure of the wool fibre under the best natural conditions.



23. WOOL FIBRE
[Enlarged 294 diameters]

As the wool fibres are bent, the contraction of one side is not at all ugly, and the cylindrical part shows up well; and such fibres when treated properly in the machines they pass through, become well cleaned, and act well as they interlock and incorporate with companion fibres in the felting of the cloth.

Silk Fibres. Silk fibres, when seen under the microscope [26], have, on account of their transparency, been likened to a cylindrical glass rod. They are a wonderful development of the animal kingdom. Silk is a consolidated, flexible gum, and its value can hardly be overestimated in the textile industries. It is produced from two glandulose structures or *spinnerettes*, one on each side of the body of the silkworm. The silk fibre is thus a twin fibre, with a groove between the two parts, as clearly indicated in the photograph. This grooved structure is not visible to the naked eye, but is shown very plainly under high magnification. It is probable that the grooved structure adds strength, but, in any case, it allows the light to penetrate the body of the fibre and shows up the tinctorial hues and dyes which silk retains so well and which makes it so highly prized as a fabric of fashion. The fibres of silk may be distinguished from those of cotton or linen by the use of Schultze's solution, which is also the chief test for cellulose structures of the plant kingdom.

The character and structure of a silk fabric may be readily seen to advantage when viewed with a "Coddington" lens, which is of high magnifying power. If the details are not seen as clearly as desired, a microscope may then be used; but in all cases of raw fibres where specific and structural discrimination is desired, it is wise to carry a "Coddington," or, at least, a triple lens, in order to bring out details not easily seen with the naked eye. The "Coddington" lens is used by many yarn agents, cotton and silk manufacturers, buyers, and some cotton brokers.

Fibrine is the chief constituent of silk. It is surrounded by a coating of albumen, which is, in turn, covered by a layer of gelatine. Other constituents of the silk fibre are fat and some colouring matters. The waste of silk is known as *flourette* and *bourette*.

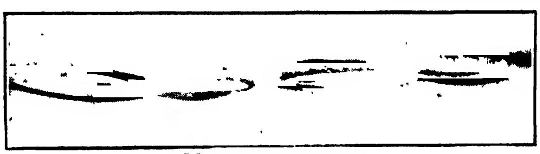
Cotton Fibres. Cotton fibres must be seen under the objective of the microscope in order to observe the natural convolutions of the cell fibre, upon which the real spinning qualities depend; and this method of examination is more important than the price paid in the cotton markets. At many of the best secondary and technical schools in Lancashire the structure of fibres is not clearly taught. Young men trained in such schools accept important situations where fibres have to be dealt with and judged every day, and they lack a knowledge of fibre structure; while young Germans, thoroughly instructed in this important department of textile technology, step into the same office and push them aside.

A glance at 27 shows most clearly the highest stage of development which a cotton fibre can undergo. The fibres shown were "alive" on the cotton seed not long before being photographed. The terminal parts of the fibres are not shown on the plate, but if they were they would mark out the solid end of the fibre which is unsuitable for spinning, and is, therefore, cast out. The solid end referred to has been styled the *cone* of the fibre.

At the top of the photograph are two fibres of special interest. That on the left-hand is fully ripe, with a spiral outline, and at every necklace-like division there appears a dense mark, which

represents the inner colouring matter of the protoplasm, which has been termed the *Endochrome.* This colouring matter is almost entirely absent in many of the American cotton lint, staples, and fibres. The brown Egyptian cotton fibres so highly represented on the field in incumbent positions, show the colouring matter well, and may fairly represent the fibres of the brown yarns, of fancy twists, and wefts. One of the fibres near the centre of the plate curved to the left shows a broad diameter in the middle portion, and is typical of East Indian cotton fibres generally. At the bottom of the plate are two fibres with a uniform diameter, one curved to the right and the other to the left of the plate. This feature is characteristic of the American group of cottons, and the fibre area, highly magnified [**24**], shows the clear cell and wall. The fibre on American cotton seeds is persistent, and when the lint has been removed a downy coating of shorter fibres invests the seeds. This coating is sometimes used for paper-making, and in commerce the name of *Shakers* has been given to it. There are no stomata in cotton fibres, not even in the one separately photographed and so highly magnified.

Flax Fibres. In the illustration [28] there is shown an example of the bastose tissue fibres of the well-known flax of commerce. The fibres, when in a young state, are centred in the inner tissues of the straw-like structure of the stem, and when the cortex or outer tissue has been removed by a process of retting, which has a destroying action on the over or outer coat of the stem, we have the fibres as shown.



24. COTTON FIBRE
[Magnified 294 diameters]

The plant is an annual, but it grows fast, and the fibrillous root hairs pick up quickly the food in the soil, and transform it into the protective and reserve tissue material.

The photomicrograph shows the character of the structure which facilitates the spinning qualities of flax. The fibres, as seen on the plate, are round and taper to an exceedingly fine point at each end. They are almost mucronulate. From the fine-pointed ends the fibres are broader, as may be observed, and of hard bastose consistence, with numerous pits or depressions. The presence of these pits prevents the fibres, when contiguous, from slipping, and this makes flax similar in its cohesive qualities and behaviour to cotton.

It must not be forgotten that the flax fibre is a multicellular structure, and is endowed with properties which cotton does not possess; therefore, flax must be regarded as a *true fibre;* while cotton has a single-celled structure. Commercially, however, flax is commonly termed a "linen fibre." The natural structure of the flax fibre facilitates spinning and weaving, and imparts the peculiar and valuable properties distinguishing *true* linenwoven fabrics. The flax fibres have an incumbent tendency in the cloth, and this has much to do with the secret of making the finest and most durable fabrics that can be woven.

Jute Fibres. The fibres of jute are obtained from the bast tissue, the most strengthening portion of the stem of the jute plant. They must be styled *bastose* fibres in contradistinction to those of cotton. The surface hairs of the cotton seed are intended to transport the seed when thoroughly mature.

Jute fibres have been compared to gas and water pipes. The finer cellulose features may be likened to the micellæ of fine tissue which has only partly undergone the woody change in the cell wall and tissue structures. The fibres are strong, and they owe their strength to the structural parts of the tissue and the glossy, silky tissue of the cells which have become solid.

When the cells have undergone their hardening process, the vital or protoplasmic, active element of the cells may move to other important building-up parts, and so leave a cavity or space, which imparts value in the spinning properties. This hardening of the cell tissues may be compared to the grand period of growth that takes place in a cell wall when it arrives at its mature stage of development.

The strength and distending property of hard bast fibres of jute, ramie, and, in a less degree, of flax, must depend on and has been compared in mechanical structure and fineness to steel. Nevertheless, the fibres of jute and similar plants are found to be the best cellulose material for pliability, elasticity, and cohesion in the making of cordage and fabrics to stand hard wear, and for strings for spindle wharves. The fibres in **29** are good examples of the jute fibrous structure. It must always be remembered that the strength and fineness of the tissues are the chief factors of jute fibres.

Ramie. Under the microscope, ramie appears as a flattened tissue structure, with very delicate transverse markings. In the illustration [30] there are some fibres with faint lines apparently longitudinally striated, and if these depressed lines were constant in the tissue we should have a stem structure that would compete with that of cotton fibre. The faintness of the markings on the stem or bastose tissues probably causes the fibres to be so highly polished, and so tender in the bend. The same characteristic imparts the fine elasticity when stretched, and causes them to break with an extreme springiness when distended beyond their tensile strength, but they pull finely when skilfully drawn out with the fingers of both hands. When these fibres have undergone a bleaching process, the faint markings seem to be suppressed, and the lustre shows up much better.

The ramie of commerce has its fibres always centred in the stem structures.

WHAT DARWIN BELIEVED

Darwinian Theory of Evolution. Doctrine of Natural Selection. Facts on which the Doctrine is Based. Adaptation to Environment. Formation of New Species

Continued from page 651

By Dr. GERALD LEIGHTON

THE Darwin theory of organic evolution was given to the world simultaneously by Charles Darwin and Alfred Russel Wallace in the year 1858. These two great naturalists had been working quite independently upon facts which they had collected in entirely different parts of the world, and, as the results of their independent consideration of these facts, they reached a common conclusion as to the mode of origin of the various species of animals and plants now found in the world. The history of the publication of these views is one of the most interesting pages of scientific records.

How Darwin Changed the Trend of Thought. It is not too much to say that the publication of Darwin's views has changed the whole trend of thought in the modern scientific world. At first his opinions were received with strong and even bitter opposition in many quarters, especially after the issue, in 1859, of "The Origin of Species;" but from that date to this they have gradually gathered support from all educated people, until now either Darwinism, or some view of organic evolution which has been built upon Darwin's work, is held by everyone who has taken the trouble to make himself familiar with the facts of biology. A theory which has achieved such a result, which has altered our conception of things in almost every department of life, demands careful attention, and must be studied somewhat more fully than others which have been more or less discarded.

Although Darwin accepted the theory of Lamarck to a certain extent, he very clearly perceived that it was totally inadequate to explain all the facts. He was also of opinion that acquirements may be transmitted to offspring, and play their part as factors in organic evolution. But he also saw that parental surroundings and environment could not be the sole cause of the variations of offspring, or else a litter of puppies all born from parents having the same environment would all inherit the *same* acquirements. Instead of that being the actual case, Darwin noted that such puppies might be superior or inferior to their parents in regard to particular qualities, and that they might present entirely new variations. He deduced from cases of this kind the opinion that there must necessarily be some other reason or causes of variations in offspring than merely the transmission of the acquired characters of the parents. On that undoubted fact he based his theory.

From this deduction he proceeded to enunciate the doctrine which will ever be associated with his name—*viz.*, the doctrine of *Natural Selection.*

What Natural Selection Means. It is to be noted that Darwin did not attempt in his theory to account for the differences or variations he found to exist. He simply noted the fact of their existence, and pointed out that some of them could not be attributed to the transmission of acquired characters. In the absence of any adequate explanation of these variations they were termed *spontaneous* or *accidental*, in the sense we have already explained. Darwin then came to the conclusion that Nature acted as a breeder would do, selecting certain of these variations from which to continue the race, and rejecting others. Those which were rejected were in time eliminated. He supposed that as a general rule Nature selected the *superior* individuals to continue the race, the superior individuals being those which possessed some variation which rendered them particularly well adapted to the environment in which they found themselves. He was driven to the opinion that some sort of selection was at work by ascertaining that the number of individuals in any species of plant or animal which survive and have offspring of their own is not identical with the number that come into the world. Some disappear.

The question which suggested itself to him was, Which individuals do not survive, and why are they the ones to be eliminated? The answer which forced itself upon him was that the survivors must be those which are better fitted to their surroundings. Nature selects these and eliminates the less fit. This is Darwin's doctrine of natural selection.

The Struggle for Existence. For a considerable time there were many people who could not, or would not, see the necessity for some kind of selection among offspring. Indeed, there are still a few who deny the struggle for existence. They are an ever-diminishing number, and in view of the facts of the case it is very difficult to account for such an attitude.

In the first place, it is perfectly obvious that there is only a limited amount of space on our earth which is habitable for any given species. There must, therefore, be some limit to the number of either plants or animals which can "make a living" at any given time. A certain number only, from the nature of the case, can exist together. In the next place, it is a simple fact that every living creature tends to increase in numbers, some more rapidly than others, but all more or less rapidly. Yet if we examine any given species in a certain locality we find that, in spite of this fact of continuous and uninterrupted reproduction. the total number of individuals in that locality remains fairly constant. There may be some increase or some

decrease, but, speaking generally, the numbers do not change to a great extent unless the surroundings also vary. It follows that some kind of check must be operating to keep the numbers within limits.

Nature's Checks on Overcrowding. Let us take an example to illustrate this point. The elephant is an animal which increases in numbers with the *minimum* rapidity. It has a family of six only during a period of some sixty years on an average. An individual elephant lives for about one hundred years. If every elephant which is born survived and had the average number of offspring, the result would be that we should find a *total of about nineteen million elephants descended from a single pair after the lapse of from* 740 *to* 750 *years.* This, be it noted, in a species which breeds with extreme slowness. Such a result, of course, does not occur.

Still more striking would be the result in the case of an animal which increases with great rapidity. Take the case of the field vole. This little mammal produces several broods during the same summer, and some of these young ones in their turn breed before the winter. It has been calculated that if there were no checks to the increase of the field vole, *a single pair* of these animals, supposing their first brood to be born on April 15th in any given year, would produce by October 8th following no less than 193.

Occasionally it does happen that the ordinary causes which keep down these numbers fail to operate, with the result that enormous numbers make their appearance in certain localities, doing extensive damage to crops. Such seasons are called " vole years." A similar phenomenon is seen sometimes on the introduction into a new country of a species which in its native land was kept down by natural checks. These checks may not be operative in the new habitat, and the result is the enormous mulitiplication of the introduced species. The rabbit in New Zealand and Australia is a case in point. The sparrow in the same countries is another.

Life is a Constant Fight for Life. Since this enormous and phenomenal increase in numbers of offspring stated above *does not take place* under ordinary conditions, it follows that there must be some kind of very stringent means to prevent it. There is not room nor food nor opportunity for all to survive and multiply. In other words, life is a constant fight for life ; it is, in the language of the Darwinian theory, a constant *struggle for existence.* Every single plant and every single animal which is living under natural conditions is continually engaged in a more or less keen competition with others of its own species, and also with other kinds of plants and animals. Not only has the plant and the animal to compete with plant and animal, but each has also to struggle against the ever-changing climatic conditions which form part of its environment. The living have to contend with the non-living physical forces around them as well as with the competitors of their own kind. The inevitable result is that those individuals which for any reason surpass others in this continual struggle with environment are the individuals which survive and perpetuate their kind. They are *naturally selected.* The battle is to the strong. The weak go to the wall. In a word, the keynote of Nature is the *survival of the fittest by natural selection in the struggle for existence.*

Who are the Fittest? It must be carefully borne in mind that the term *fittest* in connection with organic evolution has a definite meaning. It does not mean exactly what is implied in the everyday use of the term: It does not necessarily mean what we might be inclined to call the *best.* It means the best in a biological sense only. The term refers to the individual and his surroundings. It means that individual which is most fit for the environment in which it is placed ; best in that sense. Since all individuals vary somewhat, it follows that some are more fit—are better, in this sense—for the particular environment in which they find themselves. It cannot be otherwise ; it is an everyday experience. As long as the environment acts upon all alike, as it does under natural conditions, it follows that the fittest will survive, while the least fit are eliminated.

The other factor which completes the Darwinian theory is the influence of heredity. No one can possibly deny the fact that *certain characters* can be and are transmitted from one generation to another. Darwin believed that natural selection operated in the direction of choosing in a species those individuals which had varied in a way which gave them some advantage over their fellows, and that their favourable variations were transmitted to their offspring. He did not, it will be remembered, attempt to account for these favourable variations. He termed them spontaneous.

But he came to the conclusion that, no matter how these variations originated, the individuals showing variations which adapted them to their surroundings would have the best chance of surviving and having offspring. They would be the fittest to survive in the struggle for existence. The result of the mating or pairing of individuals thus favoured would be to hand on to their offspring their useful variations by means of heredity, and as these advantageous variations accumulated, there would ultimately be produced creatures which would constitute new varieties or new species. The selection by Nature was thus a selection of useful or advantageous variations which were transmitted to offspring by heredity.

The Simple Meaning of Darwinism. These useful variations, Darwin thought, were generally slight in amount, but sufficient to confer upon their possessors some advantage in the struggle for existence. In the case of the antelope, for example, those individuals which possessed slightly more endurance, speed, scent, and so forth, would be better able to survive than their less-favoured brethren ; they would therefore be selected, would hand on advantageous variations to their offspring by means of heredity, and so in time there would be evolved the creature with which we are familiar.

This, put in the simplest way, is the meaning of Darwinism. It does not mean, any more than does evolution, that man is descended from a chimpanzee. It accounts for the origin of species by natural selection. Before considering other points in connection with this view we may conveniently summarise the whole theory.

Two Facts and Their Meaning. Darwinism is founded upon two well-ascertained facts from which two inferences are deduced.

The *facts* are as follow:

(*a*) The universal occurrence of variations in individuals of every species.

(*b*) The number of individuals in any species which survive and beget a full quota of offspring is not the same as the number of individuals which come into being, great numbers perishing before reaching either maturity or old age.

The *inferences* are these:

(*a*) As a rule the individuals which survive and have offspring are those which are better fitted to the environment in which they are placed than are those which perish.

(*b*) By this survival of the fittest in the struggle for existence and the consequent elimination of the unfit, the average of the race is raised in successive generations by means of heredity, the result being the gradual evoluti n of living creatures.

A very clear way of stating the theory is that of Professor Ainsworth Davis, which is as follows:

PROVED FACTS:

Limited surface of globe and rapid increase in numbers.
Struggle for existence and variation.
Natural selection and heredity.

NECESSARY CONSEQUENCES:

Struggle for existence.
Natural selection, or survival of the fittest.
Origin of new species.

Can Acquired Characters be Transmitted? We have now stated in the barest outline the two great theories of organic evolution—the Lamarckian and the Darwinian theories. At present neither of these theories is held, to any great extent, *in quite the same way*, or in the same terms, as those in which they were originally propounded. Much has happened in the scientific world since Darwin gave the world the theory of natural selection, and his modern followers, while accepting his main contentions, declare that he underrated his own discovery.

It will be remembered that Darwin simply accepted the undoubted fact of universal variation without attempting to account for it, and at the same time denied the teaching of Lamarck that it arose entirely from the transmission of acquirements. His modern followers, the Neo-Darwinians, go much further, and declare not merely was Lamarck partly wrong, but that he was wholly wrong in this matter. They assert that acquired characters are *never* transmitted. They believe that Darwinism does more than account for organic evolution partially—that it does so entirely. They strenuously deny Lamarck's view of the origin of variations which Darwin thought might be *partially* true.

Working of the Darwinian Theory. It will be well, for the sake of clearness, to give some illustrations of the application of Darwinism, just as we did in the case of Lamarck's theory. The central idea, be it remembered, is the natural selection of small favourable spontaneous variations. Living beings, as a rule, are so well adapted to their surroundings that great variations and abnormalities are not advantageous, but rather the contrary. For that reason they tend to die out in a few generations. Thus, a man's hand may vary from that of his father in the possession of a sixth finger, a great variation or an abnormality which is of no use, and which in a few generations disappears. Usually the difference is in size, strength, or texture—*i.e.*, small variations. The followers of Darwin suppose that all structures began originally as slight variations from pre-existing ones, and that the complex organs were evolved by the gradual and continued addition of small variations.

According to this view, the antlers of deer would originate thus. Amongst the hornless ancestors of deer there would be some which varied from their fellows in having thicker and stronger frontal —*i.e.*, forehead—bones, and these, by pushing and butting with the head when the struggle for mates took place, would be the more successful. They would be the individuals selected to carry on the race. In their offspring the thick and strong frontal bones would be still more marked, and, through the survival of the fittest and heredity, there would be gradually evolved deer with small bony prominences on the forehead. By the still further accumulation of slight and favourable variations in this direction, antlers made their appearance, and continued to enlarge so long as the enlargement was of a useful character, but no further.

The Neck of the Giraffe. The theory of Lamarck would account for the extraordinarily long neck of the giraffe by saying that giraffes were in the habit of stretching their necks to feed on branches of trees, and that this stretching lengthened the neck of the individual; the individual then handed on this acquired extra length of neck to his offspring, and thus there arose long-necked giraffes.

According to Darwinism, however, the long-necked giraffe is due entirely to a natural selection of individuals who were born with longer necks than their fellows, and had thus the best chance of survival in their particular environment. In times of great scarcity of food the shorter-necked individuals would be at a disadvantage in the matter of food, and the propagation of the race was therefore left to the long-necked individuals. This process, continued through many generations, would gradually result in the production of the modern giraffe as we see it.

The Speed of Hares, and other Examples. One or two other cases will bring out the contrast between the two views still more prominently. "Lamarckians believe that hares run swiftly because their efforts at swift running developed the appropriate structures, and this improvement, transmitted and increased generation after generation, resulted at last in that very swift animal, the modern hare. Neo-Darwinians contend that the great speed of hares is due to the fact that those animals who were *naturally* the swiftest escaped their enemics, and that by this means, during the process of ages, was the swift modern hare evolved. Say they, all animals other than giraffes also stretched upwards for food, yet their necks did not grow long; all animals other than hares strove to run fast, yet they did not become so speedy. On the contrary, their survival was secured by evolving in other directions. Lamarckians assert, but Neo-Darwinians deny, that the child of him who does hard manual labour tends to have at birth thicker skin in the palms than the child of him who labours only with his brains.

"Neo-Darwinians say that a *naturally* tall man tends to have tall children, but that, no matter how a man is stretched or how he stretches himself, his children will not be the taller in the smallest degree for the stretching. Lamarckians affirm that they will. Lamarckians maintain that if a blacksmith increases the size of his muscles by labour his children will thereby profit, and have stronger muscles than they would otherwise have had. Neo-Darwinians deny this. Lamarckians affirm that if a man develops his brains by study his children will have better brains for this purpose. This, again, the Neo-Darwinians deny. Lamarckians maintain that if a man has children, and then, after falling into ill-health, has more children, the latter will be more feeble than the former. This, yet again, is denied by Neo-Darwinians." (*Dr. Archdall Reid.*)

The Theories Compared. Having broadly stated the two great lines of thought concerning organic evolution, the Darwinian and the Lamarckian, the next step is to compare and contrast these theories and weigh the evidence for and against.

All other theories of organic evolution are, more or less, modifications of these two, in spite of what their authors may say to the contrary. It must be so from the nature of the case. There are only two possible roads which can be followed, although there are side-paths to these roads. Organic evolution must proceed either by the transmission of inborn characters from parent to offspring and by their accumulation during successive generations, or it must proceed by the transmission of acquired characters in the same way, simply because no other kinds of traits exist in living organisms but these two groups. Whatever name, therefore, may be given to a theory brought forward, it, of necessity, is either Lamarckian or Darwinian in essence.

Enough has been said, and sufficient examples given, to show that these two views of organic evolution are in violent opposition and violent contrast.

Agencies of Evolution. In the first place, we are struck with the fact that Lamarckianism attributes evolution to the operation of beneficial agencies. It supposes that good food, fresh air, healthy moral and physical surroundings, exercise, and such factors are the cause of evolution by the handing on of acquirements to offspring, as seen in the examples quoted. In the same way, the theory supposes that the injurious agencies would cause enfeeblement and ultimate degeneration and destruction of the race by injuries or disease handed on to offspring and accumulated.

On the other hand, Darwinism attributes organic evolution, not to beneficial agencies, but to *injurious* ones causing a selection of individuals. This is a profoundly important matter, and one which bears directly upon the problems of social welfare. Note most carefully that *it is not every injurious agency which can act as a factor in evolution.* It must be one which is sufficiently powerful to separate the fit from the unfit, to discriminate between what is superior and inferior in any given environment. In other words, according to Darwinians, these injurious agencies must be *selective* in order to cause organic evolution.

Selective Agents. Under the influence of factors which are sufficiently potent to cause selection of individuals of a given type, the fittest will inevitably be those who will survive and continue the race. The other less favoured individuals will to a great extent be eliminated. "It follows, if an injurious agency is so little injurious as not to influence the death (or birth) rate, or so very injurious as not to discriminate between the fit and the unfit, that it cannot be a cause of evolution. In the one case the unfit are not eliminated; in the other the fit do not survive." (Reid.) We see, therefore, that what are called accidental deaths cannot affect the cause of evolution. For example, deaths by drowning, or fire, or in warfare, although they are responsible for the loss of many lives, do not cause evolution, because they are not selective. A bullet does not select the fit or the unfit. Both alike succumb. So fire and water do not select any special types of individual for survival, and are therefore not selective agents in the evolutionary sense.

Stringent selection is therefore the Darwinian explanation of organic evolution, whereas the Lamarckian theory attributes evolution to the action of beneficial agencies upon a species. According to Darwin an injurious agency will act by eliminating the unfit; according to Lamarck it will cause degeneration by transmission of acquired effects of weakness.

Nature and the Breeder. It is a remarkable and interesting fact that during every age those who have been engaged in the breeding of plants and animals have held the beliefs of Lamarck (whether consciously or unconsciously), but have *acted* upon the

Darwinian theory (knowingly or otherwise). The Lamarckian idea of the transmissibility of acquired characters is universally believed by the mass of people who have not carefully made inquiry into the evidence for and against. And yet even those who are convinced of its truth never think of applying it in actual practical breeding experiments.

Putting aside the beliefs of the plant or animal breeder—which are of no importance—consider his plan of action and note the result, which is of great importance. Suppose that he starts out with the object of producing a plant or animal of some special type, having some definite quality which is desirable for some purpose. He knows quite well that he cannot improve a species in all sorts of directions at the same time, and he does not attempt to do so. What is his method of procedure?

He proceeds by making a stringent selection of those animals from which he intends to breed. What does he select? Does he pick out an individual which has acquired the special character he wishes to breed? Not at all. He selects individuals which have varied *naturally*, *spontaneously*, in the required direction, and he mates them. Suppose that the horticulturist wishes to produce a strain of flowers of a given colour. He does not endeavour to make a plant acquire that colour by growing it in certain soil and watering it with certain pigments or manures, in the hope that the plant after acquiring the desired colour will produce offspring similarly coloured. What he does is to select individuals which have varied naturally in the desired direction, and reject the rest. He eliminates those unfit for his purpose and breeds from the fit. He must be content to improve his stock in a few directions only.

Man as an Agent of Evolution. How can a breed of racehorses be established or produced? Does the breeder take a horse of ordinary speed and proceed to train it by food and exercise until it is able to gallop a mile in a given time, and then breed from it, in the hope that this acquired faculty of speed will be transmitted to the offspring? Not at all. The breeder observes that some horses are *born* with a greater capacity for speed than others. They are naturally, spontaneously, faster. He makes a stringent selection of such individuals and rejects all the rest. He finds that these inborn characters will give him the desired result, whether he knows the reason or not.

If the Neo-Darwinians are right, the same thing must occur in natural selection, and in that case the evolution in animals and plants could not take place in many directions at the same time. It is quite true that living species are very highly organised, and that they must have undergone evolution in all their characters, but not in all at once. For example: "For thousands of years the eyes, the ears, the hands, the feet, and very many of the characters of man, have undergone no appreciable evolution. They were evolved during different but overlapping periods of a long extended past." (Reid.)

"The proofs furnished by breeders are too conclusive. It is quite beyond dispute that offspring differ innately from their parents, that these innate differences, these *variations*, are transmissible to descendants, and that if advantage be taken of them by selecting for breeding purposes the superior individuals, while the rest are eliminated, evolution will result. The only point we have to prove is that Nature, like the breeder, exercises the necessary selection." (Reid.) This brings us to the objections to the doctrine of natural selection, which we must now examine.

Two Objections to Darwinism. There are only two serious objections which the supporters of the doctrine of natural selection have to meet. Very few scientific men hold either of them, but they are still advanced by some, and must be considered. The first objection is that acquired characters can be transmitted to offspring, and that Darwinism does not therefore explain all the facts. We shall refer to the evidence upon this point in detail when we approach the problem of heredity.

The second objection advanced by some is a more difficult one to answer. It is that Nature does not act upon the same lines as the breeder, that no real selection is made by Nature, that she works at random amongst variations; in fact, that there is no such thing as a true natural selection of the fittest in a struggle for existence. These objectors affirm that such a selection could only be made by a conscious individual such as man, and that such a selection as he makes for breeding purposes, an artificial selection, has no counterpart in the processes of Nature.

Does Nature Really Select? It may be admitted at once that it is a matter of some difficulty *to prove* definite cases of selection by Nature amongst the wild plants and animals. The reason is that we are not sufficiently acquainted with all that happens in their whole life-history. However reasonable it may be to believe that advantageous variations are selected by Nature, it is very difficult to point to actual cases in wild life, though the evidence from many sides is very conclusive as to its occurrence. But if we can prove that natural selection has acted in a very definite manner along the lines suggested by Darwin in any one species, we may reasonably conclude that such a method of action is applicable to other species.

Curiously enough, the animal which has been most neglected in this inquiry is the one best known to all men—*viz.*, Man himself. If natural selection has been the great agency of organic evolution, we surely ought to find some striking evidence of its operation in the production of its greatest result. Is it possible, then, to point out how natural selection has affected the evolution of man himself, and is still so doing?

MECHANICAL ELEMENTS APPLIED

Levers, including Air-pump and Spring Levers, Cranks and Eccentrics, Wheel-gearing and Cams. Wedges and Screws

By JOSEPH G. HORNER

WE now give a number of selected examples of mechanism illustrative of the application of the skeleton force diagrams which were embodied in the last article. The levers there shown are simply the lever crank chains of Reuleaux, and the arms are the links turning about permanent centres. The skeleton lines have no relation to the actual shape of the mechanisms, they simply give relations, ideas, as evidenced by the differences in an engine beam, a crank, a toothed wheel, an eccentric, etc. The student should exercise his faculties in tracing out the elements of mechanics through other diverse forms.

Examples of the Lever. Levers of the so-called first order [58, page 686] occur most frequently. The most familiar form after the common pair of scales is that of an engine beam, in which the arms are equal on each side of the fulcrum, or central pivot, and the loads equally balanced; that due to the steam pressure on one side, and the resistances offered by the connecting-rod and flywheel on the other. As the greatest stresses come on the beam at the centre, due to the *leverage* exerted by the arms, the double parabolic outline is adopted, a form which, varied with plain tapered outlines, recurs constantly. Such a lever is subject to forces tending to snap it off near or through the fulcrum, and therefore the thickness of metal, in cast iron, has to be very liberally proportioned. Such beams have frequently broken after years of service. A terrible colliery accident once resulted from such a beam breaking. In the older engines, timber was used largely; in modern practice, mild steel plates are commonly used for beams, large and small alike, two or more being laid parallel, with distance pieces intervening.

Air-pump Lever. An unequal-armed beam, a lever of the first order, is illustrated in **72**, being an air-pump lever for an engine of marine type. The usual proportion for such levers is 2 to 1—*i.e.*, the air-pump piston has just half the stroke of the engine piston. The load upon the pump end of the lever is found by multiplying the area of the pump piston or bucket by 30 lb. per square inch. This latter figure makes allowance for the various frictional resistances as well as the load due to suction, etc. Then, applying the principle of the lever, the load on the engine end is

$$\frac{\text{Area of pump piston} \times 30 \times A}{B}$$

A being the distance of the pump end from the pivot fulcrum, and B being the distance of the engine end from the fulcrum. The pins, bearings, and rods can then be designed to suit the resulting loads. The fulcrum pin has to sustain both loads as well as the weight of the work itself.

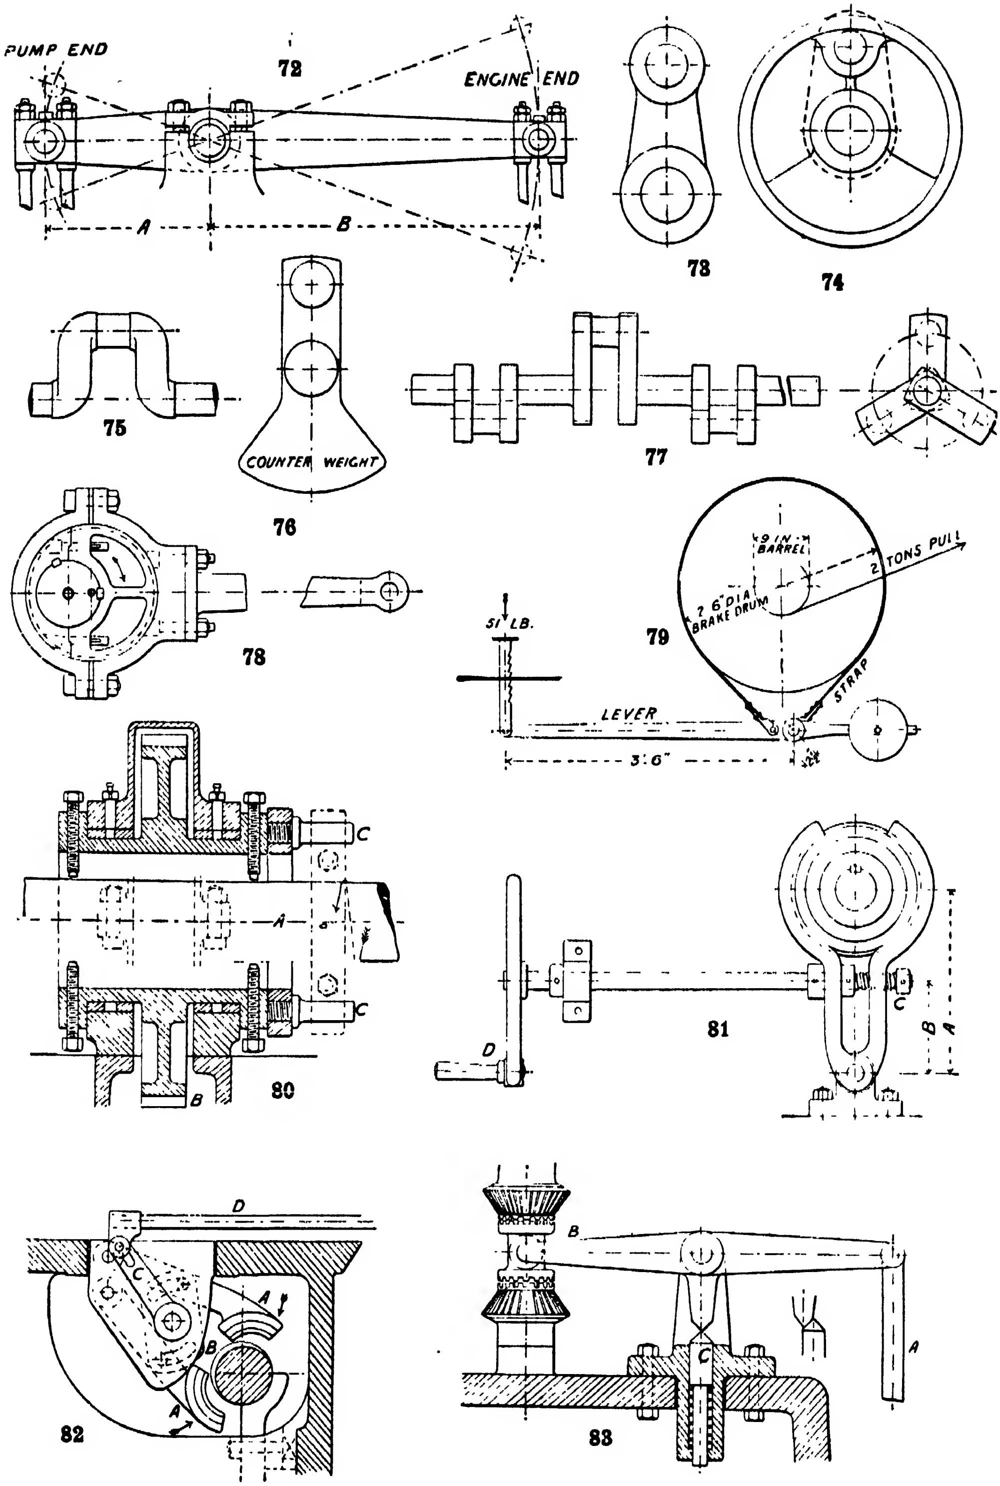
Cranks. An engine crank [**73**] is one of the most familiar examples of the same group of levers. But here one arm is absent, so that it is a disguised form. But the deficient arm is provided by the resistance which is set up in the engine shaft by the driven mechanism, and which the crank has to overcome. A crank shaft is therefore subjected to severe torsion, just as though a massive weight were suspended from an arm attached to its circumference. The crank disc [**74**] is exactly the same element, as is clearly seen by the outlining of a crank on its face. The disc form has nothing to do with the twisting stress on the shaft, but the circular shape is imparted in order to obtain a counterbalance to the crank to enable it to rotate without a jerky movement, which counterbalance does not exist in **73**.

The bent crank in **75** is another example of a one-armed lever, the resistance to which is embodied in the crank shaft. As such cranks are liable also to jerky movements, they are often counterbalanced by other leverages. Thus, to counterbalance locomotive cranks, heavy weights are inserted in the driving wheels opposite to the crank pins. Two-cylinder compound marine engine cranks [**76**] often have weights formed as extensions of their webs. But for these provisions, locomotives would knock themselves to pieces when running, and compound marine engines would be subject to excessive vibrations.

Often the one-armed crank is balanced by other similar cranks in the same mechanism. Thus a pair of engines are set with their cranks, not in line, but at right angles, or sometimes diametrically opposite. Treble-barrel pumps have their cranks arranged in the three-throw style, or at angles of 120°, to balance each other [**77**].

An eccentric [**78**] is a crank, and therefore a lever, only the fact is disguised by the *throw*, and by the fact that the equivalent of the crank *pin*, instead of being of relatively small diameter, as in **73-77**, is larger than the combined diameter of the shaft, plus double the eccentricity. The relation of the lever crank is indicated in the figure by the two small circles, centre of *throw*, and of rotation respectively.

Going from smaller to larger examples, the great lifting bascules of the Tower Bridge are levers of the first order. Only one arm of each bascule is seen, the other is hidden within its pier. The arms are of unequal length, the shorter being in the piers, but equality of moments is produced by increasing the mass



PRACTICAL APPLICATIONS OF THE LEVER

there, and adding counterweight, so that the long and short arms balance.

The application of the lever of the first order [58] to the common balance is obvious. But it is applied to a large number of weighing machines in which the arms are not equal, including the public weighing engines of the streets and platform weighing machines. An enormous disproportion is made between the long and short arms, and thus a very slight depression at one end is multiplied many times at the other, and communicated to the steelyard—another lever in the office.

Foot Brake. The second order of levers has a typical example shown in 79—*viz.*, a foot lever brake for an ordinary steam crane. The load on the brake band is, first of all, calculated by multiplying the pull by the diameter of the lifting barrel or drum, and dividing by the diameter of the brake band. The lifting drum in the example is 9 in. in diameter, the brake band 2 ft. 6 in., and the pull on the drum is 2 tons:

$$= \frac{2 \text{ tons} \times 2240 \text{ lb.} \times 9 \text{ in.}}{30 \text{ in.}} = 1344 \text{ lb.}$$

Only a portion of this comes upon the end of the strap that is operated by the lever. The exact amount depends upon the arc of contact which the strap makes with the brake drum, and upon the co-efficient of friction between the band and the drum. With a co-efficient of ·02, and an arc of three-fourths of a circle, the load will be approximately ·64 of the above sum $= 1344 \times {\cdot}64 = 860$ lb. Then, by the principle of the lever, the load on the foot treadle is

$$\frac{860 \times 2{\cdot}5 \text{ in.}}{42 \text{ in.}} = 51 \text{ lb.}$$

With a brake of this class, it is necessary to balance the treadle and lever so as to ensure the brake being released freely when the pressure is removed from the treadle. This is accomplished by forging an extension to the lever and securing a counter-weight thereon, the amount of which can be calculated by treating the case as a lever of the first order.

The construction of brakes of this class generally utilises the friction between wood—elm and poplar—and cast iron. The brake blocks are made in widths of from 3 to 4 in., and screwed to a strap of thin sheet iron, which makes a flexible element, capable of being wrapped both freely and tightly round the turned rim of the band-wheel. The lever, being subjected to severe bending stress, is a forging, and the counterbalance weight is generally cast with a hole to slide over the opposite end of the lever, to be fastened to it with a set bolt.

Axle-turning Head. An excellent example of a lever of the second order is shown in the drive of the Armstrong-Whitworth axle-turning lathe [80]. The fulcrum is at one end in the centre (A) of the axle which is being rotated. The power is at the opposite end, at the pitch line of the hollow toothed wheel (B) which rotates the axle, and the weight or load is at the circumference of the axle, being turned by a cutting tool there. The smaller the axle, therefore, the greater is the mechanical gain.

Power is gained also for turning the wheel by another lever, the driving pinion at the back (not shown) making with the wheel a pair of levers of the first order [58]. The pins (*CC*) standing out from the head are a Clement's driver, employed to produce equal driving movements about the axle being turned. Lathe men will recognise this as the familiar device adopted to balance the driving effort, and so prevent one-sided jerky movements of work about the centre.

Clip. The third order of levers is not nearly so much in evidence as are the first and second. Having no mechanical advantage, it finds applications only under peculiar conditions. An example is given in 81, in the form of a clip, that is used to prevent certain portions of machinery from revolving, and which is a useful detail when fitted to a derrick gear worm on a crane. The power to be exerted by the hand wheel and screw is, of course, determined by multiplying the pressure required on the clip by the distance A, and dividing by the distance B.

The illustration also shows the application of a screw (C) operated by a lever, the hand wheel (D) to gain sufficient power on the clip to overcome the turning movement of the worm gear. Here, as in the case of the lever [79] with long and short arms, enormous mechanical advantage is obtained by the exercise of the power of one man.

Clasp Nut. Fig. 82 is a familiar example of a lever of the same order—the Whitworth clasp nut. The hinged levers (A A) have the nut portions attached at one end (in the form of half-brasses), while the power to operate them is derived from the cam plate (B), the pins of which transmit power. The cam plate is attached to the lever (C), the handle (D) of which extends to the front of the lathe.

Spring Levers. There is a large number of levers in every order in which a spring is the element of either power or weight. They occur in the treadles of some forms of power hammers, and in the automatic trips of many machine tools.

Fig. 83 shows a lever trip of one kind applied to the reversing motion of a grinding machine. The rod (A), being moved by a dog at a certain stage of the table travel, throws the fork (B) and its clutch in either one or other direction, so putting the bevel wheels shown into engagement. To retain them thus, the spring plunger (C) has its end bevelled to match a bevel on one arm of B. The plunger is forced up as B pivots by the coiled spring behind it, when the bevelled faces lock.

Force Pump. Levers are made with movable fulcrums to suit different pressures, as, for example, in 84, where an ordinary hydraulic force pump is shown. Two fulcrums (A and B) are arranged by fitting a removable pin to the two holes in the framework. The short arms of the leverage available measure 6 in. and 3 in.

PRACTICAL APPLICATIONS OF THE LEVER AND WEDGE

respectively, and the long arms 48 in. and 45 in. respectively. When working on fulcrum A the mechanical advantage is $\frac{48 \text{ in.}}{6} = 8$ to 1. When the pressure rises and the work becomes harder, the fulcrum pin is moved to B, and the mechanical advantage becomes $\frac{45 \text{ in.}}{3} = 15$ to 1, the stroke of the pump ram being correspondingly shorter.

Safety Valve. A case where a lever is designed to give the load per square inch upon a given area is illustrated by the spring-balanced safety valve in **85**. The valve is 2 in. in diameter, and the spring of course records pounds. The proportion of the lever depends upon the area of the valve. If the valve were 1 sq. in. in area it is manifest that the recording spring could be placed directly over the valve, or fitted on a lever of equal proportions. If the valve was 2 sq. in. in area a lever of 2 to 1 would be required. A 2 in. diameter valve is 3·14 sq. in. in area, and so the lever is arranged in the same ratio. Fixing the fulcrum at 3 in. from the valve centre, the lever becomes 3 in. × 3·14 = 9·42 = $9\frac{7}{16}$ in. long. The spring safety valve is an alternative design to that, having a lever arm loaded with a weight.

Wheel Gearing. Toothed gears are disguised levers ; the teeth are only incidents, since smooth-faced wheels will run by friction. It is not necessary even that the radii should be constant, but radii and leverage may vary. And thus we have elliptical gears, triangular gears, square gears, and others, all transmitting variable but constantly recurring rates of motion.

It is an axiom in kinematic chains that they may be converted into mechanisms in as many ways as they have links, because any one link may be made the fixed one, leaving the others movable. This can be studied in the spur gears, which are levers, or turning pairs connected by means of the teeth, which in theory have line contact. In ordinary wheels the centres are fixed by bearings, and the rigid connection thus imposed is a mechanical link. There is no motion of the centres in space. In what are termed epicyclic trains, only one centre is thus fixed, and one or more revolve round it in one direction or the other, with a minute gain or loss in speed.

Cams. A cam is a lever, but with its arms of varying lengths, corresponding with the outlines imparted to the edge or groove, as the case may be. The centre on which the cam rotates is the fulcrum to the edge or grooves. In cams the lengths of arm vary, changing from maxima to minima, or passing through variable but irregular movements. In the modern practice of the engineers' machine shop they fill a place of constantly increasing importance, inasmuch as they take the place of movements otherwise effected by the hands of the workman, with more or less inaccuracy. The cam is both tireless and precise. Its movements can be relied on, for they are timed in the design itself. In feeding movements especially, the cam is of most value. It is embodied notably in the various automatic screw machines for controlling the relative movements of the tools and work.

Fig. **86** is a heart cam, giving variable but regular movements on each lobe. Fig. **87** is a grooved-face cam, giving an irregular motion, and Fig. **88** is the regular two-slot cam plate for clasp nuts, etc., another example of which occurs in **82**.

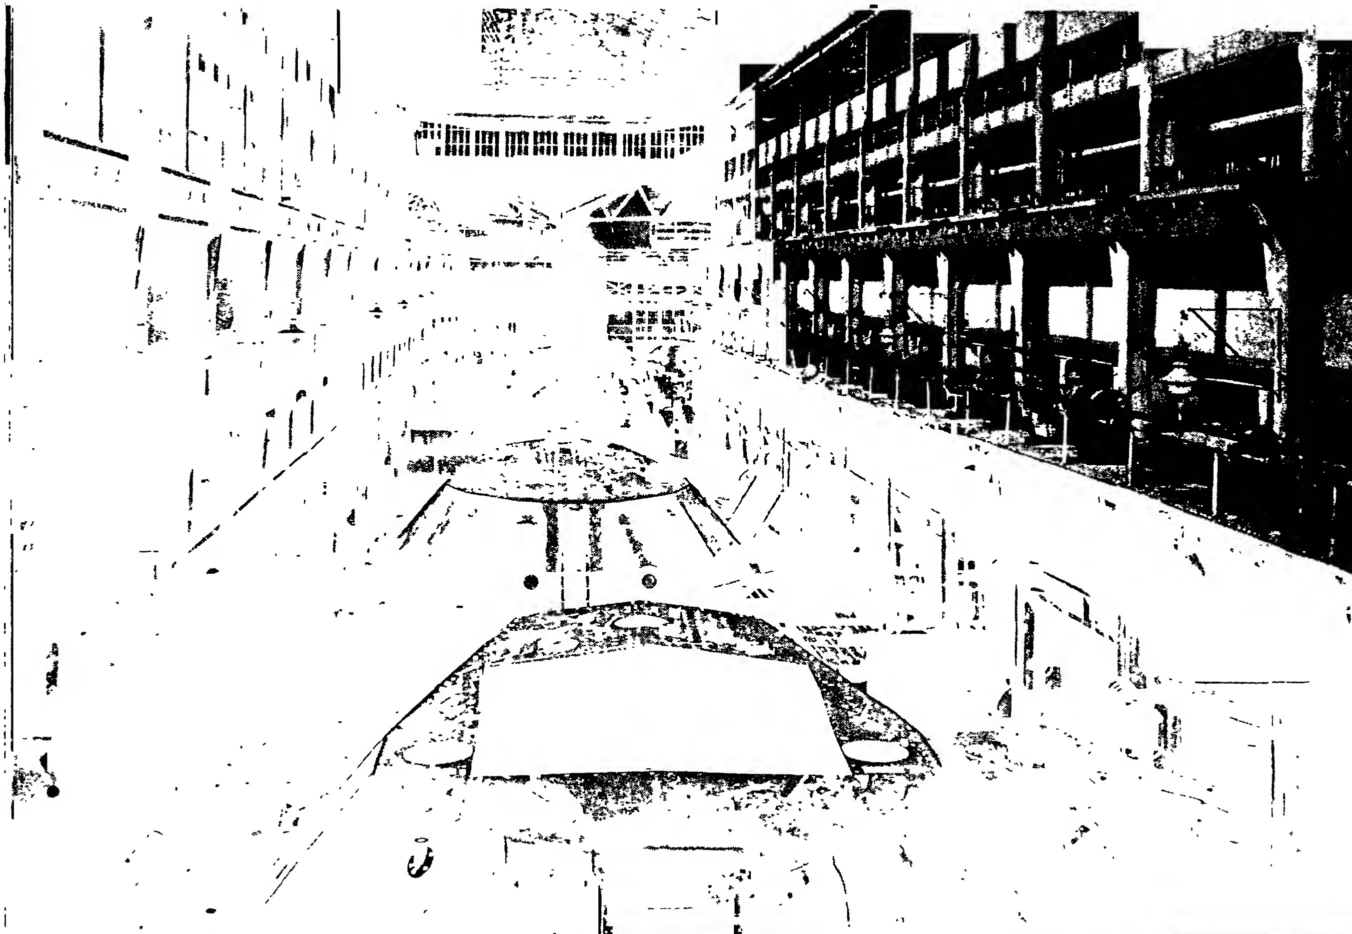
Fusee. In the fusee barrel [**89**] we have another example of a variable leverage, resembling the cams in this respect. But the object in this case is to maintain uniformity derived from variable movements, not only in horological instruments, but in cranes. In the latter, in the jibs of derricks which pass from greater to less radii, and *vice versâ* from the perpendicular, the fusee drum keeps the load at a uniform height.

Tension Organs. The wheel and axle, like its primal mechanical element, occurs in very many forms. The principle [**62**, page 686] is the putting of a rope on or around a large pulley (lever) by which the weight is drawn up on a smaller "axle" (pulley, drum, or lever). This device lends itself to many applications. These form one of the great groups termed by Reuleaux *tension organs*. In other words, they only operate in tension, being useless in compression. They owe a part of their great value to their flexibility, which feature permits of changing the directions of motion. Several materials can be utilised for tension organs, as ropes, chains, wire, and belting in its various forms. In some types of hand hoists, for warehouse work, the form occurs almost absolutely [**90**], the load being lifted by a rope coiled around a small drum, while the endless chain or rope is pulled round the large one. This is also employed in many hand travellers.

The Whip Crane. The whip crane affords another literal example, the load being lifted by a small drum, and the chain or rope pulled round a large one. The slight differences are that the large drum is more correctly described as a double-flanged pulley, and the rope is tied through a hole in one flange and coiled round the pulley by means of a winch on the post below. In hand-travelling cranes operated from below, the rope or chain is fitted around its rim in recesses to "bite" with sufficient gripping power to prevent slip from occurring.

The winch handle of a crane corresponds with the "wheel" in **62**. Its radius is fixed at from 15 to 16 in., because this is as far as a man can conveniently reach. But the diameter of the "axle"—the chain drum or barrel—can be made as small as 6 or 8 in., gaining much power, with corresponding reduction of speed of lift. The smaller the diameter of the drum the greater the mechanical advantage. In practice, this device of altering diameter is often adopted in hoisting machines of less simple character, a set of gears, for example, being retained, and a smaller or larger drum inserted to suit requirements.

But few hoisting machines are so simple as to comprise only the winch handle and drum. The power gained would be totally insufficient for



THE MODERN PALACE OF INDUSTRY: A GUN-MOUNTING SHOP AT THE ARMSTRONG WORKS, ELSWICK

SHOWING TWO 12-INCH TURRETS IN COURSE OF MANUFACTURE

the lifting of heavy loads. In the simple crabs [91], and some small cranes, the first advance on this device occurs. The winch handle is not put on the same shaft as the drum, but on another lying parallel therewith, and the two shafts are "geared" together by means of toothed wheels (levers) of unequal radii, the smaller, actuated by the winch handle, directly actuating the larger on the same axis as the drum. The mechanical gain then is

$$\frac{\text{radius of winch handle} \times \text{radius of wheel}}{\text{radius of pinion} \times \text{radius of drum}}$$

Further, this "simple train" gives place in large cranes to compound trains, in which two or more such combinations exist, and the gain is

$$\frac{\text{radius of winch handle} \times \text{radii of all wheels}}{\text{radii of all pinions} \times \text{radius of drum}}$$

In power-operated cranes, the winch handle is abandoned for the higher pressure agency of steam, water, or that derived from the electric motor. Then, in many cases, trains of gears are diminished in number, or even abandoned in favour of a direct drive.

Pulley Blocks. In the diagrams of certain pulley blocks already given, care was taken to state that the results were secured only by neglecting friction. That was necessary in order to grasp first principles. It is simply an expression of the law that the mechanical work given out by a mechanism would be equal to that put into it, if there were no such thing as friction. But since friction does exist, it happens that every additional element in a machine adds its own quota of friction—more or less severe—to make up a big total, until in one particular case, that of the differential pulley block, substantially 66,* the load will remain suspended in any position. This could not happen in 63 and 64. It happens in 66 solely by reason of the gross total of friction. The mechanical advantage, therefore, in either of these diagrams, is not that of power and weight simply, but of these plus more or less of friction, that of the cords or chains around their pulleys, and of the pulley pins in their bearings. In the application of all the elements now under discussion, the designer strives to lessen friction as far as possible, but in another set he takes advantage of friction and turns it to practical account.

Fig. 92 shows a set of pulley blocks in which the combinations 65 to 67 are embodied in a practical manner by putting the sets of pulleys side by side on the same axis. Any height of lift can be obtained by these by giving enough length of rope. Fig. 93 is a diagram of the differential block, which also embodies the principle of the Chinese windlass. The chain is pulled round the large pulley (A), passing thence to the snatch-block pulley (B) below, thence it returns and winds round the smaller pulley (C). As A and C are cast together [94], the result must be that the snatch-block is lifted by a space equal to the difference in the circumference of A and C. The chain is prevented from slipping by nibs cast in the sheaves, and the friction—due to the different diameters of A and C—equals more than half the power expended, the load therefore remaining suspended without braking. When it has to be lowered, the opposite side of the chain must be pulled on. The lifting rate is, of course, extremely slow.

Inclined Plane. This occurs in the cable ways that play so large a part in the haulage or transport of material. The ropes used are the inclined planes, and the suspended skips or buckets are the loads. Power is applied by ropes, but economy is often studied by making one bucket, or set of buckets, in their descent, serve to draw up another on another incline.

Wedges. The wedge occurs in many forms, in some as a splitting agent, in others as a means of tightening parts. As the first, its best exponents are seen in cutting tools, and if it be objected that these hardly come within the scope of applied mechanics, we must point to the immense importance of the cutting instruments which are embodied in machine tools, and around which these are built. As these will have full treatment in the course on TOOLS, attention is here drawn only to the bare fact.

Cottars. The second group includes cottars and allied forms, which device is employed in many bolts, also in the strap form of connecting rod ends, in effecting rapid union of long lengths of pump rod, of long roof ties, and very much besides. The cottar takes various forms in these examples [95-99].

The cottar pure and simple is driven by a hammer, but in the form of a tail of a bolt [99] it is tightened by screwing the nut. The angle or taper of the wedge is an important detail, not only in cutting tools but in the cottar. If the angle is too large in a driven cottar, the effect of jar on the mechanism will be to loosen it, by causing it to work back out of its seating, hence the set screw in 98. It is therefore made as drawn [95-99]. A cottar bolt may have more taper because the nut holds it against the influence of jar. The value of the cottar in these lies in the provision which it affords of taking up wear in the brasses, to be considered at length in the course on MACHINE DESIGN. Thus we have the function of the cottar as a convenient method of union, and also that of effecting minute compensation for wear.

Keys. The common key [100] is a wedge, cousin-german to the cottar. It secures wheels on their shafts by a wedging action pure and simple, and its taper is but slight, to prevent risk of slackening back. The forms of keys do not concern us here, as they will be dealt with in MACHINE DESIGN, but their relation to the wedge is properly noted.

Keel Blocks. Passing to the massive, we see in the row of keel blocks [101] under a vessel on the stocks a simple means of adjustment. Three wedge pieces, of cast iron, the upper one carrying a piece of teak wood plank, sustain a share of the load of the vessel during construction. By hammering the middle piece farther in or out the height of the block is readily varied, and with it the level of the mighty mass above. The angle is very small,

* Figures before No. 72 have appeared in previous articles.

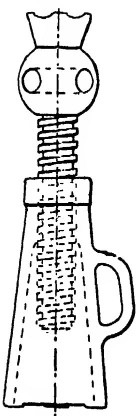
otherwise no effect could be produced, the reason for which was given in connection with **70** [page 688]. Another familiar application of the wedge is to pile driving. The pile, pointed, and having its bottom end shod with steel, is driven by the monkey into sand, clay, and shingle.

Screws. The screw occurs in hundreds of combinations, both as an instrument for gaining mechanical advantage, as a means of fastening, or as a precision instrument, so that one is rather at a loss what examples to select.

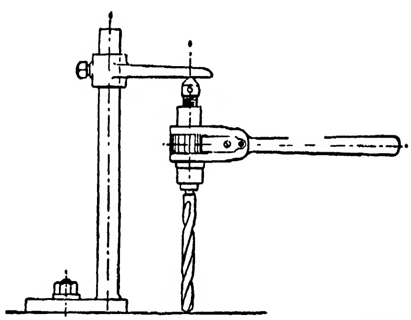
One of the most striking yet commonplace examples of the first is the screw-jack, and allied forms, such as the John Bull, the fly-press, the copying-press, pile screw, etc. We call them allied, because, though their functions are dissimilar, their method of action is the same—the exercise of immense force through a very small space, with a small expenditure of power exercised through a large space. One man can, by operating the screw by a lever, lift a load of several tons by the screw-jack [**102**]. A man using the John Bull [**103**], which is a simple screw and lever, can drill holes an inch in diameter in iron and steel. The fly-press [**104**] is essentially a double-ended lever operating a double-threaded screw of quick pitch, for stamping pens, tinned ware, medals, and much besides. The copying-press is an allied form operated similarly. In these elementary machines the gain in power and its compensating loss in speed is obvious. The screw being simply an inclined plane wound round a cylinder, the smaller the angle of the incline the greater the power gained. Therefore, in the screw-jack and the John Bull, the screws are of what is termed fine pitch, or low pitch, or flat pitch. In other words, their angle is low, and consequently the number of turns or threads in a given length is large. But when speed of movement is required, with moderate power, they are of quick pitch, or sloped very much, and the number of turns is less. This is the case in the fly-press [**104**], where momentum is necessary, and that can be obtained only by a screw of rapid traverse, or of considerably more slope than that imparted to the screw-jack. And as a single thread of coarse pitch would cut too deeply into the body, two or three threads are run side by side of the same pitch, which thus results in a stronger body and a larger thread surface to withstand wear.

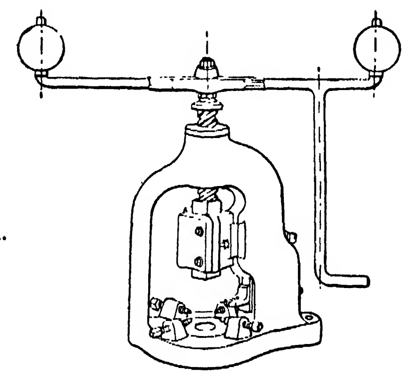
The Pile Screw. The pile screw is an application of the same kind to the turning of iron piles into the beds of rivers. It is capable of penetrating, not only sand, but gravel, clay, and broken rock. The movement is slow. It is produced, generally, by employing another screw and lever in the form of worm gears, a worm wheel encircling the head of the pile and being turned by a worm, actuated by hand or by an engine.

The propeller embodies segments of a screw of quick pitch. That is, if the screw were completed, the distance between threads would usually be from 18 to 24 ft. Even then the movement of propulsion would be slow, but for the fact that the shaft to which the propeller is attached is driven at a rapid rate, from 60 to 80 revolutions per minute.



102





104

Conveyor screws have no end-long motion themselves, but they transmit that motion to loose stuff shot into them. Corn, cement, and other pulverised material is compelled by its own inertia to be carried along by the blades of the continuous screw, and at a rate which is controlled by pitch and rate of revolution.

The screw, as a means of measurement, occurs in the lead screws of lathes. It is the first element in cutting screw threads in this machine tool. Though of one unvarying pitch, it controls the cutting of hundreds of other possible pitches by the change wheels—variables introduced between the screw and the mandrel of the lathe. The same element is found in the universal milling machine, in the screws of micrometer calipers, and in the Whitworth measuring machine. We cannot here trace the screw into the numerous worm, spiral, and helical gears, which will be treated in MACHINE DESIGN. The same observation applies to toothed gears and other mechanisms mentioned in these papers, but the design and proportioning of which belong properly to the subject of MACHINE DESIGN.

SHORTHAND

Sixth Instalment of the Special Course of Shorthand Taught by Sir Isaac Pitman & Sons on their Twentieth Century Plan

By Sir ISAAC PITMAN AND SONS

IN addition to the general method of doubling consonants already described, eight consonant forms are specially hooked or thickened to express an additional sound.

Additional Double Consonants. The following signs represent the double consonants indicated below :

Letters.	*Sign.*	*Name.*	*As in*
KW		kway	*qu*ick, re*qu*est
GW		gway	*gu*ava, an*gu*ish
WL	 (up)	wel	*w*ai*l*, un*well* .
WHL	 (up)	whel	*wh*a*l*e, *whel*p
LR	 (down)	ler	fee*ler*, nai*ler*
RR	 (down)	rer	poo*rer*, sha*rer*
MP, MB		{ emp } { emb }	ca*mp*, e*mb*alm
WH		whay	*wh*ere, *wh*ig

The initial hook in *wl* and *whl* is read FIRST; thus

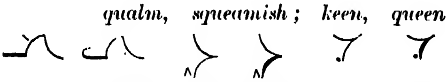
ill, *will*, *willow*, *whale.*

If a vowel precedes *w* or *wh*, write the stroke and not the hook ; thus

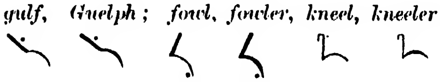
awhile.

The remaining six characters are vocalized like the single consonants ; thus

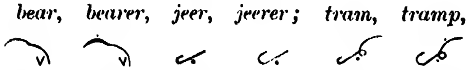
qualm, *squeamish* ; *keen*, *queen* ;



gulf, *Guelph* ; *fowl*, *fowler*, *kneel*, *kneeler* ;



bear, *bearer*, *jeer*, *jeerer* ; *tram*, *tramp*,



mire, *empire* ; *way*, *whey* ; *weasel*, *whistle.*

The double consonants LR and RR are employed only to indicate the terminations *ler* and *rer* ; separate letters must be written when another vowel occurs in the termination, or when a vowel follows ; thus

foiler, *failure* ; *railer*, *raillery* ;

fairer, *furor* ; *usurer*, *orrery.*

The double consonant with a small initial hook becomes *mpr* or *mbr* ; thus

scamp, *scamper*, *clamber*, *limber.*

EXERCISE.

4 

1 Quack, quaker, quince, quiver ; linguist, languoR.
2 Welsh, welfaRe, wool, Willie ; whilst, whalebone.
3 Caviller, ruler, scholar ; adorer, assurer, sneerer.
4 Damp, pomp, Jumbo, Sambo ; whey, anywhere, whipper.

The Aspirate. The aspirate is represented, in addition to the downward and upward , by a downward tick, thus, , (a contraction of the lower half of the sign), and by a dot.

The downward stroke is used when *h* stands ALONE, or is followed by — or — ; thus

high, *Hugh* ;

also when it gives a better outline than the upward stroke, as

hawser.

The upward stroke is generally used when *h* is followed by a downstroke, a straight upstroke, the curves *n* and *ng*, or by a hook, circle, or loop ; thus

hop, *hobby*, *haughty*, *hid*, *hatch*, *hedge*, *huffy*,

heath, *heathen*, *hush*, *harrow*, *hero*, *hurry*,

honey, *hung*, *hewn*, *hove*, *hews*, *hackle.*

When following another consonant, the stroke *h* must be so joined that the circle of the character cannot be read as the circle *s*; as

cohere, mohair, Soho; behave, outhouse, unholy.

The downward tick *h* is used initially, and is always read FIRST. It is prefixed to the stroke consonants (the fact that these are the four consonants in the word SMALLER forms a useful mnemonic) or to any of the double consonants to which it will easily join; thus

hiss, hazy, ham, hem, hemp, hall, holly,

hear, hearer, Hebrew, hydra, hedger, hither.

The dot *h* is placed before the vowel which is to be aspirated. It is used as an alternative to the stroke *h*, usually in order to avoid an awkward or long outline; thus

happening, handy,

apprehend, perhaps, manhood, loophole.

Grammalogues. The following grammalogues should be memorized:

had, happy.

EXERCISE.

1

1 Hicks, Hawkins, hackney, huckster, hoop, hitch, heap, heady.
2 Hone, housed, hammer, hardy, unhook, Sahara, abhor, unhitch.
3 Hymn, horn, haze, hasty, Gingham, uphill, household, Redhill.

Upward and Downward L and R. The following rules govern the writing of the consonant *l* in either the upward or the downward direction, and the use of the upward or downward forms of *r*:

INITIAL *L* is generally written upward, thus

loud, aloud, life, alive.

In the following cases it is written *downward.*

(a) When *l* is preceded by a vowel and is followed by a horizontal letter not hooked initially; as

elk, elm, Ellen, almoner.

(b) When *l* precedes and ; as

illusive, lesson, Lessing.

FINAL *L* is generally written upward, thus

Paul, Polly, tale, Italy.

In the following cases it is written *downward.*

(a) After the letters and any straight upstroke, if no vowel follows the *l*; thus

full, vile, scale, quail, sequel,

rail, yell, Howell.

But if a vowel follows, *l* is written upward, as

fully, villa, scaly, Aquila, rally, yellow.

(b) After a straight downstroke if two vowel-signs come between; as

duel, trial.

(c) After a curve and circle, final *l* follows the same direction as the circle; thus

fossil, vessel, thistle,

Kingsley, Cecil, muscle.

(d) After the consonants *n* and *ng*, *l* is also always written *downward;* as

kneel, only, strongly.

(e) The double consonant *lr* is used for the sound of *ler* where a final downward *l* would be written; as

fowler, kneeler, roller.

INITIAL *R* is written upward; thus

rain, rose, ration, rail.

But when *r* is preceded by a vowel it is written *downward*, thus,

air, oar, Arab, argue, arm, arrive,

arraign, arose, oration, early, arena.

When *r* precedes *t, d, ch, j, th, kl, gl, w*, it is written upward, whether a vowel precedes or not; thus

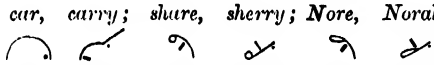
irritation, aridity, arch, original, orthography,

oracle, argal, ornamental, Trevin.

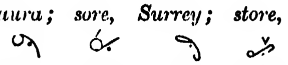
Final *R*, in short words, is written downward when it ends a word, and upward when it is followed by a vowel; thus

pair, perry; tare, Terry; jeer, jury;

car, carry; share, sherry; Nore, Norah;

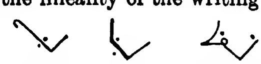


leer, Laura; sore, Surrey; store, story;



swear, soirée; stern, siren.

When *r* is preceded by two descending strokes, it is generally written upward, so as to preserve the lineality of the writing; thus

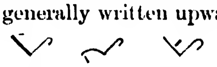


prepare, debar, Shakspere.

Write upward *r*, irrespective of vowels, rather than an awkward outline; thus

officer, reviser, answer, rear, wore, yore, where.

When *r* follows another stroke and is hooked finally, it is generally written upward; thus



born, morn, portion.

The double consonant *rr* is used for the sound of *rer* where a final downward *r* would be written; thus

adorer, borer.

Key to Exercises in Last Lesson.

1 Pin, Dan, chin, bone, tun, dine, down, twine, tune, brawn, blain.
2 Beef, duff, chief, buff, tiff, dive, Dave, jove, chaff, brief, trough.
3 Roan, rove, won, wove, hen, huff, rife, Rhine, yawn, hone.
4 Vine, thine, main, noon, gain, gave, line, sheen, zone, ocean.
5 Pansy, economy, gainsay, reverse, toughness, profane, tin, tiny.
6 Vain, avenue, deaf, defy, wave, wavy, partial, insinuation.

1 
2 

3 
4 
5 
6 

1 Tense, tenses, trounce, trounced, puns, punster, punsters, chains, chances.
2 Cleanse, cleansed, blossom, presume, hansom, lancer, Spencer.
3 Vines, mines, nouns, shrines, doves, gloves, roves, thrones, oceans.
4 Menaces, moans, ominous, assigns, essence, Romans, romance, excellence.

1 

2 

3 
4 

1 Notion, lotion, motion, mansion, delusion, salvation.
2 Potion, portion, operation, reduction, derision, occasion.
3 Fiction, section, Prussian, oppression, expression, tradition.
4 Occupation, reputation, divisional, rational, actionable.
5 Pulsation, sensational, positions, incisions, situation, fruition.

THE ELEMENTS IN DETAIL

The Elements and their Compounds found in Nature. Hydrogen, Sodium and Soda, Potassium and Gunpowder, Calcium and its Salts

Continued from page 696

By Dr. C. W. SALEEBY

The Elements Found Free. It has already been noted that occasionally the elements occur in the native, free, or uncombined state in Nature. We may make a note of some of these cases.

Oxygen and nitrogen occur in abundance in the atmosphere. Free hydrogen also occurs in very minute quantities. It is somewhat more abundant in the neighbourhood of volcanoes. Iron occurs in the free state in certain meteors, as does the element nickel. Carbon occurs in several forms, as coal and charcoal, derived from the bodies of vegetable organisms long dead. It occurs also as minute crystals, very misleadingly called blacklead, and better named *graphite*, since this form of carbon is used in pencils for writing purposes (Greek, *grapho*, I write). Thirdly, carbon occurs in the form of larger crystals, which we call diamonds. Sulphur, like hydrogen, is found free in the neighbourhood of volcanoes; arsenic, antimony, and bismuth occur in very small quantities in various parts of the world; the very valuable element platinum is found free in tiny particles mixed with the sand of some rivers in Russia and South America. Silver and gold occur free in many parts of the world, as everyone knows. Mercury is sometimes found as such in California, and copper occurs near Lake Superior in North America.

Elements in the Stars. But hitherto we have spoken only of the distribution of the elements on the earth. We must see if these elements occur anywhere else. Are they found in the stars or the sun, and, if so, do they occur in the free state or as compounds? This is one of the most fascinating and important subjects in the whole realm of science, and it will be dealt with in a special chapter at the end of this section. Meanwhile, however, we may briefly note that the elements we know on the earth *are* found, and are found in their free state, in the sun and the stars. In general, we may say that the elements most abundant on the earth are the most abundant in the heavens. A still more remarkable fact is that we are not acquainted with any element in any of the heavenly bodies which is not to be found on the earth. There have been exceptions to this rule, but only temporary ones. For instance, the gas called helium was first discovered in the sun, as its name implies, but it was subsequently found on the earth in the rare mineral cleveite.

Elements Found to be Combined. Nevertheless, by far the greater mass of all the matter with which we are acquainted consists of compounds of the elements, and we must now learn to recognise these compounds by the names given them by chemists. Of course, their number is almost endless, but here we are concerned merely with the principal ones. The compounds of four elements—chlorine, bromine, iodine, and fluorine—have various names, which we shall see later, but those that occur in Nature are called chlorides, bromides, iodides, and fluorides. Of these, the chloride of sodium is common salt, and as the Greek word for salt is *hals*, these four elements are often called the *halogens*—that is, the "*salt makers*." Hence, their compounds may be recognised under the general term of *halides*. Very common also are certain compounds of oxygen and sulphur, which are called oxides and sulphides. The rule is that the termination *ide* is applied to a compound which contains two elements—as, for instance, sodium chloride ($NaCl$), the molecule of which contains one atom of sodium and one of chlorine.

A great many of these compounds are able to combine with each other, forming double compounds, such as the double chloride of magnesium and potassium, or magnesium and sodium. We have learnt that nearly all the salts of sea-water exist in this complex state of loose union.

Acids, Bases, and Salts. We have said that the compounds of oxygen are called oxides, but this term is only applied to one half, so to speak, of the compounds of oxygen—those which we have already called *bases*. A special name is given to the double oxides of hydrogen and the non-metals. These are called acids; for instance, sulphuric acid, H_2SO_4 is, as the formula shows, a double oxide of hydrogen and sulphur, which is a non-metal. On the other hand, caustic soda, $NaOH$, as the formula shows, is a double oxide of hydrogen and a metal. These last we call *hydroxides*. Thus the technical name for soda is *sodium hydroxide*. In the case of the acids, for convenience, we make a point of writing the hydrogen first in the formula, so as to indicate that they are acids.

Now, when these two kinds of oxides—*viz.*, the acids and the hydroxides—are mixed with one another, there frequently occurs a rearrangement of their elements, which is called a double decomposition. For instance, when sulphuric acid and soda are mixed, the metal of the hydroxide displaces the hydrogen of the acid; thus, instead of H_2SO_4, we get Na_2SO_4; whilst the displaced hydrogen unites with the oxygen which is left over, to form water. The name given to the double oxide now formed, sodium sulphate, which is a double oxide of a metal and a non-metal, is a *salt*. We have already seen that this term salt is also applied to the halides, such as common salt or sodium chloride.

Preparation of Elements. Given, then, that we have a number of compounds of the elements, and that we wish to obtain the pure elements from them, how are we to proceed? There are three possible methods of breaking up the compound and obtaining the element desired.

In the first place, we may break up the compound by electricity. This is possible only when the compound can be dissolved or melted, and when it is a substance which conducts electricity. If these conditions are satisfied, we may pass an electric current through the compound, and may obtain the freed elements by this means. The simplest and most important instance of the employment of this method is the passage of an electric current through water, which is decomposed and provides us with free hydrogen and free oxygen. In other words, the electricity splits the water up into two invisible and colourless gases which have not the smallest resemblance to it. This process of passing electricity through a liquid, by means of which the liquid or some substance contained in it undergoes decomposition, is known as electrolysis; it need not further be discussed here, as it is dealt with in ELECTRICITY.

Other elements that may be prepared by means of this method are sodium and potassium, barium, calcium and strontium, copper, silver, gold and fluorine.

This principle is of very great practical importance, since it is the essential one of electroplating and electrotyping, each of which is separately discussed in the SELF EDUCATOR.

The Compounds and Heat. But, *in the second place,* a compound may also be resolved into its constituent elements by heat. It is believed that when the temperature is sufficiently high, no compounds can exist, but though this method is thus theoretically applicable to all cases, there are not very many instances in which it is of practical use. One or two may be noted. The very useful element sulphur frequently occurs in union with iron, as what is called *iron pyrites.* When this is heated (say, for instance, in a hard glass tube) some of the sulphur is given off, and can be immediately seen, since it produces a yellow coating upon the glass.

The preparation of oxygen by this method is of historic interest. Priestley discovered oxygen, as we saw in our introductory chapter, by this method. He applied heat to the red oxide of mercury (HgO), and thus decomposed it, driving off free oxygen, which he was able to collect after passing it through water. Very shortly afterwards the Swedish chemist Scheele obtained oxygen by heating another of its compounds, the oxide of manganese, which has the formula MnO_2.

But by far the most common method of preparing the free elements is, *in the third place,* by displacing them from their compounds by means of their action on another element. The displacing elements usually employed are sodium, which turns out magnesium and aluminium from their compounds with the halogens; hydrogen, which turns out a number of elements, such as iron, tin, lead, arsenic, etc.; and carbon, which is really the most important of all, since, to begin with, it turns out the hydrogen and sodium themselves, and thus enables us to use them for turning out other elements. Carbon also turns out potassium, zinc, tin, lead, phosphorus, arsenic, bismuth, etc.

The Groups of Elements in Detail. We must now proceed to consider the groups of the elements in detail. The first group we will take consists of hydrogen, sodium, and potassium.

Hydrogen (literally the "water-maker," since it is one of the constituents of water) has been recognised as an element ever since the work of the great Cavendish, already referred to. It occurs on the earth to a small extent in a free state, and to a very large extent as a compound, as we have already noted. It is present in vast quantities in the stars, and the sun is completely surrounded by an atmosphere of hydrogen. Many of the stars are so eminently characterised by the amount of hydrogen they contain that they are generally described as the hydrogen stars. A typical example of such a hydrogen star is the most brilliant star in the whole heavens, Sirius, or the Dog-star.

The preparation of hydrogen is most commonly effected by the action of metals upon acids. We have already seen that an acid always contains hydrogen*, and we can obtain the hydrogen by itself if we turn it out from the acid by means of a metal which takes its place. The usual substances employed are sulphuric acid (H_2SO_4) and zinc. The reaction is represented by the formula

$$H_2SO_4 + Zn = ZnSO_4 + H_2.$$

When it is desired to obtain hydrogen in much larger quantities the element may be obtained from water by the interaction of red-hot iron and steam or by the action of steam—that is to say, gaseous water—on red-hot coke. The coke, which is carbon, takes the oxygen from the water, leaving the free hydrogen. When prepared by this method the gas is impure, since it is mixed with a certain amount of a compound of carbon and oxygen.

Properties of Hydrogen. Hydrogen is a colourless, odourless, tasteless gas, the lightest of all known substances. (It is understood, of course, that the ether of the physicists, not to be confused with ether, the chemical compound, is excepted when we make this statement.) Of all the known kinds of what the chemist calls matter, hydrogen is the lightest. We have already seen that on this account the weight of this element has been taken as the unit for comparison with the weights of other elements. The weight of hydrogen is less than $\frac{1}{11000}$th that of water, and its density is about ·07 that of air. Hence it may be poured upwards from one jar to another. So light is

* The reader must not be confused by carbonic acid, CO_2. This is really an acid without its water—an *anhydride.* Its full formula would be H_2CO_3. (Compare potassium carbonate, K_2CO_3.)

hydrogen that light vessels filled with it will rise in air. The first balloons were filled, not with hydrogen, but merely with hot air. Of course, as soon as the air cooled, the balloons descended, but balloons are now filled with hydrogen, and can float for an indefinite period.

The gas is only very slightly soluble in water, the universal solvent, which is capable of dissolving at least some quantity of nearly all substances. One hundred volumes of water will absorb about two volumes of hydrogen. The gas may be breathed without causing any deleterious effects, but it is incapable of supporting life, nor will it support combustion.

Liquid and Solid Hydrogen. Until recent years hydrogen had never been converted into a liquid, still less into a solid, but both these feats have lately been accomplished by Sir James Dewar, the famous professor of chemistry at the Royal Institution, London. Liquid hydrogen presents no striking appearance. It is by far the coldest liquid that can be obtained. When it is rapidly evaporated under certain conditions its temperature is still further reduced, so that a small quantity of solid hydrogen is formed; this frozen hydrogen represents the lowest temperature yet attained by the chemist. It is probably about 260° below the freezing-point of water. This is reckoned on the Centigrade scale, in which the freezing-point of water is zero, so we may say that the temperature of solid hydrogen is about $-260°$ C. The recent ability to liquefy hydrogen has been of great use in the study of low temperature chemistry, since by its means very low temperatures can be conveniently obtained and maintained.

Certain substances such as carbon and many metals have the power of absorbing hydrogen in a very extraordinary fashion. The rare metal palladium, for instance, absorbs about 900 times its own volume of hydrogen. We cannot doubt that this is more than a merely physical action; there must be some sort of chemical combination. The hydrogen taken up in this form by a metal is known as *occluded hydrogen*. When the metal is heated the gas is given off again. Iron, similarly, has the power of occluding hydrogen, and thus the gas is sometimes found in the iron that has reached the earth in meteors or shooting stars.

Hydrogen and the Halogens. Reference has already been made to the group of substances known as the halogens—chlorine, bromine, iodine, and fluorine. Each of these substances unites with hydrogen to form an acid. Of these the most important is hydrochloric acid (HCl). The most important compound of hydrogen, of course, is water, which is really the oxide of hydrogen (H_2O). When the two gases hydrogen and oxygen are mixed in the form of jets and ignited, they unite, producing a very intense heat. This oxyhydrogen jet is largely used for raising the temperature of lime, thus producing a brilliant light known as limelight.

If we compare a simple acid, such as hydrochloric acid (HCl), with a salt of that acid, such as sodium chloride or common salt (NaCl), we see that there is a certain resemblance in chemical behaviour between hydrogen and a metal. In general we may say that an acid differs from a salt in that the hydrogen of the first replaces the metal of the second.

Thus it was for long thought that hydrogen was really a metal, and that if we could obtain it in a solid form it would have metallic characters, but now that hydrogen has been solidified this view has to be abandoned.

Sodium. This exceedingly important element has a very wide distribution in Nature; it is a constituent of common salt, it is a necessary constituent of all or nearly all living tissues, and it occurs in enormous quantities in the form of many other salts found in the soil and in minerals. Finally, it is abundant in the sun and in the stars. Sodium, when heated, yields a brilliant yellow light which is very characteristic. It is so universally present that in practical chemistry there is no little difficulty in getting rid of all traces of it. It is nowhere found free or uncombined on the earth, though, no doubt, it exists in the free state in the sun and stars. The symbol for sodium is Na, and its atomic weight is about 23. This element was discovered by Sir Humphry Davy in 1807. Davy was one of the greatest of English chemists; he invented the safety-lamp and discovered laughing-gas; he was connected with the Royal Institution of London, and the now famous laboratory in Albemarle Street, where Sir James Dewar has made so many great discoveries, is known, after Davy and Michael Faraday, as the Davy-Faraday Laboratory.

Davy obtained sodium by passing a very powerful current of electricity through the hydrate of sodium (NaOH), previously fused or melted. The metal is now prepared in a different manner, by heating a mixture of carbonate of sodium and charcoal.

Characters of Metallic Sodium. When the metal is obtained, it is found to be of a silver-white colour and very soft, so that it can be readily cut with a knife. It is exceedingly light, and floats on water. It has an intense affinity for oxygen, which it immediately takes from water. Thus, when sodium is thrown on to water decomposition occurs, and evolves free hydrogen, which immediately burns in combination with the oxygen of the air. When sodium is exposed to air, the surface rapidly tarnishes, owing to the formation of a film of oxide of sodium. This oxide of sodium is formed when sodium is thrown upon water, but it also combines with some more of the water that is present, forming the substance known as caustic soda, or sodium hydrate, which has the formula NaOH. The equation represented in this decomposition runs as follows: $2H_2O + Na_2 = 2NaOH + H_2$. Caustic soda is an important substance which has very powerful alkaline properties. It is called caustic because of its action on the skin. Sticks of solid caustic soda have a very powerful solvent action on the skin, and were formerly used to remove warts.

When the oxide, or the hydrate of sodium meets with carbonic acid (CO_2) it forms a compound known as carbonate of sodium, which has the formula Na_2CO_3. As this usually occurs, however, in its crystalline form, there is combined with it a quantity of water. Water which thus combines with salts in the formation of crystals is known to the chemist as water of crystallisation. The number of molecules of water that combine with one molecule of carbonate of sodium is 10, so the formula of the substance in its crystalline form will read Na_2Co_3, 10 H_2O. On exposure to air, however, the water tends to leave the crystals, which break down a· l fall into powder. This tendency to lose their water of crystallisation is a general characteristic of the salts of sodium. The property is known as efflorescence, the opposite of which is deliquescence.

"Washing" and "Baking" Soda. Carbonate of sodium, known to the housewife as "washing soda," is found in Nature to a small degree in soda lakes, in the water of some geysers, and also in the soil. It used to be obtained in considerable quantities from certain marine plants. These were burnt, their ashes were treated with water, the solution thus obtained was evaporated, and yielded a very impure form of sodium carbonate, or soda, which was known as *barilla*. This was largely used in the making of soap. The process has now, however, fallen almost completely into disuse, since the salt can now be prepared much more satisfactorily by other means. Of these the first is known as the Leblanc process, and the second as the ammonia process.

The bicarbonate of soda, or baking soda, differs from the last in that it contains twice as much carbonic acid in proportion to the sodium. Its formula is $NaHCO_3$. It is a white powder somewhat less soluble in water than washing soda; it is largely used in medicine, as a non-irritant alkali.

Borax. Several other salts of sodium are important. The borate, for instance, is known as *borax*. Its full chemical name is biborate of sodium, and it occurs in large quantities in Borax Lake, California. It used also to be obtained from lakes in Tibet. It may also be prepared by the union of carbonate of soda and boracic acid. It is used in medicine, in glass-making, as an enamel, and for other technical purposes. It usually occurs in the form of prismatic crystals which, like those of carbonate of soda, have 10 molecules of water of crystallisation.

The nitrate of sodium ($NaNO_3$) is often known as "Chili saltpetre," or sometimes as cubic saltpetre, since its crystals are very nearly cubical. It occurs in the soil in various parts of South America. Like ordinary saltpetre—soon to be discussed—it is used in making nitric acid.

The silicate of sodium, known as "soluble glass," is soluble in water; it is used for fire-proofing. The phosphate is a constant constituent of the animal body and a necessary ingredient of the food.

Potassium. Potassium is an important metal, which has many resemblances to sodium. Its symbol is K, and its atomic weight is 39; it was discovered by Davy at the same time as the discovery of sodium, and in the same way—by passing electricity through fused potash. Potassium is abundant in Nature, but, like sodium, is never found in the elemental state. It occurs in all living tissues, and when plants are burnt, it remains in the ash, hence the name potash, or potashes. It is an important ingredient of seawater, and occurs abundantly in the form of its nitrate in the soil of certain parts of South America.

Preparation of Potassium. Potassium is now prepared in similar fashion to sodium, by means of the interaction of charcoal and the carbonate of potassium. The charcoal (which is simply carbon) and the carbon in the carbonate unite with the oxygen of the carbonate to form a poisonous gas, *carbonic oxide* (CO), leaving the potassium behind in the form of a gas, which solidifies inside a flattened box of metal that receives it. There is some danger in the manufacture. The decomposition is represented by the formula $K_2CO_3 + C_2 = K_2 + 3CO$. (Potassium carbonate plus charcoal = Potassium plus carbonic oxide).

Thus prepared, the element is found to be a whitish metal which strongly resembles metallic sodium. It floats on water, which it decomposes in a similar fashion to that of sodium. When sufficiently heated—and the same applies to any salt of potassium—it yields an exceedingly beautiful violet colour, which contrasts markedly with the brilliant yellow colour yielded by sodium. Like sodium, potassium forms certain oxides or compounds with oxygen, but these are of no practical importance.

Caustic Potash. Potash is of great importance. It is otherwise known as caustic potash, potassium hydrate, or potassium hydroxide. Its formula is KOH—which may be compared with the formula of water HOH—usually written for convenience H_2O. When we institute this comparison, we see that the difference between potash and water is that one-half of the hydrogen of the latter has been replaced by potassium. (A similar statement is true of caustic soda.) Potash is formed by the action of potassium on water. It is prepared for practical purposes by a process similar to the Leblanc soda process. The potassium is obtained from potassium chloride, which occurs in enormous quantities at Stassfurt. This yields potassium carbonate, and from the latter, by its interaction with slaked lime (solutions of the two being boiled), there is obtained caustic potash KOH. This is usually cast in the form of sticks. It is a very powerful caustic, very similar in properties to caustic soda. It has great affinities for water and carbonic acid, and is very largely used as a reagent in chemistry.

As we have seen, the ashes obtained from burnt plants were called potashes. The carbonate of potash, now prepared as we saw in the last paragraph, may still be obtained by burning wood, in places where wood is cheap and abundant. The plant does not manufacture its potassium carbonate, but it takes it ready-made

from the soil. It is a necessary ingredient of all soils in which plants are to grow, and, if deficient, must be added in the form of a manure. The purer form of potashes, obtained by recrystallising the crude product, was called *pearl-ash.* Carbonate of potassium is largely employed in chemical research, in various industries, in glass-making, and also in the making of soap. All soft-soaps contain potassium.

Reference has already been made to chloride of potassium, a white, crystalline, easily soluble salt, usually obtained from Stassfurt.

Chlorate of Potassium. The closely allied salt known as the chlorate of potassium, $KClO_3$, is of considerable importance because of its large superfluity of oxygen, which it is very ready to give up to any substance that will take it. So ready is it that when mixed with sulphur and charcoal it forms an explosive mixture. It is an ingredient of certain kinds of matches, and it is largely used in medicine as a safe and powerful antiseptic, which it is in virtue of its ability to give off nascent oxygen. In simple ulceration of the mouth no other remedy is so valuable as chlorate of potash.

The iodide, KI, and the bromide, KBr, are of no great chemical importance, but they are amongst the most valuable of all drugs. The sulphate, K_2SO_4, is occasionally used in medicine. The two salts containing chromium—the chromate and bichromate—are also used in dyeing, in chemical research, in photography, and the latter occasionally in medicine. The cyanide, KCN, owes all its properties to the fact that it is practically equivalent to hydrocyanic, or prussic acid. It is a whitish salt used in photography, in chemistry, in electroplating, and very occasionally in medicine.

Saltpetre. The nitrate of potassium, KNO_3, is usually known as nitre, or saltpetre, the latter name being a modern version of the alchemists' name for it, which was *sal petræ*, or *salt of rock.* It occurs in the soil, as already stated, being formed by a highly complicated and interesting process into which bacteria enter. [See BACTERIOLOGY.] These bacteria form nitric acid in the soil by a union of the nitrogen in organic substances derived from the bodies of animals and plants with the oxygen of the air, the process being known as *nitrification.* The nitric acid combines with the potash salts present in the soil to form potassium nitrate, or saltpetre. Sometimes this method is employed for the preparation of saltpetre, but, as a rule, the salt is prepared by the interaction of potassium chloride and Chili saltpetre, or sodium nitrate. When strong solutions of the two are heated together, a double decomposition occurs, the potassium and sodium changing places. Common salt, or chloride of sodium, is precipitated or solidified in the solution, whilst saltpetre remains in it, and can thus be separated. The salt forms clear crystals, usually prismatic. It is very readily soluble in water. At high temperatures water will dissolve much more than its own weight of saltpetre.

The salt is still used in medicine, being sometimes given internally, and sometimes burnt in a saucer, when it yields fumes which often relieve attacks of asthma. It is much used in the making of fireworks and fuses, and also in ordinary chemical processes. It is a most important ingredient of ordinary gunpowder, of which, indeed, it forms about three-fourths.

Gunpowder. Gunpowder is really a mixture of saltpetre, charcoal, and sulphur, all the ingredients being mixed in the form of a granular powder. Nitre has to be used rather than sodium nitrate, for this salt, contrary to the usual rule of sodium salts, has an affinity for water, and thus the powder made with it cannot be kept dry. It is said that gunpowder was invented in the eighth century. The value of the mixture depends upon the fact that when it is fired the saltpetre gives up its oxygen very rapidly to the charcoal and sulphur. The results of the oxidation of these latter are gaseous, and the nitrogen of the saltpetre is also given off in gaseous form. The smoke which is produced serves no practical purpose; it consists of various solid salts, such as sulphide of potassium. Owing to the fact that a very high temperature is produced, the gases which are evolved demand a large amount of space—about 2,500 times as much as the space occupied by the powder. It is the sudden and imperative expansion of these gases rapidly produced at such a high temperature that gives gunpowder its explosive property.

Alkaline Earths. The next group of elements which we may discuss consists of *calcium, barium,* and *strontium.* In their elemental form these do not occur in Nature, and they can be obtained in this form only with much difficulty. When a powerful electric current is passed through the chlorides of these metals in a melted state they can be obtained, but they are very unstable, having intense affinities both for oxygen and water. If only the first be supplied to them they immediately form oxides, but if water be present, they form hydroxides, or hydrates. These three elements are usually known as the *alkaline earths.*

Calcium is a very widely diffused element. It is a necessary ingredient of the living body, especially of the bones. It occurs in the sun and stars in considerable quantities. The other forms in which it occurs on the earth will be named when its various salts are discussed. Of these salts the most important is the carbonate, which has the formula $CaCO_3$. It is one of the most widely distributed of all minerals. It occurs in the forms of limestone, marble, chalk, and coral. Chalk consists of the calcium carbonate remains of the bodies of countless myriads of minute creatures that once lived in the sea. These have left a sort of "shells" behind them. The structure of the shells can often be detected with a microscope. But calcium carbonate also occurs in a very large number of crystalline forms, such as calc-spar, or Iceland spar, also the mineral known as aragonite, and in many other forms. Crystalline calcium carbonate, when pure, is colourless, but very frequently it contains various impurities, such as salts of iron, which give it various tints.

The term oolite is applied to the form of calcium carbonate which occurs as minute rounded grains which, like chalk, are of organic origin. Sometimes it is known from its appearance as roe-stone. This structure is so common in a certain level of English rocks that they are known to geologists as the oolites. [See MATERIALS AND STRUCTURES.]

Changes in Rocks. Under certain conditions the carbonate of lime, or calcium, is constantly liable to undergo a very important change, which plays a great part in geology, for it conditions a number of the slow but incessant changes which determine the form of the earth's surface. The process is simple to understand. On the earth are rocks containing carbonate of lime, much of which acts as a sort of cement, holding rocks together. In the air is a quantity of carbonic acid, CO_2. As rain falls it absorbs some of the acid. The rocks are thus constantly exposed to the action of carbonic acid in solution, and this produces a very important change. Carbonate of lime is converted into bicarbonate—sometimes called acid carbonate. When a salt contains twice the usual amount of the acid constituent—which in this case is carbonic acid—its character may be indicated by using the prefix *bi*, from the Latin *bis*, twice; or it may be described as an acid salt, in order to indicate that it contains a certain amount of acid, which, so to speak, is "to spare." There is this great distinction between the carbonate and the bicarbonate—that, whilst the first is quite insoluble in water, the second is readily soluble; hence the supporting structure of the rocks is broken down, and they are washed away, as sand or clay, to form what are called alluvial plains. Thus mountain ranges are slowly crumbled away.

Stalactites and Stalagmites. Another important change produced in a similar way consists in the formation of what are called stalactites and stalagmites. The first consist of long crystals of carbonate of lime, which hang down in very striking fashion from the roofs of limestone caves, looking very much like icicles. They occur along the lines where there are cracks or joins in the roof of the cave—that is to say, along the lines where water from above drips through. As the drops fall upon the floor of the cave the process which resulted in the formation of the stalactite continues, and there is built up from the floor a sort of pinnacle which is known as a stalagmite, and which grows up to meet a stalactite growing from above. Often they join, forming pillars of indefinite thickness. Now, how does this process occur?

The water that percolates through the roof of the cave brings with it a quantity of carbonic acid derived from the air, and is thus enabled to dissolve some of the carbonate of lime from the rock through which it passes, with the formation of bicarbonate. But when the drop reaches the surface of the roof of the cave, and begins slowly to evaporate, the extra carbonic acid in the bicarbonate can no longer be retained. In other words the bicarbonate undergoes decomposition, yielding the insoluble carbonate, which is immediately deposited. A similar process occurs when the drop reaches the floor. The action may be represented by the formula

$$H_2Ca(CO_3)_2 = H_2O + CO_2 + CaCO_3.$$

Attempts have been made to estimate the age of caves by means of the size of the stalactites and stalagmites which they contain, but these are highly unsatisfactory. Needless to say, stalagmites do not occur except when the floor of the cave is sufficiently level.

Hard and Soft Water. The difference between hard and soft water depends entirely upon the fact that the former contains more than a certain quantity of bicarbonate of lime in solution, whereas the soft water contains very little, or none. Two kinds of hardness are distinguished in water, one which depends on the presence of the sulphate of calcium, and is called permanent, while the other depends upon the presence of bicarbonate of calcium, and is called temporary. It is this alone that concerns us here. The adjectives are applied to indicate the fact that, in the latter case, the hardness can be removed with comparative ease. Perhaps the simplest way of removing it is by boiling the water, which decomposes the bicarbonate exactly according to the equation given above to explain the formation of stalactites. Another way of getting the bicarbonate of lime out of the water is by adding more lime to it. The lime that is to be added is usually known as milk-of-lime; chemically it is called calcium hydroxide, and its formula is $Ca(OH)_2$.

How to Soften Water. This substance is only very slightly soluble in water, but when it is partly dissolved and partly suspended in water it forms the opaque white fluid which is called milk-of-lime. Now, when this is added to water containing the bicarbonate, the milk-of-lime takes from the bicarbonate its extra share of carbonic acid, which it combines with itself to form carbonate of lime, and this same salt is also formed from the bicarbonate when it has lost its extra carbonic acid. If the water is now filtered or is allowed to stand, the insoluble calcium carbonate is disposed of, and so the water is made soft. The following formula represents the decomposition:

$$H_2Ca(CO_3)_2 + Ca(OH)_2 = 2CaCO_3 + 2H_2O.$$

(Calcium bicarbonate plus calcium hydrate = Calcium carbonate plus water.)

Calcium carbonate may further be used to illustrate some other simple chemical changes. For instance, if limestone consisting of this salt be raised to a very high temperature, it undergoes a decomposition according to the formula

$$CaCO_3 = CaO + CO_2.$$

The carbonic acid is driven off, and there is left behind the oxide of lime, CaO, or *quicklime*. This quicklime has an exceedingly strong affinity for water. When this thirst is slaked by the addition of water, the oxide of lime is converted into the hydrate, or hydroxide of lime mentioned above, which is commonly known as *slaked lime*. The difference between these two last substances is typical of the difference between an oxide, and a hydrate or hydroxide.

POETRY OF THE ELIZABETHAN AGE

2. The Dramatic Poets—continued. Dealing with Ben Jonson, Beaumont and Fletcher & Shakespeare's Contemporaries, & concluding the Study of this Period

By J. A. HAMMERTON

Ben Jonson. The greatness of Shakespeare could not be better illustrated than by contrast with the character of BEN JONSON (b. 1573; d.1637). In almost any age Jonson would have been accounted a writer of the most extraordinary parts. His scholarship was profound—indeed, Shakespeare's learning is, by comparison, almost superficial—but in all his serious efforts to produce a dramatic work of the highest he gives evidence of scholarship only, and not of that divine, ineffable "something" which makes the poetry of Shakespeare as harmonious a part of the world's intellectual life as seed-time or harvest is of its physical life. It is hard to determine how Jonson came by his learning, as we have evidence of only a few weeks spent at St. John's College, Cambridge, in his sixteenth year, after leaving Westminster School. In his youth he had to work for a time, to his never-forgotten disgust, at bricklaying, and he was a soldier in the Low Countries when only eighteen years of age. It has been asserted that at nineteen he returned to Cambridge and completed his studies, but this theory rests rather on the desire to explain his wonderful knowledge of the Latin poets than on any direct evidence. He was as injudicious as his great contemporary in contracting an early marriage, and perhaps poverty, as much as inclination, led him to become an actor, in which profession he excelled no more than Shakespeare did.

Influence of Classical Models. Steeped in the works of the pagan poets, his native genius was undoubtedly more lyrical than dramatic in inspiration, though he gives evidence of a certain saturnine temper which, inclining to tragedy, but modified by the former impulse, expresses itself in satire. It was with a comedy, however, that he first essayed to win success on the stage, and "Every Man in His Humour," produced in 1596, and performed two years later by the company of which Shakespeare was a member, had a considerable success, which led to his following it with "Every Man out of His Humour." Both are admirable comedies, and, like his two tragedies, "Sejanus" and "Catiline," follow classical models; but the author is so obviously subjected to the strict rules of classical composition that his work lacks spontaneity and natural grace in the comedies and tenderness in the tragedies. This is the fault of all his plays: they are overlaid with the weight of his learning; made coldly accurate by the careful observance of his models; and neither in tragedy nor in comedy does he sound the depths of human emotions. Though the character is always perfectly observed and represented, he does not take us to the hidden springs, as Shakespeare does, not so much by art as by intuition, even in his lesser works. For these reasons Jonson's dramatic works earned small popularity in his time, and have ever since been dead to all but students of literature. "Every Man in His Humour" has occasionally been revived on the stage, but never with lasting success.

The Masque. Such prosperity as Jonson enjoyed came from the composition of masques, which, in his time, were a favourite amusement of the Court and the aristocracy. The masque is a form of stage entertainment midway between a pageant and a play. It may be said to have been originated by the introduction into royal processions of masked, or disguised, persons representing allegorical or fictitious characters. This developed into entertainments resembling the tableaux vivants, still popular in our own time, in which Henry VIII. is known to have delighted. Under Elizabeth the masque rose into extreme popularity, and most of the dramatists, with the notable exception of Shakespeare, set themselves to supply their lordly patrons with such entertainments. They were written both in prose and verse, the dialogue being interspersed with songs, and afforded opportunities for the display of gorgeous costumes and scenic decoration quite foreign to the stage of the time, where no attempt was made at scenic effect or accuracy of "make-up." Ladies also took part in these private theatricals, whereas on the stage all the feminine parts were discharged by boys or young men. The finest example of this class of poetic composition is Milton's "Comus," written for the Earl of Bridgwater, and acted at his residence, Castle Ludlow, in Shropshire, on Michaelmas Night, 1634, in which the masque as an acted entertainment may be said to have culminated, for it died out under the Commonwealth and has never been revived.

Jonson's Lyric Poetry. Some of the best specimens of Jonson's verse are to be found in his masques, but his exquisite little song, "Drink to me only with thine eyes," is one of fifteen lyrics in a collection entitled "The Forest," published in 1616. Jonson, in his personal character, had some traits which suggest likeness with his great namesake of the eighteenth century, and "rare Ben" anticipated Samuel's satirical treatment of the Scots, as he came near to having his ears clipped for making fun of King James's countrymen in "Eastward Ho," a drama in which he collaborated—a rare thing for him, as he was vain of personal achievement—with Chapman, Marston, and Martin. He died 6th August, 1637, having experienced loss of friends and favour in his later years. His

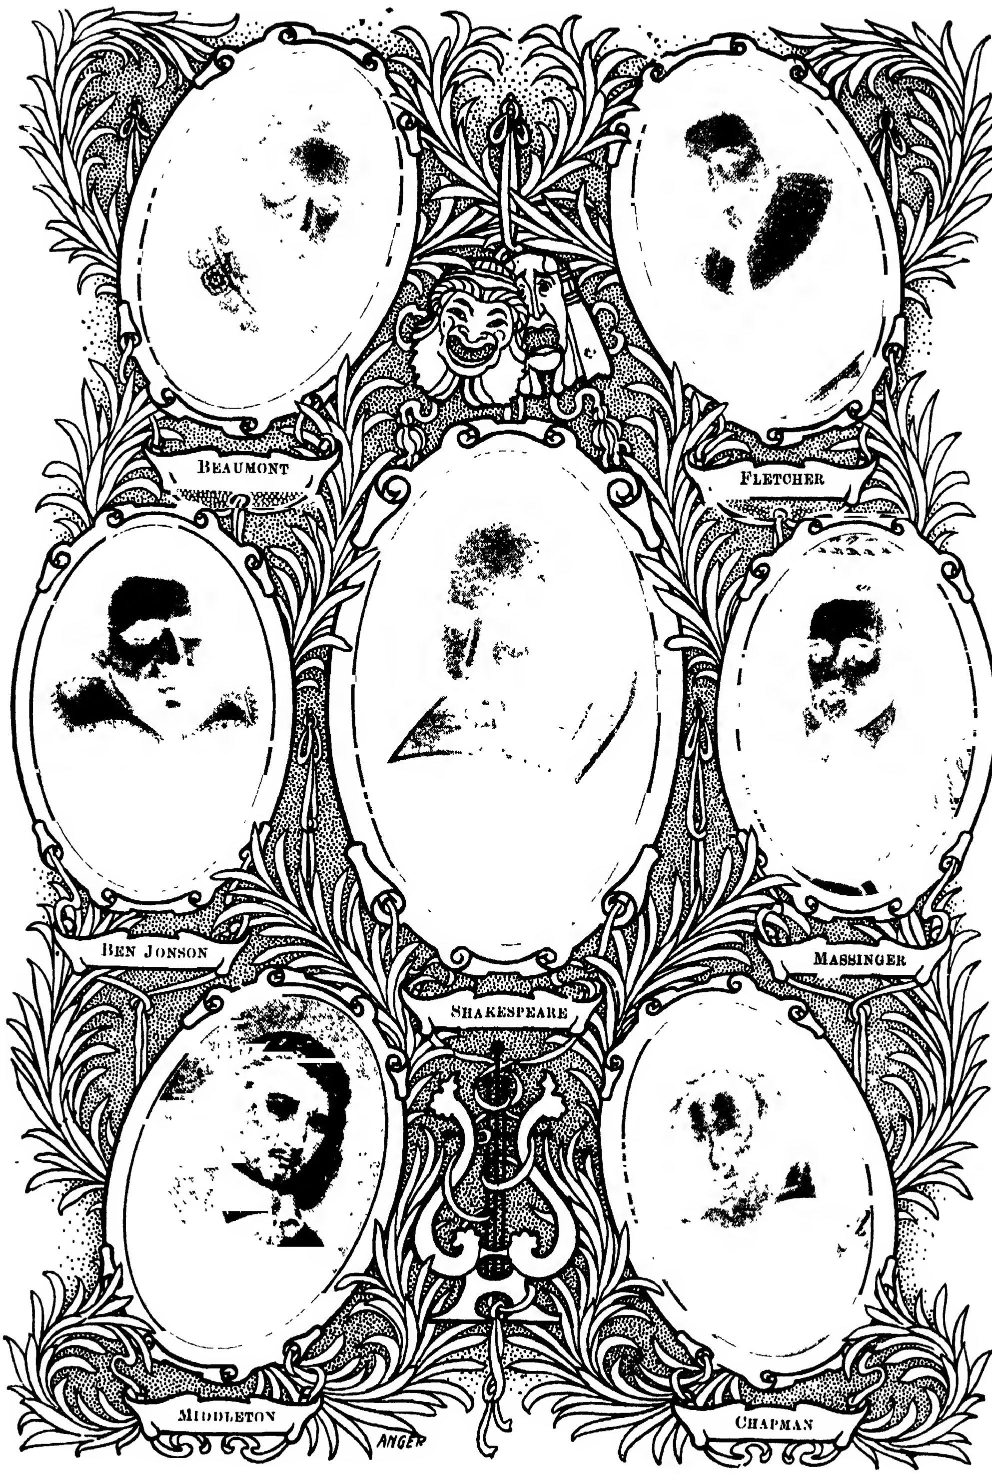
gravestone, in Westminster Abbey, is inscribed, "O Rare Ben Jonson." On the whole, every reader with any pretension to knowledge of our literature must make some first-hand acquaintance with the works of Ben Jonson. Specimens of his lyric poetry are to be found in most collections, and several anthologies are devoted to it entirely, while some of his best plays have also been reprinted in recent years.

Beaumont and Fletcher. Reference has been made to Jonson's collaborating with other dramatists. This was a favourite method of work among the Elizabethans, as it is in our own time with the French dramatic writers. But the most noteworthy example of collaboration was furnished by Beaumont and Fletcher, who were so intimately associated in their lives that they had house and clothes in common. Both were of gentle birth, scholars, and men of genius. Their plays — chiefly comedies — were even more popular than Shakespeare's, being, if anything, more in harmony with the temper of the period. FRANCIS BEAUMONT (b. 1584; d. 1616) probably became acquainted with his friend JOHN FLETCHER (b. 1579; d. 1625) at the meetings of the celebrated Mermaid Tavern, frequented by Shakespeare, Jonson, and the wits of the time, as celebrated by Beaumont in his verses to Jonson:

"What things have we seen
Done at the Mermaid! heard words that have been
So nimble, and so full of subtle flame,
As if that every one from whence they came
Had meant to put his whole wit in a jest,
And had resolved to live a fool the rest
Of his dull life."

Characteristics of their Work. The dramatic writings of this celebrated pair are full of fancy and bright pictures, though there is no denying their "studious indecency," in which they reflect, more racily than need be, the manners of their age. Fletcher had probably the greater share in the composition of the plays which bear their joint names, and alone he wrote at least twenty, Shakespeare being thought to have collaborated with him in "The Two Noble Kinsmen," while Fletcher had a hand with Shakespeare in the writing of "Henry VIII." It is hard to differentiate between Beaumont and Fletcher, though it seems easy enough by comparing their individual and their joint productions; but perhaps it is not wrong to say that the one had a more strongly marked lyrical gift, while the other was essentially dramatic in his inspiration. Both men were immensely popular with their contemporaries, and theirs will ever remain among the great names of Elizabethan drama. By way of summing up their characteristics, we cannot do better than quote this comparison from the poet Campbell's "Specimens of the British Poets": "There are such extremes of grossness and magnificence in their dramas, so much sweetness and beauty, interspersed with views of nature either falsely romantic or vulgar beyond reality; there is so much to animate and amuse us, and yet so much that we would willingly overlook, that I cannot help comparing the contrasted impressions which they make to those which we receive from visiting some great and ancient city, picturesquely but irregularly built, glittering with spires, and surrounded with gardens, but exhibiting in many quarters the lanes and haunts of wickedness. They have scenes of wealth and high life, which remind us of courts and palaces frequented by elegant females and high-spirited gallants, whilst their old martial characters, with Caractacus in the midst of them, may inspire us with the same sort of regard which we pay to the rough-hewn magnificence of an ancient fortress."

Other Dramatists. It is not possible within our space to continue, even in this faint outline, our review of the Elizabethan dramatists, so we must now dismiss many names in briefest mention, though most of them are almost as worthy of some detailed notice as Beaumont or Fletcher. PHILIP MASSINGER (b. 1583; d. 1639), who was laid in the same grave as Fletcher, at St. Saviour's, Southwark, was so variously associated with Fletcher and other dramatists in playwriting that it is difficult to form an estimate of his individual work. But he is certainly no less gifted in comedy than Beaumont and Fletcher, and in tragedy he displays real power. His only play that has held the stage is "A New Way to Pay Old Debts," a brilliant and mordant comedy. JOHN FORD (b. 1586) was a dramatist of real tragic power, to whom only the darker emotions of the heart seemed to appeal, for his plays are sombre and unredeemed by the finer feelings of fancy and imagination. His "Perkin Warbeck" is a good historical drama, and "'Tis Pity——" is a remarkable tragedy. He collaborated in several plays with THOMAS DEKKER (b. 1570), a prolific and able writer, both of tragedy and comedy, who in turn was associated with JOHN WEBSTER, of whose life hardly anything is known. Webster was a dramatist of extraordinary power in tragedy, and over his works gloom, profound and chilling, seems ever to brood. "The Duchess of Malfi" is his greatest play, and must rank with the finest of the period; but it is easy to understand how he had scant favour from contemporary audiences. THOMAS MIDDLETON (b. 1570; d. 1627) wrote many charming comedies, while WILLIAM ROWLEY (b. about 1585), an actor-playwright of no remarkable qualities, collaborated at various times with the five last-mentioned dramatists, and also with THOMAS HEYWOOD, who had a large share in the writing of 220 plays up to the year 1633, and is believed to have lived until 1648. "A Woman Killed with Kindness" has real pathos and simplicity to distinguish it, and may be accounted the best of Heywood's plays. JOHN MARSTON (b. 1575; d. 1634) was a poet of most unequal achievement, associated with Jonson and GEORGE CHAPMAN (b. 1559; d. 1634) in the production of "Eastward Ho," as noted above. Chapman was greater in comedy than in tragedy, "All Fools" being an excellent play of the former class, while his tragedies are usually marred by bombast and



ELIZABETHAN DRAMATISTS: SHAKESPEARE AND HIS

fustian. His great achievement was the translation of Homer's "Iliad" and the "Odyssey" into rhymed verse of fourteen syllables. These translations, despite numerous faults, are in many ways unsurpassed by Pope's more familiar versions of the same works, and well worthy of every reader's attention.

Last of the Elizabethans. With James Shirley (b. 1596; d. 1666) we reach the last of this school of dramatists; for though he was but a boy when the reign of the virgin queen ended, his early associates were the later Elizabethans, and all the influences on him were Elizabethan; he had come to manhood at the time of Shakespeare's death. Charles Lamb says of him: "James Shirley claims a place amongst the worthies of this period, not so much for any transcendent talent in himself, as that he was the last of a great race, all of whom spoke nearly the same language, and had a set of moral feelings and notions in common. A new language and quite a new turn of tragic and comic interest came in with the Restoration." This, rather than Campbell's somewhat perfervid panegyric of the dramatist, is a proper view of Shirley, for while the tragic and pathetic passages of his plays, which are chiefly tragi-comedies, are often distinguished by great tenderness and true feeling, he fails on the whole to rise to the level of his models, Beaumont and Fletcher and Ben Jonson.

The English Spirit. We have now reached the conclusion of a most important stage of our study, for on our knowledge of and sympathy with the poets from Chaucer to Shirley will depend much of our understanding of English Literature. The Elizabethans, especially, are the beacon-lights of the English spirit, if the metaphor will pass. To know them well is to have the whole character of England illumined for our better appreciation. They represent more directly than any body of writers in England, before or since, the spirit of their time and country. This may be thought an over-statement, when we remember how the spirit of the eighteenth century is reflected in the writers of the period. But that is not the real spirit of England; it is a passing phase; whereas the spirit of the Elizabethan age is no passing phase, but the very pulsing of England's heart. In a sense, the Elizabethans are more "in touch" with us of this later day than are the writers of the eighteenth century. We shall even find that the literature of the Victorian age, rich to abundance though it is in great writers and in great works, is not so thoroughly in tune with the English spirit as is that of the Elizabethan. For the creators of the latter were poets to a man, and the poet is ever the truth-teller. He is not so apt to temporise with passing moods and whims as the prose-writer is; he utters himself with greater freedom, fearless, because "It is in me, and shall out." Thus the age of Elizabeth remains for ever the epoch in which—with the awakening of all those varied energies that have since made the British Empire the unmatched wonder of the world's history—there lived, surely by no mere chance but inevitably, a splendid company of poets whose poetry enshrines for all time the English spirit—patriotism, heroism, idealism, the love of liberty, beauty, Nature, domesticity.

Morals and Sincerity. That the Elizabethan poets were as capable of expressing grossness as of voicing the noblest aspirations of the soul is no argument against them. Every country has its standard of good taste: an ocean wider than the Atlantic separates the English of to-day in matters of taste from their nearest neighbours across the Channel. And every age of any one country has had its own standard of good taste. That of the Elizabethan was assuredly different from that of our day; just as that of fifty years hence promises to be strangely different from the standard of twenty years ago. The Elizabethan poets—since, for all their superiority to the multitude, they were still men of their time—necessarily reflect in their writings the looseness of their age in the treatment of morals. It does not follow that they were one degree less moral than we are to-day; but they spoke of subjects which with us it is bad taste to discuss. They were, for that very reason perhaps, the more honest; and sincerity is the master-note of all the great Elizabethans; indeed, sincerity is the one infallible test of all enduring literature.

Nowhere is the value of sincerity so admirably appraised as in Carlyle's "Heroes and Hero-Worship," and we feel that, in order to appreciate this vital factor in all literature, the student might do worse than read that work at this stage, with his mind on this point alone. Sincerity lifts everything in which it is present on to a higher plane, and where we find it associated with other qualities of a derogatory kind—as we do in some, if not all, of the Elizabethan poets—it still remains the great preservative, purifying, vivifying the poet's work, in spite of all.

Supremacy of Shakespeare. And it is Shakespeare, again, who towers above his glorious company of contemporaries in his comparative freedom from all besmirching elements, but by that token he is, as we have already hinted, really less the mirror of his age—but more the mirror of the English spirit—than, for example, Beaumont and Fletcher. He is the most modern writer in our language. It would seem that in one fruitful moment the genius of England gave birth to a poet who interpreted his country to itself and to the world once and for all time; his thought and language being the everlasting mind and utterance of his race at its highest. His contemporaries are small when ranged beside him, yet mighty in their individual and collective strength. But after what has been said, it is surely unnecessary to insist further on the importance of gaining a good knowledge of Shakespeare and his contemporaries—this must be apparent to all who have come with us thus far in our studies. And we may now take leave of the Elizabethans by quoting the summary with which Taine begins his study of the theatre in his "History of English Literature."

"Forty poets, amongst them two of superior rank, as well as one, the greatest of all artists who have represented the soul in words; many hundreds of pieces, and nearly fifty masterpieces; the drama extended over all the provinces of history, imagination, and fancy—expanded so as to embrace comedy, tragedy, pastoral and fanciful literature—to represent all the degrees of human condition, and all the caprices of human invention—to express all the perceptible details of actual truth, and all the philosophical grandeur of general reflection; the stage disencumbered of all precept and freed from all imitation, given up and appropriated in the minutest particulars to the reigning taste and public intelligence: all this was a vast and manifold work, capable by its flexibility, its greatness and its form, of receiving and preserving the exact imprint of the age and the nation."

Such is the Elizabethan drama, the most important of all periods of English literature, not to the student only, but to the general reader who desires to possess a reasonable knowledge of our great literary heritage.

Continued

THE CHOICE OF BOOKS IN ELIZABETHAN LITERATURE

The subjoined list is by no means exhaustive, but it contains reference to the most convenient editions of the poets and to standard works in criticism and biography. We have purposely chosen only those books which, published at low prices, may be added to the reader's own private library. At public libraries many other and more expensive works are available to the student. It should be noted that some of the books are no longer included in the current lists of their publishers, but these are regularly to be met with at the secondhand dealers. The "Mermaid" series was originally published by Vizetelly at 2s. 6d., and latterly by Unwin, at 3s. 6d. Many of this admirable series are still in print, but the collector will find single volumes at almost any secondhand bookseller's.

GENERAL.
- *Specimens of the Elizabethan Drama.* From Lyly to Shirley. Edited by W. H. Williams. Clarendon Press. 7s. 6d.
- Marlowe's *Dr. Faustus* and Greene's *Friar Bacon and Friar Bungay.* Edited by A. W. Ward Clarendon Press. 6s. 6d.
- *The Shakespeare Anthology.* Edited by Prof. Arber Frowde. 2s. 6d.
- *The Jonson Anthology.* Edited by Prof. Arber. Frowde. 2s. 6d.
- *Shakespeare's Predecessors.* By J.A.Symonds. 1884.
- *My Study Windows.* By J.R.Lowell. Scott. 1s. 6d.
- *Specimens of English Dramatists.* Charles Lamb. Dent. Two vols. 3s. 6d. net. each.

NICHOLAS UDALL.
- *Ralph Roister Doister.* Temple Dram. Dent. 1s. net.

JOHN LYLY.
- *Campaspe.* Temple Dramatists. Dent. 1s. net.

GEORGE PEELE.
- *Plays and Poems.* Morley's Universal Library. Routledge. 1887. 1s.
- *Dramatic Works.* Edited by A. H. Bullen. 1888.

ROBERT GREENE.
- *Tragical Reign of Selimus.* Tem. Dram. Dent. 1s. net
- *Green Pastures.* A Selection from his Works. Edited by Dr. Grosart. Stock. 1894.

CHRISTOPHER MARLOWE.
- *Plays and Poems.* Newnes. 1905. 3s. net.
- *Edward II.* Edited, with Notes, by O. W. Tancock. Clarendon Press. 7s. 6d.
- *Edward II.* Temple Dramatists. Dent. 1s. net.
- *Works,* including Translations. Edited by Col. Cunningham. Chatto & Windus. 3s. 6d.
- *Selections.* Canterbury Poets series. Scott. 1s.
- *Faustus.* Morley's Univ. Lib. Routledge. 1883. 1s.
- *Faustus.* Temple Dramatists. Dent. 1s. net.
- *Best Plays.* Edited by Havelock Ellis. Mermaid.

WILLIAM SHAKESPEARE.
- "Oxford" Edition. Frowde. 2s., 3s. 6d.
- "Globe" Edition. Macmillan. 3s. 6d.
- "Leopold" Shakespeare. Cassell. 3s. 6d.
- *Select Plays.* 17 vols. Each complete, carefully edited and annotated. From 1s. to 2s. per vol. Clarendon Press.
- "Arden" Edition. Each play in separate volume. Methuen. 3s. 6d. each.
- *Lectures and Notes on Shakespeare.* S. T. Coleridge. Bell. 3s. 6d.
- Essay by Lowell in *The English Poets.* Scott. 1s. 6d.
- Essay by Lamb "On Shakespeare's Tragedies" in *Critical Essays.* Dent. 3s. 6d. net.
- *Introduction to Shakespeare.* By Prof. Dowden. Blackie. 2s. 6d.
- *Shakespeare Primer.* Prof. Dowden. Macmillan. 1s.
- *A Life of Shakespeare.* Sidney Lee. Smith Elder. 7s. 6d.

BEN JONSON.
- *Plays and Poems.* Newnes. 1905. 3s. net.
- *Plays and Poems.* Morley's Universal Library. Routledge. 1883. 1s.
- *Best Plays.* Edited by B. Nicholson and H. C. Hereford. Mermaid series (3 vols.).
- *Works.* Memoir by Gifford. Edited by Cunningham. Chatto & Windus. Three vols. 3s. 6d. each.
- *Every Man in His Humour.* Tem. Dram. Dent. 1s. net.
- *Brave Translunary Things.* Selections from Jonson's Prose and Verse. By Grosart. Stock. 1895.
- *Selections.* Canterbury Poets series. Scott. 1s.
- *Discoveries.* Temple Classics. Dent. 1s. 6d. net.
- *Ben Jonson.* By J. A. Symonds. English Worthies series. Longmans. 2s. 6d.

BEAUMONT AND FLETCHER.
- *Best Plays.* Edited by Strachey. Mermaid series.
- *Philaster.* Temple Dramatists. Dent. 1s. net.

PHILIP MASSINGER.
- *Best Plays.* Edited by A. Symons. Mermaid series.
- *Plays,* from the Text of Gifford. Edited by Col. Cunningham. Chatto & Windus. 3s. 6d.
- *New Way to Pay Old Debts.* Tem. Dram. Dent. 1s. net.

JOHN FORD.
- *Best Plays.* Edited by Havelock Ellis. Mermaid.
- *The Broken Heart.* Temple Dramatists. 1s. net.

THOMAS DEKKER.
- *Best Plays.* Edited by Ernest Rhys. Mermaid series.
- *Old Fortunatus.* Temple Dramatists. Dent. 1s. net.

THOMAS MIDDLETON.
- *Best Plays.* With Introduction by A. C. Swinburne. Mermaid series.
- *A Woman Killed with Kindness.* Temple Dramatists. Dent. 1s. net.

THOMAS HEYWOOD.
- *Best Plays.* Ed. by Symonds and Verity. Mermaid.

GEORGE CHAPMAN.
- *Best Plays.* Edited by B. Nicholson and W. G. Stone. Mermaid series.
- *Plays, Poems, and Translations of Homer.* Three separate volumes. Chatto & Windus. 3s. 6d. each.

JOHN WEBSTER.
- *Best Plays.* Edited by J. A. Symonds. Mermaid.
- *The Duchess of Malfi.* Temple Dram. 1s. net.

JAMES SHIRLEY.
- *Best Plays.* Ed. by Edmund Gosse. Mermaid series.

THE GEOGRAPHY OF EUROPE

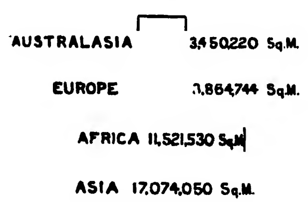
Land and Water of the Old World. Europe and Asia Compared and Contrasted. Position, Climate, Plains, Rivers, and Productions of Europe

By Dr. A. J. HERBERTSON, M.A. and F. D. HERBERTSON, B.A.

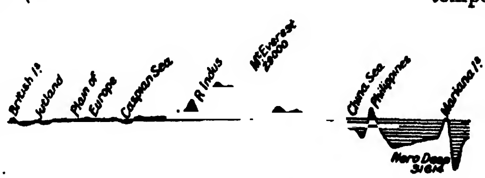
The Old World. The Old World [56] is the greater of the two huge islands into which most of the land of the earth is grouped. It contains 32,000,000 sq. miles out of an estimated 55,000,000 sq. miles, or approximately three-fifths of the total land area. Viewed as a whole, it is roughly rhomboidal in shape, and very compact, the seas which penetrate it being insignificant in comparison with its vast extent, though of the greatest importance historically and commercially. The most northerly point of the Old World is about 12° from the North Pole—that is, about half way between the Arctic Circle and the Pole. The most southerly point is about four and a half times that distance from the South Pole.

56. THE OLD WORLD
Showing the continental land masses of the eastern hemisphere

South of the Equator, as we have seen, the land tapers rapidly, so that by far the greater part of the Old World lies in the northern hemisphere. Its greatest extension from east to west coincides approximately with the parallel 40° N. lat., which passes near Madrid, the capital of Spain; Constantinople, the capital of the Ottoman Empire; Samarkand, one of the great rallying points of Russian Central Asia; Peking, the capital of China; and the northern part of Honshiu (or Hondo), the largest of the islands of Japan. The greatest extension of the Old World from north to south is along the meridian of 20° E. long., which passes near Tromsö, in the north of Norway; Cracow in Poland; Budapest, the capital of Hungary; and Cape Town, in the extreme south of Africa.



57. COMPARATIVE AREA OF THE CONTINENTS OF THE OLD WORLD



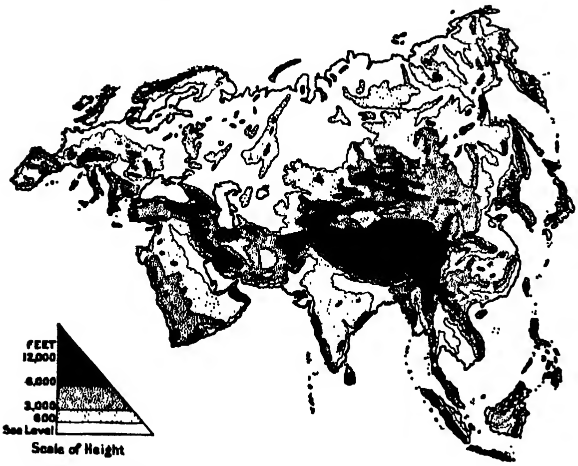
58. A SECTION ACROSS EURASIA, SHOWING THE GREATEST HEIGHT AND THE GREATEST DEPTH IN THE WORLD

Oceans of the Old World. The northern shores of the Old World are washed by the practically ice-bound Arctic Ocean, its western shores by the Atlantic, its south-eastern and southern shores by the Indian Ocean, and its eastern shores by the Pacific. From these oceans many arms of the sea penetrate deeply into the land, two of which must be specially noticed here. The Mediterranean Sea, by a breach in the west, forms an arm of the Atlantic, and separates the southern shores of Europe from the northern shores of Africa. The Red Sea, an arm of the Indian Ocean, all but severs the east coast of Africa from the west coast of Asia. The continent of Africa (11,500,000 sq. miles) is thus nearly cut off from the main mass of the Old World, and is connected with it only by the narrow Isthmus of Suez, between the Red Sea and the Mediterranean, which is little more than 80 miles wide. The remainder of the Old World forms the double continent of Eurasia, the western part of which is known as Europe (3,800,000 sq. miles) and the eastern part as Asia (17,000,000 sq. miles) [57].

Home of the Human Race. Eurasia, with an area of nearly 21,000,000 sq. miles, or approximately two-fifths of the land of the globe, is the most varied and interesting division of the earth's surface. Off its shores lie the greatest ocean depths, and its continental portion contains the culminating height, the vastest mountain area, and the most extensive plains in the world [53]. Every zone of temperature and climate is represented, from Polar to Equatorial, and the range of economic products is consequently extraordinarily varied.

It is probably the original home of the human race, and by far the most densely populated portion of the globe. No enduring civilisation has ever yet originated outside its borders, for the great commonwealths of the white race in other continents are but applications under favourable conditions of principles discovered by the pioneer people of Eurasia. Eurasia, moreover, has been the cradle of all the exalted religious faiths of the world, and thus in every sense it is the great motherland of the world.

Europe and Asia Compared. The structure of Eurasia will not be described in detail here. But one fact is too significant to be overlooked. That fact is the unity of physical structure which characterises Eurasia and makes it, in spite of the conventional division into two continents, really but a single one. Physically, it is impossible to say where Europe leaves off and Asia begins, and the boundary between the continents has shifted with the course of history [59].



59. PHYSICAL MAP OF EURASIA
The solid black patch corresponds roughly with the country of Tibet. The majority of the large towns are below the level of the 600 feet contour

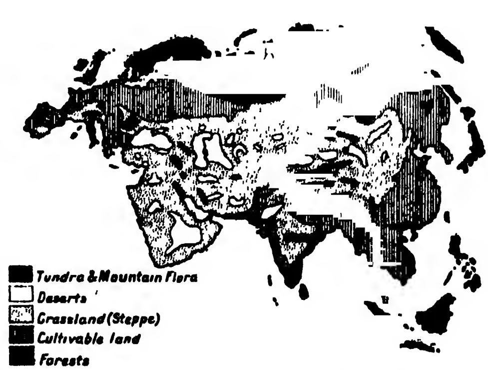
Any good map will show how the great natural features are continuous across both continents. Broadly viewed, the northern part of Eurasia is one vast lowland, extending from the shores of the Atlantic almost to those of the Pacific. South of this we trace across Europe and Asia, from ocean to ocean, a zone of varying breadth and height, but everywhere of considerable elevation. In Europe this zone of elevation, which we may call by the general name of the Eurasian Mountains, is represented by the mountains of Northern and Southern Spain, the Alps, Balkans, and Caucasus, and in Asia by a complex series of double and triple mountain chains, culminating in the great Himalayas. South of the Eurasian mountain system, which attains its greatest breadth as well as its greatest height in Central Asia, is a series of tapering peninsulas, all mountainous, and connected with the mountain core to the north.

All these run south—into the Mediterranean Sea in Europe, and into the Indian Ocean in Asia. Notice, however, that while in Asia these extend far south of the tropic of Cancer, no part of Europe is within 12° of it. Asia, therefore, has a greater variety of climate and products than Europe, which lies wholly in temperate latitudes.

Vegetation. Corresponding with this symmetrical arrangement of highland and lowland from east to west across Eurasia, there is, allowing for differences of elevation, distance from the sea, and other modifying circumstances, a similar arrangement of the zones of climate, which finds a broad expression in the natural zones of tundra, forest, steppe, desert, etc., already described. These may be traced across Eurasia [60], but they are best marked where the continent is widest—that is, in Asia. The tundra, a mere narrow fringe in Europe, forms a broad band in Asia, which has a much greater extension of land within the Arctic circle. Similarly, the belt of temperate forest which covers Northern and much of Eastern Europe attains vaster dimensions in the great plains and highlands of Asia.

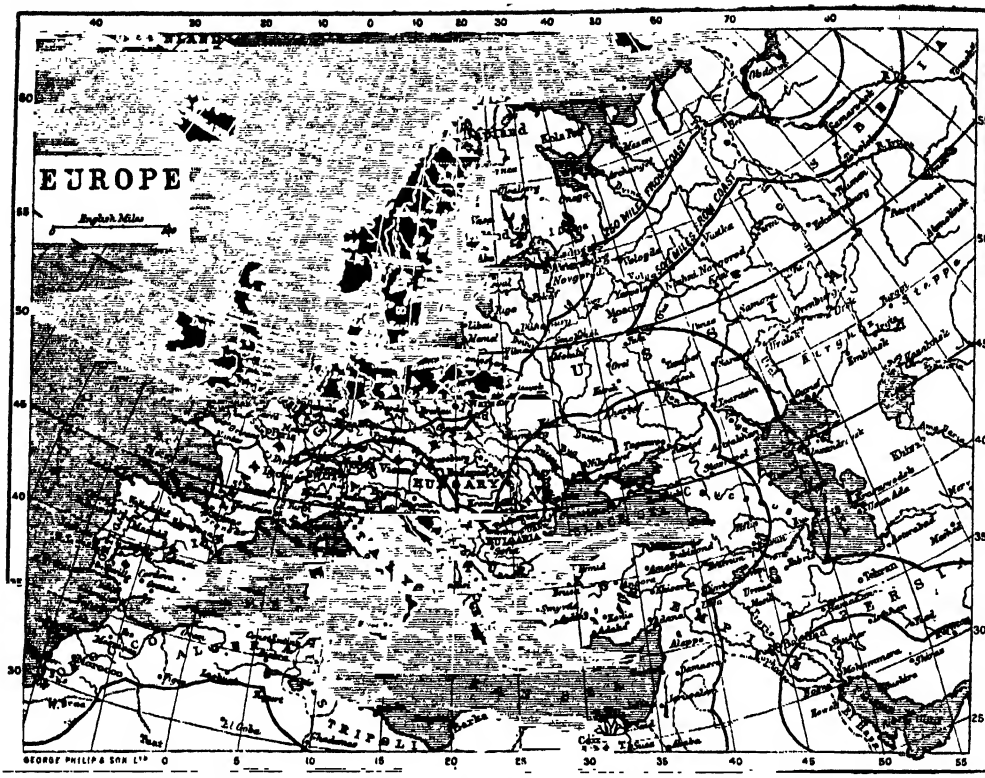
The steppes of Europe, which may be traced across Hungary and Southern Russia, widen similarly as we go east across the southern part of the Asiatic lowland. Towards the drier interior they pass gradually into the desert. This desert belt, which is a mere thread in Europe, extends across the whole of Central Asia, through Arabia, Persia, Russian and Chinese Turkestan, and Mongolia, broken by oases great or small where irrigation is possible. The southern boundary of the Eurasian desert belt may be broadly indicated by a line drawn from Aden, along the Indus valley to the Pamirs, and south of the deserts of Mongolia to Peking. South of the central mountains and deserts lie the monsoon lands, in which the rainy season occurs at the season of highest temperature.

The monsoon winds, as already explained, do not blow far outside the tropics, and this zone



60. VEGETATION MAP OF EURASIA
The tundra lands lie along the northern lowlands, bordering the Arctic Ocean; the mountain flora occurs in the high mountainous regions of Central Asia. The cultivable land includes forests in isolated areas

is consequently absent in Europe. Wherever the rainfall is sufficient the monsoon lands are fertile agricultural lands, often of the savana type. As the equatorial region of constant heat and moisture is approached, the vegetation becomes more exclusively and



61. GENERAL MAP OF EUROPE, SHOWING BOUNDARIES OF COUNTRIES, AND AREAS WITHIN 250 AND 500 MILES FROM THE SEA-COAST

distinctively tropical, and in the Malay Peninsula and the adjacent islands are dense forests of the true equatorial type.

Europe and Asia Contrasted. Why, then, it may be asked, in view of these similarities, has the destiny of the eastern and western continents of Eurasia been so different? Such a question is well asked, but it cannot be answered without a very profound knowledge of the geography of both continents. It may be pointed out, however, that the physical features of Asia, though broadly comparable to those of Europe, are on a vastly greater scale. Barriers of impenetrable mountain, desert, and forest cut off the interior from the sea, and hinder the free movement of peoples and ideas. The country is densely populated only where fertile lowlands open to navigable seas. Here the Indian and Chinese civilisations are highly developed; but they have been little influenced by the rest of the civilised world, and have exercised little influence upon it, because India and China are backed by the loftiest mountains in the world and by some of its most formidable deserts.

The barrier of the desert is practically absent in Europe, the mountains are less formidable in height and breadth, while many other circumstances, of which more will be said later, have combined to promote that free movement of population on which depends the circulation of new ideas and new discoveries, and consequently a rapid progress in the arts of life and of civilisation generally.

EUROPE

At the beginning of our study of the geography of the different regions of the world we are confronted with one of the great difficulties of the subject—what to leave out. Our maps are crammed with the names of seas, mountains, rivers, and towns, and about each of these much of undoubted interest might be said. This would make a series of large volumes, and a similar series might then be written describing how men live in different parts of the world, and how they obtain, utilise, and exchange each of the innumerable animal, vegetable, and mineral products which the earth offers. In a series of articles like the present, where there is room only for the most essential of the myriads of interesting facts there are to know about the world and its people, much space can be saved if those who use them do not expect to find in the text lists of names which they can and ought to find out for themselves in the carefully chosen maps which illustrate them. A student who is not prepared to consult maps as frequently and as carefully as the text is advised to lay aside the study of the subject. In the following pages it will be assumed that the student has ascertained the general position of the various countries of Europe [61].

What it is essential that we should know

about all the countries to be studied are the circumstances which affect them individually as the possible or actual home of man. These include its position in latitude and longitude, which determines its general climate, and consequently the range of its possible products; the distribution of its seas and land, which, besides their effect in modifying its climate, aid or hinder free communication between all parts, and thus, indirectly, the rate of progress in civilisation and commerce; the distribution of its highlands and lowlands, which act in the same direction, and also exercise a great influence on the density of population in particular areas, and the nature of its natural products.

Position of Europe. To state the position of Europe in latitude is to state its relation to the Pole and to the Equator—that is, to polar and tropical conditions of climate. To state its position in longitude is to state its relation to other parts of the world in similar or different latitudes. To know its latitude is to possess far more actual information about it than to know its longitude.

The only satisfactory way to ascertain latitude or longitude is to look at a map, or, better still, a globe, and to reflect at the same time what the figures mean. If this is done for Europe, it will be seen that the parallel of 70° N. cuts the extreme north of the continent, and that very little land lies north of it. The continent is but little wider where the Arctic Circle (67½°) cuts it, and only a few hundred square miles are within it. This means that practically no part of Europe is within the polar zone. The solid core of the continent lies mainly between 55° and 45° N. This means that the great bulk of the continent is in the cool temperate belt. The most southerly of the southern peninsulas, Spain, just reaches 36° N. This means that only the extreme south of Europe is in the warm temperate belt.

Excluding Iceland, which is, of course, part of Europe, the parallel of 10° W. may be taken as the western limit of the continent proper. It cuts the extreme west of Ireland, and passes a little west of the west coast of Spain. The very irregular land frontier with Asia is about 74° E. at its most eastern point, and for a considerable distance roughly runs along 60° E.

The boundaries of Europe should be looked out on the map.

The Seas of Europe. Europe, which may itself be regarded as a large irregular peninsula of Eurasia, is a continent of seas, peninsulas, and islands. The most important of these are shown and named in the map.

The sea penetrates deeply into the land, both north and south, greatly reducing the breadth of the continent west of 30° E. long. The Mediterranean Sea, in the south, is land-locked but for the Strait of Gibraltar, nine miles broad, its only exit and entrance. Look out on the map its great gulfs—the Lion Gulf, the Gulf of Genoa, the Adriatic Sea, the Ægean Sea—and notice in particular the Strait of the Dardanelles, leading through the Sea of Marmora, by the narrow Bosphorus, to the Black Sea and the Sea of Azov. The Caspian Sea, farther east, is entirely land-locked, and has no connection with the Mediterranean. In the north there is also an almost land-locked but much shallower sea, the Baltic, with its gulfs. The only exit from the Baltic is by the Sound, between Sweden and Denmark, leading through the stormy Kattegat and Skagerrak to the wider North Sea, from which the only practicable passage to the Atlantic Ocean, its great gulf the Bay of Biscay, and the Mediterranean Sea, is by the narrow English Channel. The Arctic Ocean, to the north of Europe, has one arm, the White Sea, which gives Russia its port of Archangel.

This cutting up of the continent by the sea is very important. Not only does it give to almost every important country access to at least one sea, but it makes the climate of Europe much more uniform than would otherwise be the case. Only in the extreme east, in Russia, is any part of Europe more than 500 miles from the sea, and only there is a really continental climate experienced.

Climate. The climate of a country, so far as its temperature is concerned, is best understood by examining the direction of the isothermal lines, and, in particular, the isotherms for January, the coldest, and July, the hottest month of the year. Temperature is affected by many other causes than latitude, for the isotherms do not correspond with the parallels of latitude, though they do so much more nearly in summer than in winter, and more nearly in the western than in the eastern part of the continent. The western half of Europe is exposed to the westerly winds from the Atlantic, which, in winter, are mild and rainy, and, in summer, cool and rainy. The reason of this has already been explained.

The influence of the Atlantic winds on the climate of Western Europe is well shown by the manner in which the July isotherms are bent north in eastern Europe. In July, Kazan, in Russia, in the latitude of Edinburgh, is as warm as Oporto in Portugal. Archangel, on the White Sea, is as hot as Edinburgh, though it is 20° farther north. In winter, when the severity of the winter is greatly lessened in Western Europe by the Atlantic winds, the eastern part suffers from intense cold. No one who has ever noticed the remarkable manner in which the January isotherms bend south in Central Europe, and has reflected what this bending south means, is ever likely to forget it [62].

Water freezes at a temperature of 32° F. The isotherm for this temperature, the freezing point, shows that Iceland, nearly all Scandinavia, the greater part of Germany, Austria-Hungary, the northern Balkan States, and all Russia (except the southern part of the Crimea), are held in the grip of frost. In January it is warmer in the extreme north of Scotland than in Sofia, the capital of Bulgaria, which is in the latitude of Rome. To show how severe is the winter of Eastern Russia, take the isotherm of 14° F., which indicates 18° of frost. Shown on a map it would pass east of St. Petersburg, and

curve south almost to the Caspian Sea, in the latitude of Paris. Compare this with the climate of the British Isles, where weather cold enough for several days' skating is the exception rather than the rule, or with that of France, Western Germany and the Mediterranean lands.

We summarise the climate of Europe, therefore, by saying that it is equable in the west and south, and extreme in the east.

Distribution of Rain. As a result of the influence of the Atlantic on the climate of Europe, we should expect to find the west of Europe wetter than the east, and the western slopes of mountains wetter than the eastern. This the rainfall map of Europe shows to be the case [63]. The rainy Atlantic winds strike full on the mountainous shores of Scandinavia, upon the British Isles, and particularly Ireland, and less directly upon Northern

62. EUROPE, SHOWING SUMMER AND WINTER TEMPERATURES

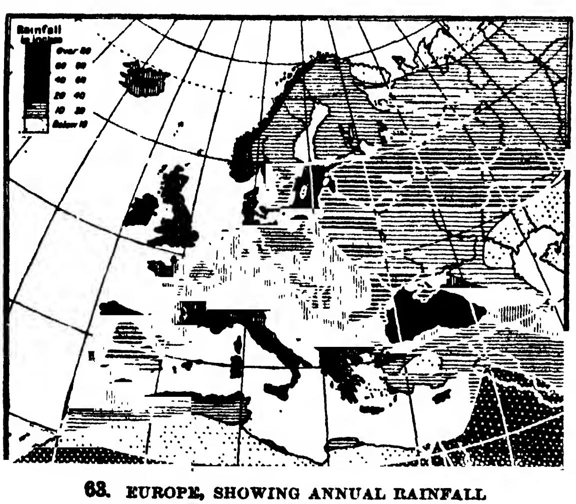
shore of the Spanish peninsula. Ireland and the western half of Great Britain are considerably wetter than the eastern parts, as we may learn by unfortunate experience if we spend a holiday on the western shores of our island. In Scandinavia the winds part with much of their moisture on the western slopes of the western mountains, while the eastern slopes, and indeed all of Sweden, are comparatively dry.

In this part of Europe the rainfall is fairly equally distributed at all seasons, but is heaviest in autumn and winter. Another area which is shown in the map as having a high rainfall is the mountain district of Switzerland, with the mountains to the north and south. The reason why mountain regions have a relatively high rainfall has already been explained, and should be borne in mind. The peninsulas to the south, and the Mediterranean lands generally, have dry summers, and the rainfall is in the winter half-year. The reason of this, the shifting north of the dry area in the belt of calms at the northern limit of the trade winds in summer, and the extension southwards of the rainy westerly winds in winter, has already been explained. In the east of Europe the map shows that few areas have as much as 20 in. of rain in a year, against 80 in. in the wettest parts of the British Isles. Round the Caspian Sea there are regions with less than 10 in. a year, where the desert conditions of Central Asia are beginning to be felt. The other very dry area of Europe is in Central Spain, where the rainfall is under 20 in.

The Lowlands of Europe. It is no longer thought necessary to learn by heart the names and heights of the highest and most inaccessible peaks of a continent or country. What we want to know, for most practical purposes, is where the lowlands are and how to get from one to another by the natural breaks or passes in the mountain chains.

Looking at a map of Europe [64] in which the distribution of high and low ground is shown, we see that the lowlands of Europe are very extensive, and that more than half the continent is less than 600 feet above sea-level. A great lowland, forming part of the Eurasian lowland, runs through the southern part of the British Isles, Northern France, Belgium, Holland, and Northern Germany, and widens out into the great plain of Russia, which stretches on, far beyond the boundaries of Asia, almost to the Pacific. In Europe it would be possible to walk from the frontier of Asia to the Bay of Biscay, by a fairly direct route, without ever seeing a hill as high as the Eiffel Tower in Paris.

North and south of this vast



63. EUROPE, SHOWING ANNUAL RAINFALL
The darker the tint, the heavier the rainfall

lowland are bands of much higher land. To the north are the mountains of the British Isles and Scandinavia, separated from each other by the shallow North Sea. To the south, the highlands are broader, higher, and much more irregular in arrangement, forming part of the great Eurasian mountain system, which stretches from the Atlantic to the Pacific. To this system belong the mountains of Spain, the Pyrenees between France and Spain, the Central Plateau of France, the Vosges, Black Forest, and other mountains of Southern Germany, the Jura and Alps of Switzerland, the Apennines, running south from the Alps into Italy, the mountains of Bohemia, the Karpathians of Hungary, and the ranges running from the Alps through the Balkan peninsula, as well as the Caucasus, between the Black and the Caspian Seas, forming part of the frontier between Europe and Asia. A number of smaller, fertile lowlands lie south of these Central Mountains, the largest of which are the plain of Lombardy, between the Alps and the Apennines, the plain of Hungary, enclosed by the Alps, the Karpathians and the mountains of the Balkan peninsula, and the plain of Roumania or Valakhia (Wallachia), south of the Karpathians.

Rivers. A long though not continuous barrier of mountains is thus interposed between the north and south of Europe, and has always rendered communication between north and south a matter of some difficulty. The fact that this barrier lies far to the south, with the longer, gentler slope to the north, causes most of the great rivers of Europe to flow north to the North and Baltic Seas, and gives to these seas, and the countries which border them, a very great importance. The only notable exceptions among the rivers of Europe are the Rhone, which flows generally south to the Mediterranean, and the Danube, which forces its way east to the Black Sea through one mountain barrier after another, forming the great physical, commercial, and political link between Central and Eastern Europe. The Volga and other great rivers of Russia also flow south, but they have no such importance for Europe as a whole as has the Danube. Note on the map how each of the principal countries of Europe has its great river linking its seas with the mountain centre of Europe. In France the Seine, the Loire, and the Rhone connect the English Channel, the Bay of Biscay, and the Lion Gulf of the Mediterranean with the centre of Europe. Germany has the magnificent Rhine, which enters the North Sea by way of Holland, as well as the Elbe, Oder, Vistula, and others of less importance, bringing her distant mountain provinces into touch with the many busy ports which fringe the North and Baltic Seas [84].

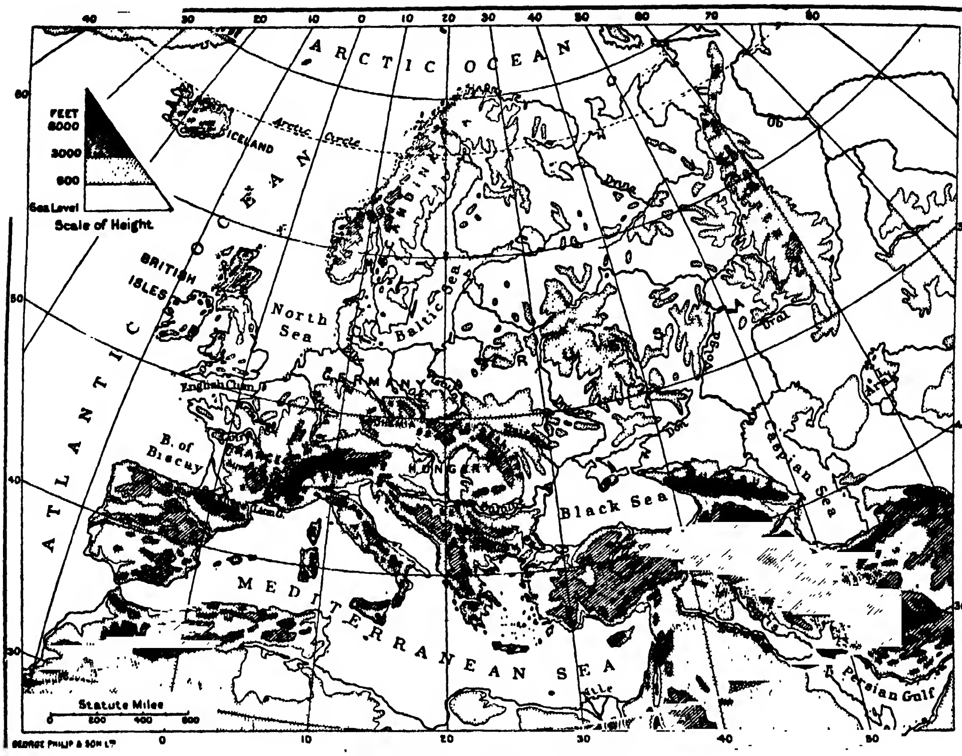
Austria-Hungary has the Danube, Italy the Po, and in Russia the Dnieper may perhaps be reckoned in the same group of rivers. Some of these rivers, with their tributaries, form the great natural lines of communication across Europe. The easiest route across Europe is by way of the Rhine and its upper tributaries to the famous walled city of Luzern, whence the lake of the same name leads deep into the Alps, through the core of which is cut the famous St. Gothard Tunnel, to strike one of the tributary valleys of the Po, leading to the plain of Lombardy. Hardly less important is the route by the Seine and Rhone valleys and the Mont Cenis Tunnel through the Alps to the head of another tributary valley of the Po, and thus to the great centres of Italy. The principal route to the east goes by the Rhine and Danube valleys.

Vegetation. The natural zones of vegetation—tundra, forest, steppe, and even desert—and their relation to each other and to the corresponding zones in Asia, have already been described [60]. In Europe, however, man has been at work for centuries—if not millenniums—in transforming the face of the earth. Impelled by the need of fuel, and still more of land on which to sow and reap, he has steadily cleared the forests—at first, no doubt, along the rivers, and later up the side valleys and far up the hillsides. In Central Europe only the higher slopes of the mountains are still forested, and in the valleys below orchards and meadow land have replaced the dark pine-woods. Nature, however, still asserts herself, and sets limits to the regions in which particular plants can be cultivated.

Of all the chapters in the eventful history of our race none is more interesting than that of agriculture. When history begins this art was already old, and as man's knowledge of the world has widened, plant after plant from other lands has been introduced into Europe with more or less success. Many of the most familiar cultivated plants are really not of European origin at all.

The Cereals. The most important plants cultivated by man are the cereals, or bread stuffs, from which the staff of life is manufactured. Of these the most productive as well as the most palatable is wheat, which is grown all over Europe south of the North and Baltic Seas, as well as in the British Isles. In the hotter, drier parts of the southern peninsulas it is largely replaced by maize. All through the wheat belt rye, oats, and barley are grown on the poorer soils, the latter cereal being so hardy that it can be cultivated as far north as the Arctic Circle, though of course with a diminishing yield.

Fruits. Next in importance to the cereals, and almost as ancient, are the fruits. These include many different varieties adapted to different climates. The king of the northern fruits is the apple, which has made famous the orchards of Southern England and Northern France. In the rather drier countries of Central Europe the stone fruits—cherry, apricot, and plum—become more important, the latter being one of the staple products of the northern Balkan provinces. The Mediterranean has two famous fruits, anciently reckoned as the best gifts of the gods to man. These are the olive,



64. PHYSICAL MAP OF EUROPE

with its nutritious oil, and the vine. The vine, however, though it loves the sunny South, can be grown with care far north of the Central Mountains, on the terraced southern slopes of the hills. A few hundred years ago it is said to have flourished in these islands and in Northern France, though we must suppose that its juice must always have lacked something of the mellow sweetness which only long, steady sunshine can give.

The Root Crops. A third group, hardly less important, is the root crops. These are among the youngest of the staple crops of Europe, but their introduction has caused a revolution in the conditions of life. Formerly cattle were killed in late autumn because winter food was not to be had. The flesh was salted down or smoked, and this unpalatable fare formed the principal winter diet.

The introduction of root crops of the swede type has made it possible to have fresh meat and milk all the year round. The potato, transported from the New World, has brought a cheap and palatable food within the reach of all classes. A recent but very important food crop is the sugar beet, which is largely grown all over France and Germany, and might with advantage be introduced into this country.

Fibre and Fodder Plants. Another group of plants is grown for fibre. Of these the most useful are flax and hemp, largely grown around the Baltic. Besides these great groups we may note plants grown for fodder, including grasses of various kinds. In Southern Europe the principal fodder plant is lucerne, a pulse with long roots, which is better suited to the drier climate. The pulses [see BOTANY] are widely grown, but are specially important in the Mediterranean region. In the same region the mulberry is largely grown to feed silkworms Many other plants, such as hops, used in the making of beer, might be mentioned, without exhausting the useful plants grown in many parts of Europe.

Animals. The ancient wild animals of Europe have now almost disappeared, and have been replaced by the domestic animals—cattle, horses, sheep, goats, which are kept wherever pasture is available. The goat and the sheep, the hardiest and least dainty, have a wide range. The goat does well in the Mediterranean region. The sheep of many parts and particularly of Britain and Saxony, are famous, as are the horses of Hungary. The Mediterranean region is too dry for cattle, and the mule becomes more important than the horse. In the extreme north of Europe the reindeer is the only domesticated animal, serving for purposes both of draught and food.

OUTLINES OF EDUCATIONAL TOURS ABROAD

Model Itineraries indicating how in the Least Time and with Minimum Expense Tourists may see Germany, Norway and Holland

By J. A. HAMMERTON and WILLIAM DURBAN, B.A.

GERMANY

Germany is not, on the whole, a land of imposing natural scenery, but it is the seat of the most intellectual civilisation in the world. Its cities are almost all quaintly interesting, historic, and beautiful, and its agrarian tracts uniquely attractive to the student of agricultural conditions. Its cathedrals are epitomes in stone of the religious history of a thousand years, and its picture galleries rival those of Italy. Travel is exceedingly comfortable, inns are excellent, the people sincere and reliable; the manners and customs are fascinating with the survivals of picturesque mediævalism, and the development of modern industry is astonishing. Germany is specially interesting as the link between North and South, and between East and West. Fresh and bracing with the breath of the Baltic, it is with its lovely vineyards suggestive of the attributes of the South; while its exquisite scenery along the Rhine, in the Black Forest, and in Saxon Switzerland can scarcely be excelled anywhere in Europe for those who aim at the maximum of enjoyment with the minimum of fatigue.

As Germany is a very populous country, and its attractive cities are fairly distributed over the whole area, the tourist who wishes to gain a general acquaintance with this extremely interesting land has a great latitude of choice. But a delightful trip of a fortnight is easily planned for those who go for the first time.

A Fortnight in Germany. The wisest

gramme of the tour would then be as follows:

First and Second Days. In Berlin the main objects to be visited are the *Palace*, the *Royal Library*, with its 800,000 volumes; the *Picture Gallery*, containing 1,500 paintings; the *University*, attended by 4,000 students; and the old and new *Museums*. These will occupy the first day. The second day will be delightfully spent among the interesting open-air sights. The famous *Unter den Linden*, or grand double avenue of lime-trees; the splendid park called the *Thier Garten*, and the *Zoological Gardens*, which are among the finest in Europe; the magnificent *Brandenburg Thor*, or Triumphal Arch; the noble equestrian statue of *Frederick the Great*; the *Warriors' Monument*, and the Royal Chateau of *Monbijou*, all invite pleasant attention.

Third Day. A day is ample for the inspection of Potsdam, after Berlin the finest and best built city in Prussia, with the sights in the environs. These are the *Triumphal Arch*, copied from Trajan's at Rome, the celebrated *Sans Souci Palace*, erected by Frederick the Great; the villa called *Charlottenhof*, with its lovely gardens; and the old *Royal Palace*, with its Grand Colonnade.

Fourth Day. This may well be spent at Dresden, where the "things to see" are compactly situated. The *Japan Palace* contains the immense Public Library, and in the Green Vault the wonderful collection of pearls, precious stones, and curiosities. The *Court Theatre* is a magnificent edifice, but the pride of Dresden is, of course, the *Picture Gallery*. Here, amongst many masterpieces, are Raphael's "Sistine Madonna," Titian's "Tribute Money" and "Venus," Correggio's "La Notte," Da Vinci's "Francesco Spraga," and numerous works by Rubens, Vandyke, etc.

Fifth and Sixth Days. Two days must be devoted to Leipzig. Life here is full of fascination. The chief of the sights are the beautiful *Rosenthal Park*, the stately *Rathhaus*; the *Gewandhaus*, famous for its concerts; the old *Pleissenburg Castle*, the fine *Museum*, the *Grand Theatre*, the *University*, with 3,000 students, and the *Conservatorium of Music*. If the tourist is in the city at New Year, or Easter, or Michaelmas, he will be fortunate in seeing the marvellous Trade Fair held three times a year; the famous Book Fair being also held at Easter.

Seventh Day. A short journey takes one to Halle. Here are striking sights, including *Handel's Monument* and the house where the musician was born; the ancient *Red Tower* in the Market Place, the fine *Town Hall*, the *University*, and that most famous orphanage in the world, the *Francke Institution*, with 4,000 inmates. All can be seen in a day.

Eighth Day. Near at hand is Wittenberg, which claims a day. It is full of memories of Luther and Melancthon, whose graves are in the *Schloss Kirche*, where Luther preached, and to the doors of which he nailed his theses. Their monuments are in the market, and *Luther's House* is a wonderful museum of his relics.

Ninth Day. Although Magdeburg and Brunswick are charming with their quaint, historical aspect, one day is sufficient to see both towns. The old thirteenth century *Cathedral* in the former contains Tetzel's great money-box, and in front of the fine old *Town Hall* is the monument to *Otho the Great*, erected

relics brought from the Holy Land by Henry the Lion. In the *Museum* are works of art by Dürer, Rembrandt, Holbein, Guido, Angelo, etc. A fine avenue of lindens leads to the *Ducal Palace*, a very imposing edifice.

Tenth Day. This could be devoted to Hanover and Hildesheim, which can both be seen in the time. In Hanover the curious old streets in one part of the city, the ten bridges over the Leine, the *Column of Victory* in the Waterloo Platz, the stately *Town Hall*, dated 1439, the *Royal Library*, the fine *Royal Palace*, and the splendid *Theatre* are all worth special attention. In Hildesheim are the most wonderfully picturesque mediæval wooden houses in Europe, with balconies on their upper stories, and marvellous carved gables and walls. The eleventh century *Cathedral* has magnificent bronze gates of that period, as well as lovely paintings on glass. The *Church of St. Michael* is an ancient basilica. On the wall of the *Church of St. Godehard* is a rose-tree supposed to be nearly a thousand years old.

Eleventh and Twelfth Days. The traveller reaches the beautiful Rhine at Cologne, with its glorious *Cathedral*, whose twin towers soar to the height of 500 feet. Here are the reputed skulls of the three Wise Men from the East. The *Church of St. Ursula* contains the bones of 11,000 virgin martyrs, and at the *Church of St. Gereon* are the

bones of 6,000 Theban martyrs. In *St. Peter's* is the famous altar-piece by Rubens, representing the Crucifixion of St. Peter. To Cologne and the neighbourhood two days may well be given.

We have allowed for a day's journey at the beginning of the tour, and the fortnight's progress will end with the day required for returning to London, and the tourist will have the satisfaction that he has gained an excellent acquaintance with the most important region of Germany, the heart of the Empire.

Longer Tours. *Three weeks* would give the visitor the opportunity of including at least a portion of South Germany, for it would enable him to go, after seeing Dresden, down to Munich, the splendid Bavarian capital, then to take in Nuremberg, Ratisbon, and Heidelberg, resuming the above tour by going from Heidelberg up to Leipzig. *A month* would enable the tourist to see most of the Rhine, to go also to the Falls of the Rhine at Neuhausen, and to spend three days in the Black Forest.

Fares from London to Berlin. *Viâ* Harwich and Hook of Holland or Flushing: Single, £4 6s. 9d., £3 2s.; return, £6 4s., £4 8s. The fares *viâ* Hamburg to Berlin are each way (with no reduction on return ticket). First class, £2 14s.; second class (train), with first class on boat, £2 5s. 6d.; second class throughout, £2 0s. 6d. Train fares in Germany are slightly cheaper than in England. The second-class carriages are often superior to the first class in England.

Cost of Living. In Germany this is rather less than in most Continental countries. Good, wholesome food is to be obtained everywhere in abundance. Bread is everywhere excellent, and both meat and drink are under strict Government supervision. It is an excellent plan to dine at the popular restaurants. The old-fashioned and unassuming hotels will often be found as comfortable as the more pretentious modern establishments. Germany is a true homeland of substantial comfort.

Books to Read. Literature about Germany is abundant. Longfellow's "Hyperion" is the best for reading on the journey, and almost as delightful is Bayard Taylor's "Views Afoot." Excellent are "German Life in Town and Country," by W. H. Dawson; "German Life," by H. Mayhew; "Pictures from Germany," by Dr. Green; and "Rambles in Germany," by Hon. F. St. John.

HOLLAND

The English visitor to Holland for the first time is astonished at what a new world he has reached in a few hours. Country, people, customs, language, style of buildings, dress, and methods of business are all strange, quaint, and striking. The home of the historic Dutch people is a phenomenal country, full of extraordinary natural characteristics. It is the lowest land in the world, most of it lying several feet below the sea-level, and needing the protection of the marvellous system of dykes. Countless canals intersect the land in all directions. The lofty and narrow houses, constructed of red brick and white cement, the numerous odd-looking windmills, the trim tulip gardens, and the rows of poplars stretching along the dykes and canals for miles, impart a unique aspect to the view from every point.

A Week in Holland is sufficient for gaining some knowledge of the country well worth acquiring. It should be spent in visiting Amsterdam, Marken, Zaandam, Haarlem, The Hague, Scheveningen, and Delft. More cannot be accomplished, but the tourist will have enjoyed a memorable week.

A FORTNIGHT IN HOLLAND. FIRST DAY. ROTTERDAM: The *Boompes*, or handsome and busy quay, planted with fine trees. The *Groote Markt*, with famous bronze statue of Erasmus. The *House of Erasmus* in the Eijde Kerkstraat. *Boymans' Museum*, with fine picture-gallery, containing some famous works of Rembrandt, Hals, Ruysdael, Van Ostade, Hobbema, etc. The fine *Park*. *Zoological Gardens*.

SECOND DAY. GOUDA: The *Groote Kerk*, with its far-famed 42 stained windows containing Scripture subjects. The *Museum*, with curious local antiquities and fine pictures.

THIRD DAY. UTRECHT: The *Cathedral* of St. Martin, with beautiful Gothic cloisters and great vaults, in which are the hearts of the German Emperors Conrad II. and Henry V. Cathedral Tower, 338 ft. high, with chime of 42 bells. The view takes in nearly all Holland. The *Museum of Arts*, in which are famous pictures, the finest being various works of De Keyser and Van Schoreel.

FOURTH DAY. AMSTERDAM: The magnificent central square called the *Dam*, with the lofty monument surmounted by the *Statue of Concord*. The *Royal Palace*, built on nearly 14,000 piles, with splendid Council Chamber, and many fine pictures by Bol, De Wit, Flinck, Eeckhout, and Wappers. The *Tower*, crowned by gilded ship, gives a wonderful view from the summit. The *Nieuwe Kerk*, with famous and beautifully carved wooden pulpit, and several monuments of noted admirals, including De Ruyter. The *Stadhuis*, with famous pictures by Bol, Hals, Flinck, etc. The *Ryks Museum*, the finest picture-gallery in Holland, with Rembrandt's "Night Watch," etc. The *Zoological Gardens*, the finest in the world next to those in London.

FIFTH DAY. MARKEN: A singular island. Famous for the curious costumes of its primitive people and its houses on artificial mounds or "hills of refuge." The *Zuider Zee* is seen to advantage here.

SIXTH DAY. ZAANDAM: A very typical Dutch town. *Hut of Peter the Great*, an extraordinary historical relic. The 400 windmills along the bank of the Zaan.

SEVENTH DAY. ALKMAAR: *Town Weighing-house* with handsome tower, in front of which, on Fridays, is arranged the most wonderful cheese market in Europe.

EIGHTH DAY. HAARLEM: Thriving manufacturing town, but wonderfully clean and very attractive. Many pretty gardens and extensive promenades along the Spaarne. The *Groote Kerk*, with the world-famous organ, long the largest in the world. Public performances at noon on Tuesdays and Thursdays. *Town Hall* with museum, containing pictures by national artists, especially Hals. The *Park*, with beautiful beeches. The magnificent *Tulip Gardens*, which largely supply the world with the choicest and most costly bulbs.

NINTH DAY. LEYDEN: Very ancient and charming city, on an arm of the Rhine. Gothic Church of *St. Pancras*, with singular towers, and 38 massive interior buttresses. The Church of *St. Peter*, the largest in Leyden, with the tombs of its most famous men. The *Botanic Garden*, with hot-houses containing magnificent exotics of East Indies.

TENTH DAY. THE HAGUE: One of the loveliest cities in the world. The fashionable pleasure city of Holland. Surrounded by glorious woods. The

Vijver, or Fish Pond, a beautiful sheet of water in the middle of the town, with islands and swans. The *Binnenhof*, a curious mediæval pile, in which are many of the municipal and Government offices. The far-famed *Picture Gallery*, containing many of the masterpieces of Rembrandt, Potter, Steen, Dow, Van de Velde, Ostade, Ruysdael, etc. Most popular of all is Paul Potter's "Bull." The beautiful *Park*, with the *Huis ten Bosch* (House in the Wood), a splendid Royal villa.

ELEVENTH DAY. SCHEVENINGEN: Old and New towns. The former a quaint fishing village. The latter a popular seaside resort.

TWELFTH DAY. DELFT: Pretty town, with clean canals bordered by lindens. Only a quarter of an hour by rail from The Hague. The *Oude Kerk*, with leaning tower. Here is a monument of *Van Tromp*. The *Nieuwe Kerk*, with magnificent monument of William of Orange. The *Stadhuis*, with some fine pictures.

THIRTEENTH DAY. SCHIEDAM and VLAARDINGEN: At Schiedam are 220 *distilleries*, where are manufactured the famous "Hollands" and "Geneva." Near by is the latter town, which is the chief depot of the wonderful industry called the "great fishery," in which a fleet of smacks is employed for the herring, cod, and haddock catch.

FOURTEENTH DAY. The tour concludes with return to Rotterdam, or to Hook of Holland or to Flushing, for England.

A Week's Extension. By extending the tour another week, time may thus be had for visiting Edam, Volendam, and Hoorn. If yet another week can be devoted to Holland, it might include Broek, Monnickendam, Purmerende, the wonderful Great Helder Dyke, Woerden, Arnhem, etc.

Fares. Travelling is unusually easy in Holland, the distances being so short. The average daily cost, including railway fare and hotel expenses, should not amount to more than from £1 to 23s. a day. This may be considerably reduced by avoiding the larger hotels and taking many meals at the cafés and restaurants. The fares from London to Rotterdam are: First class, single, £1 11s. 6d.; return, £2 8s. 3d.; Second class, single, £1 0s. 1d.; return, £1 11s. 7d.

Books. Abundance of literature of Dutch travel exists. Amongst the best works are: Meldrum's "Holland and the Hollanders;" Wood's "Through Holland;" Lovett's "Pictures from Holland;" Bird's "Land of Dykes and Windmills;" Hare's "Sketches in Holland;" Havard's "Picturesque Holland" and "The Heart of Holland;" and Esquiros' "Dutch at Home."

NORWAY

No country on earth can rival in its own special features the "Land of the Midnight Sun." Within forty hours we can reach that glorious coast, the Norwegian "Skjaergaard," which, for more than eight hundred miles, with its innumerable rocky islands stretches from Stavanger to the North Cape. Thus, by a short sea trip, we are able to penetrate one of the most romantic regions on the surface of the globe, where shining fjords, dotted with islets, ramify amongst precipitous mountains; where gleaming glaciers continue the snow-fields to the edge of the sea; where verdant and flowery fjelds are haunted by the bear, the elk, the lynx, and the reindeer; and where cascades dash down from dizzy heights to slumber in magnificent lakes that are counted by hundreds in this glorious territory. The attractions of Norway abound in every district. In this respect it is absolutely unique. It matters not whether the traveller chooses Telemarken, the Fille Fjeld, of the centre, the Dovre Fjeld, further north, the passage to the North Cape, the Western Fjords, or the region round Christiania.

A Week in Norway. Although it might be imagined that very little indeed could be seen of so vast a country as Norway, crowded with scenes of beauty, in the short period of a single week, yet on account of the easy accessibility of the sublime Western Fjords, it is possible for an active tourist to become well acquainted with a number of the most famous centres of that portion of the grand coast. If no longer time can be given, the week should be devoted to the neighbourhood of Bergen and the wonderful Hardanger Fjord. A day each should be given to Bergen, Odde, Eide, Vik, Vos, and Gudvangen. Thus, the lovely Sogne Fjord is also seen, and the week covers what is, in the view of many lovers of Norway, the most exquisite section of the country.

A FORTNIGHT IN NORWAY. FIRST DAY. BERGEN: The ancient painted warehouses in the suburb of *Sandviken*. The *Fish Market*. The grand view from *Fjeldveien*. The *Museum*, with wonderful antiquities of the Stone Age, the Bronze Age, the Early Iron Age, the Viking Age, and a magnificent Natural History Department.

SECOND DAY. ODDE: On a lovely branch of the Hardanger. Excursion to the *Buar brae Glacier*. The sublime *Folgefonde Glacier*.

THIRD DAY. EIDE: Lovely scenery all around. *Vossevangen*. The glorious drive to *Gudvangen*, commanding some of the sublimest mountain scenery in Norway.

FOURTH DAY. LAERDALSÖREN: Splendid scenery on the *Sogne Fjord*. Some of the waterfalls in the district between Gudvangen and Laerdalsören are 2,000 feet high, and one is upwards of 3,000 feet. The mountains flanking the fjord in this section are seldom less than 5,000 feet high. Nature here displays her wildest, grandest, and most marvellous moods.

FIFTH DAY. BALHOLM: A favourite centre for various little summer excursions amongst the superlatively beautiful mountain scenery, lake, valley, and fjord. This is one of the finest parts of the Sogne Fjord. The *Rommehesten* can be easily ascended, and from the summit a glorious view is obtained of glaciers and snowclad mountains.

SIXTH DAY. VADHEIM: On the lovely little Vadheim Fjord, an arm of the Sogne Fjord.

SEVENTH DAY. FÖRDE: Drive on to the lovely *Jolster Lake* and then to *Ordal* by the grand waterfall called the *Hulefoss*. Arrive at *Faleide*.

EIGHTH DAY. FALEIDE: One of Norway's choicest centres. The beauty of the scene defies description. Glaciers of *Olden* and *Loen*, and the Lakes *Langseter* and *Svingseter*, famous for fishing.

NINTH DAY. HELLESYLLT: Splendidly situated at the head of the Sunnelvs Fjord, which is a mile wide and extends for 20 miles between precipitous mountains 5,000 feet high.

TENTH DAY. Steamer along the grand and gloomy *Geiranger Fjord*, considered the most wonderful of all the Norwegian waterway gorges on the coast. The *Seven Sisters Waterfalls*.

ELEVENTH DAY. AALESUND The *Park*, with a splendid panorama. The centre of the codfishing district of Sonmor. Numerous cod-liver oil factories. Drive to *Borgund Church*, one of the curious wooden churches built in the 12th century.

TWELFTH DAY. MOLDE: Styled by some enthusiasts the "finest spot in all Norway." Romantically situated on the ocean at the entrance to the *Romsdals Fjord*. The lovely little park of *Reknaeshaugen*. Beautiful walk up to *Varden*, whence is seen one of the grandest of Norwegian panoramas.

THIRTEENTH DAY. From MOLDE to the wonderfully beautiful *Eikisdals Lake* by steamer. A delightful little excursion. Romantic gorges and glaciers.

FOURTEENTH DAY. Return to Bergen by steamer. Magnificent coast and island scenery. Some travellers prefer to do this voyage at night.

Three Weeks in Norway. Such a tour will, of course, afford fine opportunity of extended surveys of this marvellous land in the north. The visitor should go from Hull to Christiania instead of to Bergen, and cross the country from the eastern side, traversing the splendid mountain tract called the Fille Fjeld. This will occupy a week, for the ride is by carriole, the pretty little vehicle of the country, which holds one traveller, drawn by a sturdy little mountain pony. Doing 50 miles a day, always amidst glorious scenery, in a bracing atmosphere, with mountains, cascades, glaciers, pine forests, lakes, alternately in view, the distance of 300 miles is done in six days, and the tourist emerges from the sublime wilderness at Laerdalsören, at the head of the grand fjord mentioned already He will have enjoyed a week never to be forgotten. Then after the fortnight on the west already described, he can go from Molde north to Trondjem, spend two days there, then take the railway for Christiania, stopping at any few of the various attractive spots on the way for a day each.

A Month in Norway. This is an ideal experience. At Molde, after the three weeks already described, the tourist should undertake the journey by the romantic Romsdal, one of the loveliest valleys on earth, which leads to the Great Dovre Fjeld. This he will cross by way of Dombaas and Jerkin, going over the magnificent, wild, and sombre juniper plateau. The experience will be unique, and innermost Norway will be seen to perfection. The railway is reached at Lille Elvdal, and between that point and Christiania the fourth week may be spent delightfully at such favourite spots as the tourist may select, all being of enchanting beauty.

Travel and Expenses. The cost of touring in Norway averages £1 a day. The fare from Hull to Bergen is: First class. single, £4 10s. 0d., return £7; second class, single, £3; return, £4 10s. 0d. This is by the Wilson Line. The fare is somewhat less by the Bergenske Line from Newcastle.

Most of the travelling in the interior of Norway is by means of the two curious national vehicles. One of these is the pretty little carriole. The tourist himself drives, for there is only room for him on the seat of this enlarged kind of perambulator. Behind his seat, on a board, his luggage is strapped, and his box or portmanteau serves as a seat for the "skydsgut," or boy who accompanies him, though the companion is sometimes a "pige," or girl. This attendant is necessary in order to take back the vehicle after the change at the next posting station on the route. The whole traffic is organised by the Government, and the tariff is rigidly fixed. The other kind of vehicle is the "stolkjaere," a kind of two-wheeled dog-cart accommodating two passengers and the driver. For riding through Norway the best receptacle for luggage is a strong portmanteau, which should not exceed 34 in. in length, 16 in. in width, and 15 in. in height.

Books. The literature of Norwegian travel is to be studied with great advantage before going on a trip to this lovely land in the north. Among the books which should not be neglected are: Du Chaillu's great work in two volumes, "The Land of the Midnight Sun;" Lovett's "Pictures in Norway;" Wood's "Round about Norway;" Olivia M. Stone's "Norway in June;" Bradshaw's "Fjords and Fjelds;" and Lady Diana Beauclerk's "Summer and Winter in Norway."

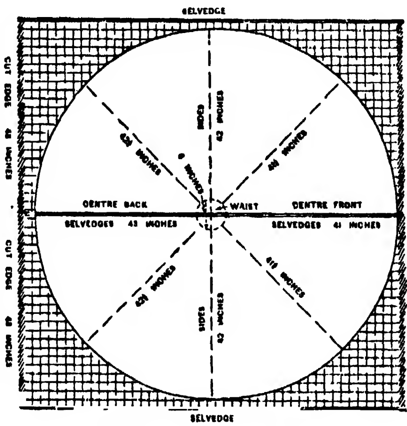
Continued

Full Skirts. Cutting on the Cross. Crossway Strips. Flounces. Stripes and Checks. Strappings. Velvet and Velveteen

By AZELINE LEWIS

A Sun-Ray Skirt. Though sun-ray skirts can now be bought ready-made for very little, it may be useful to know how to prepare one for pleating, and the next diagram [**69**] reveals the mystery.

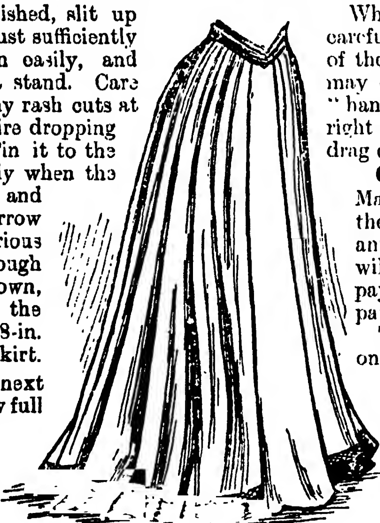
For this skirt two widths of 48-in. material are required, as with narrower goods it will not be possible to cut it with only two seams, and even with this width it will only just cut it in this way for a 40 or 41 in. front measure. With a seam back and front, for a tall person, the material would need to be 54 in. wide. The diagram shows how to cut the material, but the circle for the waist must *on no account* be touched till the skirt is pleated, which can be done at various places in London, and at many machine depots elsewhere.



69. A SUN-RAY SKIRT

The hem may be done before or after pleating; in the latter case the pleats will need pressing together when the skirt is hemmed. When pleated and the foot part finished, slit up the opening at the waist only just sufficiently to allow the skirt to slip on easily, and arrange it on the wearer or a stand. Care must be taken not to make any rash cuts at the waist, in case it may require dropping or raising at back or front. Pin it to the waist band, and sew on carefully when the skirt is removed; then hem up and neaten the opening. If narrow goods be used, join the various widths, till the whole is wide enough for the circle to be cut as shown, and remember to always snip the selvedges. 5¼ to 5½ yards. of 48-in. material are required for this skirt.

The Newest Skirts. The next sketch [**70**] shows one of the new full skirts with a panel front and wide side gores, the foot part edged with a band or shaped tuck of velvet cut to the same shape as this, and headed with silk passementerie.



70. THE FULL SKIRT

The method of cutting out from 48-in. material is shown in diagram **71**, the row of double broken lines indicating the direction to be taken if a trained skirt is desired. The quantity of material in either case is the same—that is, 4 to 4½ yards. This skirt is also unlined, the foot part being faced with lining cut to shape.

Diagram **72** shows another five-gored shape for the full skirt gathered at the waist. This is better suited to plain or thin materials than to checked or plaid goods; for these the circular form is best, as it allows the material to hang naturally, and there are no bias edges of the seams to interfere with the pattern. By increasing the slope of the gores, this shape can be made any width desired; in the diagram it measures 5½ yards at the foot part.

A bell-skirt, or jupe-cloche, is shown in the next diagram [**73**], and this, as will be easily seen, is but a modification of that shown in No. **71**, the cutting out of which would be carried out on the same lines. Pleated and yoke skirts are dealt with in TAILORING.

When cutting out a skirt, be careful not to slope off the corner of the waist-curve at back, as this may completely upset the fit and "hang," and, if pulled up to the right length, will probably make it drag or wrinkle across the front.

Cutting on the Cross. Material which has to be cut on the cross plays such an important part in dressmaking that it will be well for the student to pay particular attention to this paragraph.

Take the material, fold over one corner till it exactly meets the selvedge and forms a point in the opposite corner, as in the example marked A in diagram **74**. Mark off on each selvedge the width of the strip desired, fold or rule across carefully to each mark, and cut out, using up the corner pieces. Velvet or velveteen will need careful handling in order to avoid crushing the pile.

In the second example shown in **74**, marked B, we have the method of cutting on the cross when

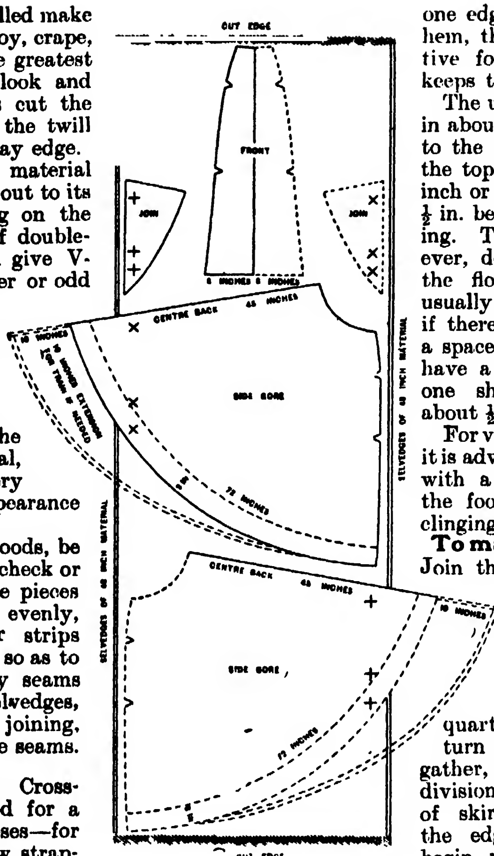
the material is of a twilled make like serge, frieze, corduroy, crape, etc., as it will make the greatest difference both in the look and set of the fold if it is cut the wrong way—*i.e.*, with the twill parallel with the crossway edge.

Remember that the material must always be opened out to its full width when cutting on the cross, or, in the case of double-width goods, it would give V-shaped strips. Any corner or odd pieces left from cutting out the garment can and should be utilised, as there ought not to be any waste; but these must be cut on the true cross and the right way of the material, or they will show very plainly and spoil the appearance of the fold.

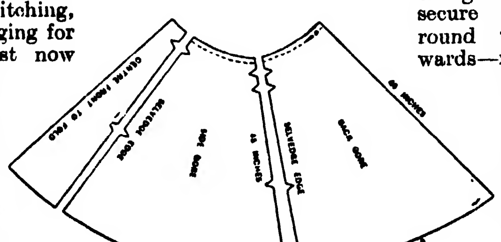
In the case of plaid goods, be careful to match the check or pattern. When all the pieces are cut out, join them evenly, using up the shorter strips among the longer ones, so as to avoid having too many seams together. Snip the selvedges, or cut them off before joining, then open and press the seams.

Crossway Strips. Crossway strips are required for a great variety of purposes—for binding, piping, narrow strappings, folds (either stitched or slip-stitched to the edges of revers, etc.), narrow ones for fancy yokes for faggot-stitching, also those used as an edging for crape folds; whilst just now there is a revival of the hand-made ornamentations of the Victorian era, both in velvet and silk, as well as "rouleaux," or rolls done over wadding, narrow quiltings, reversed pleatings, etc.

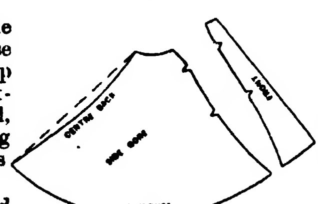
When cutting out crossway strips, allow good turnings, as it is not easy to get a perfectly even edge without, and the fold will set much better if these are fairly deep. A crossway strip has an unhappy knack of twisting; to obviate this, it is well, when making up, to fold along a good way to see that it is right before tacking or sewing.



71. CUTTING OUT THE FULL SKIRT



72. FIVE-GORED FULL SKIRT



73. BELL SKIRT

Flounces. Narrow gathered frills and flounces are usually of crossway material, finished off at one edge with a stitched or roll hem, the latter being very effective for thin materials, as it keeps the edge well out.

The upper one may be turned in about $\frac{3}{8}$ in. and gathered close to the fold, or over a cord, or the top may be turned in an inch or so, and gathered about $\frac{1}{2}$ in. below this to form a heading. The depth of this, however, depends on the width of the flounce, and a heading is usually only put to the top one if there are several. If there is a space between, each frill may have a heading, but if not, each one should overlap the other about $\frac{1}{2}$ in.

For very thin goods like muslin, it is advisable to put on the frills with a cording, as it prevents the foot part getting limp and clinging.

To make and put on Frills. Join the separate pieces into a circle—see that all are on the same side and are not twisted—press the seams open, hem the lower edge, divide and mark the halves, quarters, and also eighths, turn in the upper edge and gather, using one thread for each division. Mark the lower part of skirt to correspond, place the edge away from you, and begin with the bottom frill. Pin one division to a corresponding one of skirt, pin, draw up the gathers to fit the division, secure the gathering thread round the pin—point downwards—regulate them evenly, pin or tack in place, and proceed in the same way for each division. Remember not to put a join in the centre-front, and to keep the bottom frill even with the skirt edge.

When the half, or whole, of the frill is arranged in position, *sew* to the skirt and fasten off the gathering threads firmly on the wrong side. Proceed with the other frills in the same way. Crossway flounces are a little more troublesome than pleated ones, but are more advantageous, as they take less material.

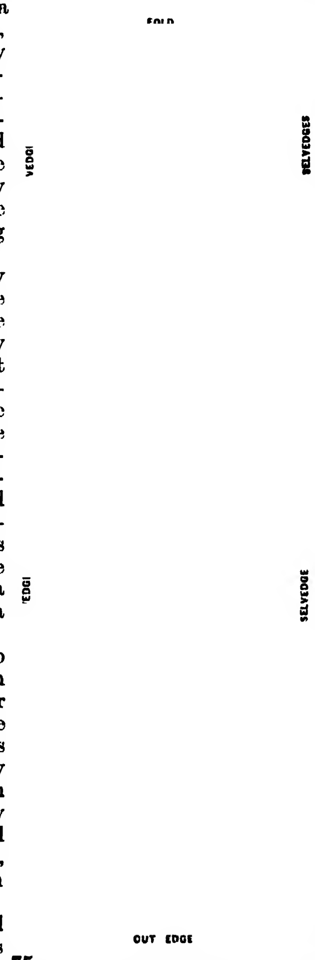
To put on pleated flounces, the same method can be followed, except that it may not be necessary to divide either skirt or

flounce into eighths. To find the quantity required, pleat up enough for a quarter of the skirt, measure and calculate from this. The quantities usually allowed have already been given. The joins must always come under a pleat, and the seam arranged to go in the centre-back, or in the least conspicuous position possible.

Stripes and Checks. An important, and sometimes very troublesome, part of dressmaking is in matching stripes and checks, particularly if the pattern be a large one. It is important, because the same material may be made up into either an extremely smart gown or the reverse, according to the arrangement of the plaid or stripes and the way it is cut, though the effort to produce the former may cause the cutter not a little tribulation of spirit in getting the design to match.

Plaids and checks are generally more effective if made up on the cross, certainly as far as the bodice is concerned, and very often this applies to the skirt also. For the latter, the two-piece shape like that of the striped skirt [diagram **64**] with the front seam on the cross, is perhaps the best; but the three-gore variety is sometimes used with great success. This, however, requires more material, as the side gores must match the fronts, and this may cut into a good deal of stuff if the plaid is a large one.

Diagram **75** shows how to place the various parts of a plain blouse on the cross; if tucked or gathered, pieces will have to be joined on the lower corners, as the joins must come where they will not be seen. This diagram is merely intended to show how the centre-back and front should be arranged to come on the cross, and also how to match these in the centre-fronts.



75. TO CUT A BLOUSE ON THE CROSS

With respect to stripes and checks, a point to remember is that they should all be arranged to slope towards the waist at back and front [diagram **37***f*], whilst for the skirt they should slope *outwards* from the waist to the hem. The slope, however, should be a gentle and not an abrupt one, as the latter would have a broadening effect and the former quite the reverse.

These rules also apply to the perpendicular arrangements of trimming on bodice and skirt, and should always be borne in mind when making or designing for stout figures.

Be very careful to match the line of the checks in folds, crossway bands, or flounces, or anything of the kind used for trimmings, or there will be a succession of broken lines, which will much detract from the harmony of the gown. For the fronts of a bodice or coat also the pattern must be very carefully matched.

Strappings and Folds. Strappings may be cut on the cross (if for seams), and straight or moderately curved designs; but where these are of any definite shape or curve (as in the front foot part of the striped two-piece skirt) they must be cut to that shape, and to fit the garment they are to ornament. This matter, however, is fully dealt with in TAILORING.

The narrow shaped tucks which are often arranged on the foot part of a skirt in a group, one overlapping the other, are cut from the skirt-edge to get the right curve [diagram **76**]. If the material be somewhat thick, these may be lined, the edges of material and lining being turned in to face, and machine-stitched. They are, however, usually unlined, and have the edges turned up and stitched. Be careful neither to stretch the lower edge when turning up, nor the upper one when putting on.

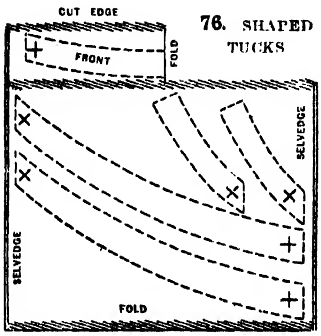
Piping must always be made of crossway material, and when sewing on, particularly if to go round a curved edge, the cording should only be held tightly enough to keep to the shape, and not pucker the material. A pointed bodice looks best with the waist part finished off with piping, but it requires much care and practice to put this on well. The point will require particular attention to keep it sharp, and when turning over to cut away correctly the superfluous parts.

When working round curves the raw edges of the piping should be snipped at the points between the rounded portions to allow it to set quite flat.

Shaped Flounces. The shaped, or godet, flounce is now used for ornamental purposes, or as a foundation for narrow frills for a trained or other skirt of thin material, to its great improvement in look and hang.

For this we must turn to diagram **77**. Measure the bottom of the skirt, then draw a line two-thirds of this (this allows something for fulling on slightly; it can be a little less if the material be rather thick), mark the centre, also the tape for the half-length of line just made, and pivot from this for the inner curve with chalk or pencil.

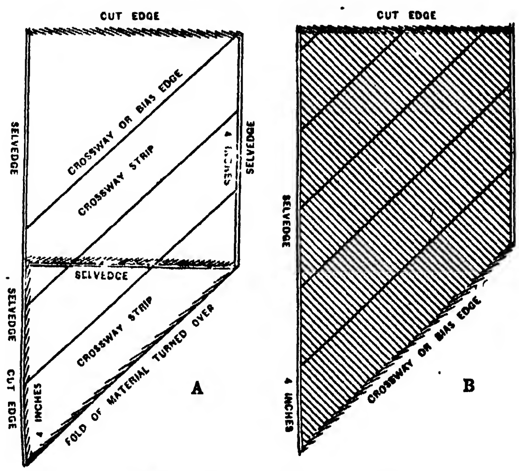
Mark off from the half circle thus drawn the depth of flounce required, and draw the outer circle as shown in A of the diagram, the



76. SHAPED TUCKS

broken line indicating how to alter if we wish to make it deeper at back and sides. A more circular arrangement is shown in B, suited to thin goods, when a full, frilly effect is required. C is also obtained from the same drafting by reducing the outer curve and making it less full. D shows the spiral frill, sometimes used for capes or where required to go round a shaped edge. E and F are a collar and cuff, which are given as further examples of the application of the circular shape.

From these we think the worker will see how to get any other variation she may be called upon to make, remembering that, where fulness at the lower edge only is needed, it will be cut on the principle shown; the greater the fulness at the lower part, the more complete must be the circle, and vice versa.



74. CUTTING ON THE CROSS

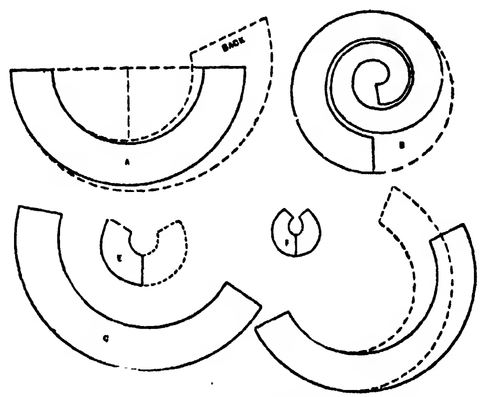
When cutting the upper part of skirt, allow for the depth of flounce, with an inch or two extra, as such skirts require to be cut fully an inch or two longer than a plain one.

Velvet. Materials with a pile, like velvet and velveteen, require very careful manipulation both in cutting and making—firstly, in order to get the right way up of the material, and, secondly, because every tack and pin mark will show.

The closely fitting style is usually adopted for these materials, either as a plain bodice and skirt or a princess gown; but either must be faultless in cut and fit, and should not be attempted by any but an experienced worker. The bodice and sleeve linings should be absolutely perfect as to fit before arranging or cutting the velvet. To find the right way up of the velvet, let the worker hold it in front of her and look down it; if a whitish sheen appears, reverse it and then cut. This is most important, as if cut the wrong way it will lose the rich, soft look which is its characteristic beauty. Remember, too, that each piece must be cut separately, and to face, as shown in diagram 27.

To press velvet, velveteen, and other pile goods, fix the iron face upwards, or let it be held in this position, then take hold of the end of the seam and pass it lightly over the iron, which should not be too hot. For long seams the better way is to secure one end, whilst the worker holds the other and passes the iron lightly along the portion to be ironed; but on no account must velvet be pressed on a flat surface. Be very careful not to crush the pile, or to hold the seams where the finger-marks will show.

Velvet also requires great care in putting together, as the two edges, owing to the pile, are very liable to slip from each other out of position; whilst the utmost care must be taken with pinning or tacking to make no marks that will show, and also to hold it lightly when working. Steel pins should always be used for velvet work; and silk instead of cotton for basting.



77. CIRCULAR FLOUNCE

HOW THE BLOOD RECEIVES FOOD

The Blood as an Agent of Nutrition. Digestible and Indigestible Foods. Effects of Starvation and Excess of Nutriment

Continued from page 677

By Dr. A. T. SCHOFIELD

Assimilation of Food. We have in detail traced the progress of the sandwich—our typical food—from the time it entered the mouth as meat, salt, bread and fat, until it reached the heart by two channels—the meat as purified peptones, and the bread as a special form of sugar arriving by the *inferior vena cava* from the liver; the salts dissolved in the mouth, and the fats from the lacteals of the lymphatic system, divided into microscopic drops of oil, reaching the heart by the *superior vena cava.*

Of the circulatory system which the food has now entered we shall speak in detail later. We only allude to it now as the vehicle by which our food is distributed round the body to the various cells. We speak of *assimilation* now because it continues the story of digestion to the end, but it will be even better understood if the chapters on circulation are read first. Enough, however, will be explained to make the process intelligible without this.

In the fat, the meat, and the bread, we have all the solid food the body requires, now converted into liquid and brought into the blood. But there is besides a liquid and a gaseous food. We will suppose, then, that besides the sandwich being eaten, the thirst has been quenched by some appropriate fluid which has entered and sufficiently diluted the blood, and likewise that the traveller has, during the eating and the drinking been breathing the fresh air. The oxygen he has thus received also enters the blood before it finally leaves the heart. Let us just look, then, at the blood stream from a nutritive standpoint as it passes through the great artery, the aorta, for distribution all over the body.

The Blood as an Agent of Nutrition. We notice in the first place that it is bright scarlet, owing to all the little discs or corpuscles with which the stream is laden being now full of fresh oxygen on their way to the body. The fluid part of the blood, we know, is laden with peptones, sugar, oil, and water, so that we see this curious anomaly, that the solids in the food are conveyed in the fluid of the blood, and the fluid or gaseous food is conveyed in the solids of the blood to the tissues. As this very blood will have returned to the heart again in little more than a minute, the process of assimilation which we are about to describe takes place at lightning speed.

Until the blood reaches the capillaries, which form an intricate network in every part of the flesh, not a single drop of nutriment passes out. The walls of the arteries, three in number, are far too thick and strong to permit of this, but in the capillaries the conditions change in several ways. Though practically innumerable, they are so minute that sometimes they will only allow a single corpuscle to pass through at a time. In the blood-vessels the size is fairly fixed and constant, in the capillaries it varies greatly; sometimes these are closed altogether, sometimes they are stretched to four times their natural size. This sudden subdivision of the stream into hundreds of tiny channels brings the speed of the flow down from a foot a second to an inch a minute.

The next point is that the capillaries have only one thin wall composed of living cells, which often opens a little, and lets some of the blood out to the hungry body cells that press round it on every side.

The Blood and the Cells. We picture, then, the blood, laden with nourishment, arriving freshly at the capillary every minute and then slowly passing along it. During its passage all the spare oxygen is taken out of the corpuscles and passes across the thin walls into the cells, enabling them to breathe. The cells, on their part, return their carbonic acid gas into the liquid part of the blood, the result of the interchange being that the colour of the blood is altered from a bright scarlet to a dull purple. Then the liquid food is rapidly seized by the cells as it passes through the thin walls, and is replaced by their refuse, which partly passes into the blood in the capillary, and partly into the lymphatic channels that everywhere surround this blood-vessel.

The blood, therefore, as it leaves the capillaries and enters the veins on its way back to the heart has lost all its food, and is of no use to the body, until it is returned to the heart to be replenished.

The cells, supplied freely every minute with fresh food and air, are kept in healthy life. This is as it should be, but the reality is often very different, as will be shown when we speak of starvation. The blood courses round, but empty of nourishment, or stored, it may be, with alcohol or drugs. If we consider well the state of the cells, which are absolutely dependent for their very existence on what we choose to put into our blood, the eating of good and sufficient food will soon take the form of a moral obligation.

Cells in Revolt. Fortunately, if treated badly, the body cells have means of making their wants known, and, if their messages are neglected, of retaliation.

In the first place, if there is too little fluid in the blood, they produce a painful feeling at the back of the throat, which we call *thirst.* To relieve this it is necessary to introduce

more fluid into the blood. It does not matter whether the fluid be injected into a vein or supplied through the skin by wet sheets, the thirst goes, just as much as if the fluid were drunk.

If there is deficiency of air the message is sent to the lungs and stimulates them to action by a feeling of *breathlessness*. In anæmia, for instance, where there is a deficiency of these red corpuscles, there is a constant feeling of breathlessness. It is not the lungs, but the cells that cannot breathe. In the third place, if there is no food in the blood a sinking is felt at the "pit of the stomach" which we call *hunger*.

If, then, these warnings are neglected, the cells soon cease to do their work well, and the whole body suffers The mind and brain get tired as well as the body, and it is well if worse symptoms do not supervene.

Indigestible Foods. We have spoken so far of the sandwich as if it were all digested. Such, however, is not the case.

The following table gives the digestibility of proteids in meat, carbohydrates in starch, and hydrocarbons in fat; and from this table we shall see that our sandwich is by no means all assimilated.

Both these tables show how very much more wasteful brown bread is than white, and how much less vegetable albumen (proteid) is digested than animal albumen. The subject may be presented from one more point of view in a table still simpler:

DIGESTIBILITY OF ANIMAL AND VEGETABLE FOOD.

ANIMAL.		VEGETABLE.		VARIETIES OF FOODSTUFFS.
Digested.	Not Digested.	Digested.	Not Digested.	
Per cent.	Per cent.	Per cent.	Per cent.	
90	10	75	25	Per cent. total solids.
81·2	18·8	46·6	53·4	" proteids.
97	3·0	90	10	" carbohydrates and hydrocarbons.

This table shows that in meats 10 per cent. of the solids are not digested; in vegetables 25 per cent.; that in meat above one-sixth of proteids is undigested; in vegetables more than one-half; that in meats 3 per cent. of the fats, etc., are undigested; in vegetables 10 per cent. These figures need occasion no surprise when we reflect that the meat comes from animals

EXAMPLES OF THE DIGESTIBILITY OF VARIOUS FORMS OF FOOD

DIGESTIBILITY OF PROTEIDS IN		DIGESTIBILITY OF CARBOHYDRATES IN		DIGESTIBILITY OF HYDROCARBONS IN	
Meat	Nearly all	Sugar	All	Butter	98 Per cent.
Fish	"	White bread	99 Per cent.	Margarine	96 "
Milk	95 Per cent.	Indian meal	97 "	Milk	96 "
White bread	90 "	Peas	96 "	Fat bacon	93 "
Indian meal	89 "	Brown bread	94 "	Fat meat	86 "
Brown bread	87 "	Potatoes	92 "		
Peas	86 "				
Potatoes	84 "				

From this point of view potatoes and fat meat are the most wasteful foods.

Let us look at the matter from another standpoint, for it is one which is little understood or written about, and concerning which reliable information is not always easy to obtain.

We have given the percentage of foodstuffs absorbed in different articles of diet. The following table, based on other experimental data, gives the amounts of food unabsorbed from certain articles of diet, and passed out of the body:

UNABSORBED FOODSTUFFS IN	PROTEIDS.	CARBOHYDRATES.	HYDROCARBONS.
	Per cent.	Per cent.	Per cent.
Animal food:			
Milk	7	5	—
Fats	—	12·7	—
Meat	2·5	—	—
Vegetable foods:			
Maize	15·5	17·5	3·2
Peas	27·8	—	7·0
White bread	18·18	·5·7	1·2
Brown bread	30·0	—	7·4
Black bread	32·0	—	10·9
Rice	20·4	7·1	·9
Potatoes	32·2	3·7	7·6

that, feeding on vegetables, have already themselves rejected what cannot be turned into flesh. Our loss in meat foods, therefore, must be less than in vegetables, where we have to do all the sorting ourselves.

In our examination of the undigested materials in various articles of food (the last we shall refer to), it was found that of meat, eggs, bread, rice, macaroni, the excreta contained about 5 per cent. of the amount taken; of milk, peas, and potatoes nearly 10 per cent.; of black bread, 15 per cent. These different results do not exactly agree, but altogether they are of considerable practical value, as has been pointed out.

Starvation. Turning now to deficiency of food, in *starvation* we get loss of weight, loss of heat, various symptoms, and death. Death, as a rule, occurs in animals when the body has lost two-fifths of its weight.

The fat disappears very soon, that in the orbit being used up first. The blood loses in water three-fourths of its weight; the pancreas and liver more than half, the muscles and stomach about two-fifths (40 per cent.), the skin and kidneys one-third, the bones about one-sixth; while the nervous system remains almost unchanged in weight, losing only 2 per cent.

The heat of the body varies at first four or six degrees, and then shortly before death (when the fat stores are exhausted) falls rapidly down to about 30° C. at death. In starvation death occurs rather from the loss of heat than from the loss of nutrition. This is easily understood when we remember that nine-tenths of our 3·400 foot-tons of daily food force are used to produce heat. Hence artificial heat will delay death for some time.

The principal symptoms of starvation are hunger, thirst, pain, sleeplessness, weakness, and delirium or stupor.

Death generally occurs in a little over a week after the stoppage of all foods, liquid and solid. There is no case known where life has been prolonged for weeks after such stoppage. As we have lately seen in England, however, only a very small quantity of food and water are required to prolong life considerably.

Excess of Food. Excess of food in the infant is got rid of generally by vomiting; in the adult more generally by the bowels. Before this riddance takes place, however, as much as possible has been digested and absorbed; and the surplus only that cannot be dealt with is thus ejected. The amount absorbed may, however, be greatly in excess of the needs of the body, or even of its storage power. We will see how each variety is dealt with.

Minerals. Excess in salts is not often now met with, though formerly it used to be very common on long sea voyages. Where it occurs, intense thirst and skin eruptions of every sort —scurvy, etc.—are the results.

Excess of Fluid is easily carried off by the kidneys up to a certain extent, but if continued it dilutes the blood, impoverishes the tissues, and weakens the digestive organs.

Excess of Alcohol at first paralyses various parts of the nervous system, and by irritation of the tissues afterwards causes great overgrowth of the connective tissues, leading to many serious diseases.

Excess of Proteids. The term "luxus consumption," used in various senses in different text-books, is by some intended to mean the direct combination in the blood of an excess of proteids beyond what are needed for building up the tissues; but the term is not of much use, since to a certain extent this combination always takes place. As an excess of nitrogenous diet is very common amongst all who can afford it, it becomes a question of great importance how it is disposed of. If very excessive, part may not be digested at all, and be excreted directly.

That which is peptonised, if in excess, may be still further changed by the pancreatic juice into leucin and tyrosin, which may pass out as urea by the kidneys. Much that is not so changed becomes *uric acid*, and lays the foundation for gout, gravel, and stone. That which can be used is stored in the blood as *serum albumen*, and some perhaps in the spleen.

Excess of Carbohydrates. These are stored in the liver as glycogen, and the excess is also largely stored in the tissues as fat. Excess can be got rid of by the kidneys as sugar. Great dyspepsia results from excess of carbohydrates.

Excess of Fat. This is stored to almost any extent in the tissues, and eventually in the muscles and various organs, causing after a time great degeneration of the tissues, and of such organs as the heart. It must not be supposed, however, that the body fat is derived solely from fat food. On the contrary, it was found in fattening a pig that 472 units of fat were stored for every 100 units of fat given. Fat is largely formed from carbohydrates and also from proteids.

Effects of Deficiency or Excess. Speaking of the general effects of malnutrition and excessive food, it might be said that, on the whole, both are well borne if the organs are sound and the general habits hygienic and regular. There are men and women, two and three stones under their weight, leading active and healthy lives, though, of course, at considerable risk. On the other hand, there are men and women three and four stones over their proper weights who complain of nothing.

It is perhaps in adolescence that these irregularities have their worst effects. If a boy or girl is a stone under his or her weight, and is growing rapidly, any hard study is sure to be fraught with bad consequences. Of all this we shall speak in detail in the Health section. [See Health.]

We now leave the subject of digestion and food, as far as its physiology is concerned, with the hope that a careful perusal of these three chapters has left a clear impression, and that the whole digestive process can be seen as in a map. Fig. 38 should especially be studied until the general course of the food is thoroughly understood.

ART SCHOOLS AND OIL PAINTING

Training. The Great Schools. South Kensington. The Royal Academy. The Paris System. The Best Colours. Colours to be Avoided

By P. G. KONODY and HALDANE MACFALL

We now come to the very serious question of where the student may get the best artistic training. Theories as to training are so hotly opposed to each other that it is perhaps as well to say a word upon the subject, and then to guide him to some of the best schools.

The Two Schools. At the start the student will be assailed by the claims of the two extreme schools. There is the school that would have the student create the masterpiece at once, learning drawing—the grammar of art—in the doing. On the other hand is the school that deliberately crushes out all personal statement and inclination in the student, until his hand has become the slave of academic precision, the slave of rule and precedent. Now, the free school, whilst it has turned out men such as Manet and Delacroix and Millet, more often turns out a stumbling mediocre artist who is never master of his tools, who speaks his art haltingly. At the same time, the academic school. whilst it turns out men of great skill, like Bouguereau and Lefebvre and Cabanal—men of great precision—rarely produces a genius; they are learned men in the arts, masters of craft, without any powers beyond craftsmanship.

The student is wisest who strikes the middle course. He must master the craftsmanship of his art, for until he is its master it will be forever mastering him; but let him look to it always as only the means to an end, never let him mistake it for the end in itself.

Let us take a poet. The boy cannot burst into the great statement of poetry; if he would write poetry in verse, or the still more profound and subtle style of prose, he must first master his grammar—the rhythm of verse and the law of rhyme. What will it avail him to have ideas and imagination and fancy if he know not how to utter them?

If the student cannot draw a foot or a head with a piece of charcoal, if he cannot deftly paint a bottle and a sliced lemon, how is he to portray all the subtle beauties of the human figure? His imagination may teem with a sense of the emotions of life, but who will find it in halting colour and incloquent line? How shall a musician utter music if he is not sure of his notes? It is the first and vital business of an artist to be able to draw with facility. In which schools may he best learn his trade?

Training in England. England labours under one grave disadvantage in relation to art education in comparison with France; she has nothing like the same enthusiasm amongst the men who have attained fame. There is, of course, a great waste of artistic enthusiasm and effort in Paris, but that is at least better than indifference.

The French schools teach from the plaster cast as long as it helps towards the drawing and painting from the life; the English schools make the antique almost an end in itself. The French student is aching to express something; the English student thinks that when he is through the schools the ideas will come to him just as patients come to the qualified doctor. From the French students' point of view, nothing matters in heaven or on earth except art.

The Grammar of Art. A man is safer in learning the grammar of his art in his own country, for he learns to speak his own tongue. The actual teaching is finest perhaps in Paris, but the danger of falling into ridiculous mannerisms is far greater. If the student, then, would learn his craftsmanship in England—mark you, his *craftsmanship*, for no man may learn to create works of art in any school—he has an excellent and marvellously cheap school in every important town throughout the kingdom, in connection with the great Government Art School at South Kensington. The schooling is very good. He may learn, then, the art of the designer, of the painter, or the sculptor. He will, if employed by day, be able to attend night classes. He will, above all, have the inestimable advantage at these schools of being in constant touch with the great fact that the craft of art is not confined to the painting of the easel picture, but extends to a hundred industries: in other words, that there is an immense and a most profitable field open to craftsmanship and artistic invention. And he will be constantly reminded that Holbein and Michael Angelo, Raphael, and Dürer and Leonardo da Vinci put as much delight into the decoration of a cabinet or a wall as into a picture or a statue.

The Great Art Schools. From his studentship at the South Kensington schools, he should emerge facile in his drawing and well fitted to proceed to the painting from the model, draped or undraped, either in those or, better still, in the Royal Academy schools. He is thus saved the tedious preliminary training from the antique, which should be mastered beforehand, and so free to give all his strength to his schooling in paint at the great centre, where his pupilage gives him special privileges when he comes to exhibiting his creative work.

If the Royal Academy schools are difficult of access to him, or if the South Kensington schools gall him with an overdose of technique, he still has excellent schools in London, where a more enthusiastic and keener art atmosphere prevails, such as the Slade, or the private art schools under the direction of well-known artists.

Indeed, it is at this stage—when, having mastered facility in drawing, he proceeds eagerly to painting—that his enthusiasm requires the encouragement of keen fellow-students and the counsel of his masters. But it is precisely at this very stage that the English academic schools are inclined to chill him; it is precisely at this stage that the Paris system urges him forward. The question, therefore, now becomes of vast significance, whether he shall go to Paris or to London.

Photo by] [*Alinari*

THE VIRGIN AND CHILD, WITH ANGELS, BY BOTTICELLI (UFFIZI, FLORENCE)

A striking instance of space composition, solving the problem of placing a group in a circle

Royal Academy Schools. These schools are visited in rotation by Academicians—in theory by each, but in practice as often as not by the less important men. The system has the advantage of preventing staleness of teaching; it also has the disadvantage that the students never get the enthusiastic attitude of pupilage towards their chosen master that they have in Paris. The training at the Royal Academy schools is absolutely free, whilst its prizes are generous and its scholarships handsome.

The highly stippled and finished drawing from the antique that took months to do—the bane and curse of the English schools—has gone out of fashion; but there is still far too much time spent upon these elaborations, and the student would do well to draw frequent casts instead of spending too much time upon a few. However, the student, if he have the will, may soon push on through the antique to the painting schools of the Royal Academy, where he will work in the company of students from amongst whom will be elected most of the future Associates and Academicians, and from his fellow-students he will learn more than from his masters.

It is a serious question whether he will not get as good schooling at the Slade or at the studios of well-known artists. But, in any case, even should he so decide, he will find the fees reasonable—indeed, the art student is not often a well-to-do person. Certainly he will find outside the Academy a keener feeling for and sympathy with the art of his day than in the drowsier shades of the Academy schools. Their very existence is

a protest against hidebound convention in training. They have no precedents of long-established years to live up to; they have no prestige of academic culture to maintain; they do not reverence age or the past because these things are of the dead, but solely glorify the splendour of good work. They go for the breadth of things rather than for their detail. And whilst they realise that *facility* in craftsmanship makes for style, they do not allow this to be mistaken for slovenliness or inaccuracy.

The Dangers of Training in Foreign Schools. Now a warning note before we go to Paris. Art in a nation must come from within; it cannot be imported, like merchandise, from without. Rome under the Cæsars, like Paris under Napoleon, had foreign art treasures poured into the city, but it created no artistic revival amongst the people. The student who goes to Paris, or anywhere else abroad, can only learn to become a good workman; he must not try to content himself with a triumph in the artistic manner of France, for it is but uttering a foreign speech—he can but become a trickster and a copyist. But schooling in workmanship he will get in Paris such as he cannot find elsewhere in the world. To begin his art training in France is to make a mere French imitation of an artist. Nothing is easier to pick up than the tricks of a Degas or a Monet or a Corot. The danger lies in his trying to paint a smart picture for the exhibition rather than to achieve an emotional statement of life as he himself sees it. Let us put aside the dangers of the academies on the one side and of foreign tricks and fashions on the other, and imagine the student simply bent on acquiring mastery and facility in the use of his tools.

He goes to Paris. He is at once in a new atmosphere—an atmosphere in which art seems to be a vital thing, a need of life. The studios are cheap. They are open to him if he but have the very small fees to pay his way and the energy to stick to his work. He sees the *masseur*, or head student; pays his fees; and, with his easel and chair, enters the studio. He goes through the tomfooleries of initiation, finds friends amongst his countrymen, and a dozen good comrades amongst the French students to cheer him on.

The Art Student in Paris. At Julian's he pays about £1 a month for the half-day (8 to 12 o'clock), or 33s. a month for the full day (8 to 12 and 2 to 5 o'clock). At Carlorossi's he will find a cheap night school; at Delacluse's an afternoon costume class. And a dozen other studios are available. If he prefer it, he can split his time between them.

But, mark this, he will find the gay and debonair French student, who skylarks between his working hours, who plays the harmless fool on the boulevard and at the café in the evening, to be a grim and serious hard worker whilst the model sits. He will find the French student standing at the studio doors before they open in the early morning; from the moment the model takes the pose the French student works with all his hand and heart and soul. He works in no dutiful scholastic spirit, but with all his might, to master technique. And even when he takes his leisure at the students' cafés, or in his walks abroad, his whole aim and talk is art. He cares little what Government is in, or what horse is likely to win the French Derby; for him there is but one mighty interest in the universe, and that is art. The result is a technical accomplishment that is a marvel. There are loafers and idlers, but they stay outside the schools.

And the whole atmosphere of the schools is in keeping with this artistic enthusiasm. At regular intervals there are trials of strength in skill between the students; then the winners compete for the supreme place and the privileges of the studio. The students have choice of place before the model as the result of these "concours." At every hand is strenuous, wholesome, artistic rivalry. At every turn is the word of praise or blame from fellow-students. And the very summer holidays are spent in the country painting.

The Luxembourg Galleries. There is the superb collection of modern art in the Luxembourg Galleries to educate the student in the picked examples of modern masters. The studios are visited by the first artists of France without thought of remuneration. Men of the rank of Sargent give a day or two days of their precious week to the youngsters. And however much their views on art vary, in craft they all say the same thing, teach the same lesson—"Search out form and colour; search and search and search."

The French student has good schools; he has enthusiasm for art; he lives in an atmosphere of enthusiasm. He has at his side not only the superb collection of old masters that has made the Louvre the talk of the world, but he has in the Luxembourg the splendid examples of the moderns purchased by the State. Here you may see John Sargent or Whistler, or Watts or Manet, or Steinlen or Degas; each at his best. The whole attitude of his masters is modern. He works in the spirit of his age.

Art in Rome is dead—the once famous home of the art student is wholly gone; its schools have passed to Paris. In Germany there are good schools, and cheap, especially in Munich and Düsseldorf, though few to rival Paris. There is nothing the student can learn in Germany that he cannot learn equally well or better in Paris, where he lives, moreover, in a far more artistic atmosphere.

The Americans, in spite of their superb school, the Art Students' League of New York, flock to Paris. The great system of the past, the apprenticeship of students to artists, shows signs of revival in America, the most astute of all nations, and still holds everywhere in sculpture.

PAINTING IN OILS

The art student should always remember that to a painter the quality of his colours is of vital importance. Many colours used with perfect confidence a few years ago have turned out to be utter trash; indeed, in water-colour,

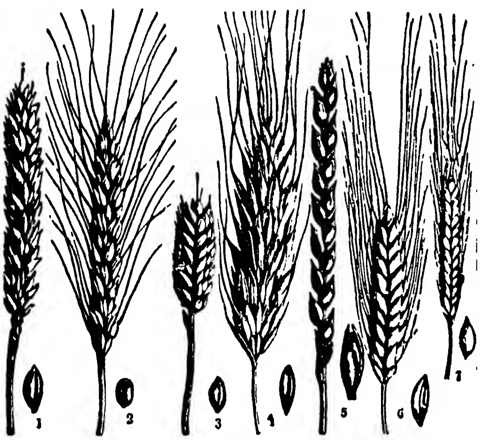
THE PLANTS OF THE FARM

Grain Crops: Wheat, Oats, Barley, etc. Habits of Various Kinds of Grasses. Weeds that Destroy Crops. Seeding Tables

By Professor JAMES LONG

Wheat. In considering the plants of the farm we may deal first with the cereals, or grain crop (natural order *Gramineæ*). Wheat is a fibrous and deeply-rooted plant (genus *Triticum*), especially suitable for cultivation on the heavier soils, although the best grain is produced on soils of rich character, such as the alluvial. Winter wheat, which is chiefly grown in this country, is much longer in the ground than either barley or oats, the period of growth continuing from October,



WHEAT

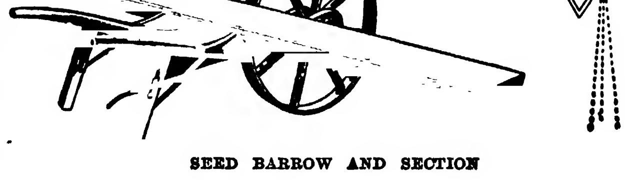
when early sowing is practicable, to the following July or August. Sowing may continue until Christmas, but while early sowing in rich soil may be followed in a mild winter by rapid growth and a *winter proud* plant, it is always advisable, owing both to the risk involved by delay and the greater difficulty in obtaining a good plant. In the farming rotation wheat usually follows a leguminous crop—clover, peas, or, on the heaviest soils, beans—owing to the fact that these plants secrete nitrogen, which they leave in the soil in their roots. Wheat is also grown upon soil which has been summer fallowed—*i.e.*, the land having been well ploughed and cleaned and no crop taken. Wheat prefers a dry climate; hence it is largely grown in those counties in which the rainfall is low. It thrives on the heavier soils, but on those which are wet fewer seeds germinate, the plants which live are less robust, and the crop takes longer to mature. The best temperature for germination is found to be 89° F., but the seed will sprout at as low as 42° F.

Varieties of Wheat. Many varieties of wheat are grown in this country, but for our purpose they may be divided into *red* and *white*. One of the former, known as *Rivetts*, is a bearded wheat, and is frequently sown on the colder clays with advantage. The weight of wheat varies from 59 to 65 lb. per bushel. In practice merchants often buy by the quarter at 63 lb. per bushel, ignoring the natural weight, but there are many other customs, although they are chiefly local. A bushel actually weighing 63 lb. contains about 700,000 grains. The average yield in Great Britain between 1894 and 1903, was 30·95 bushels—practically the English average, as the wheat area in Wales and Scotland is very small. The average yield of straw is about 32 cwt. per acre, the grain forming about one-third of the weight of the entire crop. On the average of 32 years, Sir John Lawes obtained on his most successful plot 36¼ bushels, weighing 59⅕ lb. per bushel, together with 4,530 lb. of straw per acre. The range on the various plots varied from 4¾ bushels in the worst to 63 bushels in the best season.

The wheat grain is really the fruit of the plant, inasmuch as it is the ripened ovary of the wheat flower. When milled it produces about 75 per cent. of flour, the balance, minus a small loss, being chiefly bran, sharps, and pollard. In preparation for a crop it is customary to sow from 1½ to 3 bushels per acre. The old-fashioned plan of dibbling, or making holes in the ground with a hand tool and dropping in the seed, is the slowest and most costly, although it requires a minimum of seed. Broadcasting by hand involves the employment of a larger quantity of seed, while drilling with a machine takes a medium place, but is the most simple, rapid, and economical. Less seed is required for early sowing, and the most approved depth at which the seed should be deposited is 1½ inches. Unless wheat is sown in land which is in very good heart, or well manured with dung, it may be advantageously assisted with 3 cwt. of superphosphate per acre, given at the time of sowing,



SEED BARROW AND SECTION

and 1 cwt. of nitrate of soda in the following spring.

Oats. As with wheat, so with the oat (*Avena*), there are many varieties, including the *white*, the *black*, and the *dun*. This plant is suitable for almost all soils, except those which are extreme in character. The average yield for Great Britain during the ten years ending 1903 was 39 bushels, the English average being 41 bushels. With improved varieties of seed, however, English growers have reached as many as 13 quarters, or 104 bushels to the acre, and we have seen on the Canadian Government Station of Saskatchewan at Indian Head a growing crop which subsequently reached 100 bushels to the acre. The yield of oats depends as much upon the suitability, quality, and vitality of the seed as upon the soil, the climate, and the method of cultivation. The quantity of straw produced on the average farm varies from 27 to 35 cwt. per acre. The oat varies in weight as in quality and in the thickness of its skin. In the corn trade oats are generally sold weighing 38 lb. to the bushel, and if dry and hard, they are more often preferred as a food for horses to heavier samples, which so often possess thicker skins. The natural weight of the oat varies from 34 to 48 lb. per bushel; indeed, we have seen a sample weighing less than the former figure. In an average sample there are from 700,000 to 800,000 grains to the bushel, the number varying according to the size of the grain. We once counted 485 grains on a selected ear grown by ourselves. If exceptionally fine-skinned and coarse-skinned samples are examined, their coats removed, and their kernels weighed—a sufficient number of grains being taken for the purpose—it will be found that the husk weighs from about 22 to 30 per cent. of the whole grain.

TARTARIAN OAT
[Avena orientalis]

Oats as Food for Horses. As a food for horses the oat is preferred to any other cereal, chiefly because it is naturally better balanced. The proportion of proteids, or nitrogenous constituents, to carbohydrates, chiefly starch, varies, sometimes largely in different samples. As a stock food the oat should not be used while new, and when given it should preferably be in a crushed condition. The oatmeal of commerce is produced from the kernel of the grain after the removal of the husk, and after artificially drying. The yield of meal varies from 55 to 60 per cent., the proportion naturally depending upon the quality of the oat employed. The ground oats of Sussex, however, so largely used by poultry feeders, are the flour produced by grinding the whole grain between specially prepared stones. In sowing for a crop, the seed used varies from 3½ bushels in the early season with the drill to 5 bushels by hand in the late season, or in ill-prepared or unkind soils.

Barley. Barley (*Hordeum*) is a bearded cereal largely grown in this country chiefly for malting. Its price varies greatly in accordance with its quality and its malt value; hence fine barley is grown in some districts, whereas in others it is almost impossible to obtain a malting sample. Second-class barley is chiefly employed in ground condition for feeding stock. Barley may be two-, four-, or six-rowed, many of the principal varieties grown on the English farm, such as Chevalier, being two-rowed (*H. distichum*). Four-rowed barley, or *Bere*, a grain of a rougher character, is grown in parts of Scotland and Ireland.

Barley is commonly grown after swedes or turnips, or after certain forage crops, that have been eaten off light land by sheep, which were simultaneously fed with rich foods, such as linseed and cotton cakes, grain, and hay. In this way the soil, often thin or of light texture, is enriched by the manure dropped by the flock, and a good crop of grain ensured. Barley is a shallow-rooted plant, hence its adaptability to chalky and other light soils. It may be manured, like oats and wheat, with the artificials which provide phosphates and nitrogen, but nitrate of soda must be sparingly used, inasmuch as it may depreciate the quality of the grain. Manures are seldom necessary where barley is taken on land upon which sheep have been well fed

Barley weighs roughly from 48 to 55 lb. to the bushel, a heavy sample bushel containing 550,000 to 665,000 grains. The seed is sown in the spring, often, where the sheep are long on the land, as late as May, the quantity sown per acre varying from 2 bushels with the drill to 4 bushels when broadcasted. The average yield in Great Britain during ten years is 33·17 bushels, the English average reaching 33 bushels, and the

A COLOUR INDICATOR, WITH EXAMPLE OF THREE-COLOUR PRINTING

[By Frederick Oughton

The Indicator is divided into three equal angles, each having for base one of the Primary Pigments. Tints 1 to 4 are for Backgrounds, Mountains, etc. Nos. 5 to 12 for Flowers, Foliage, etc. Nos. 13 and 18 for **Flesh.** Nos. 1 and 19 for Shadows in Flesh, etc. Nos. 14 to 17 Fruit, Flowers etc. Nos. 20 and 21 Gray Tints for Clouds and Distance. Sixteen Colours are used in mixing the Tints—*viz.*, Vandyke Brown, Sepia, Brown Madder, Burnt Sienna, Raw Sienna, Ivory Black, Terre Verte, Prussian Blue, French Blue, [illegible]

Turner even tried tobacco-juice. The student may be certain that it is best to go to good colour-makers, for the less reputable dealers only adulterate their cheaper substitutes, and call them by the same name.

Colours. The student should first of all be sure that his colours are good, and in the second place he should remember that, even being good, the fewer he uses the less chemical action is likely to arise through their intermixture.

Before setting the palette, let us see which are safe colours to use and which should be avoided. The most important pigment on the palette is white, for white is used throughout his painting to lighten the tones. And though flake-white is whitelead, and acts disastrously on all vegetable colours, on the other hand, it has a binding and preservative effect on earth colours. Several substitutes have been tried, but *flake-white* remains supreme.

Of the yellows, the pale *lemon yellow* (baryte yellow) is quite safe. The *cadmium yellows* (pale, middle, and orange) are good sound colours which have quite superseded the utterly bad *chrome yellows*. There is a very beautiful and luminous yellow called *Aureoline* (or cobalt yellow), which is permanent. The chromes are as bad in oils as was the *gamboge* of the old paint-boxes in water-colours—a wretched colour that goes green and sickly, and, being of vegetable origin, is destroyed by the whitelead which is used throughout oil painting. *Indian yellow* is also not to be recommended. *Yellow ochre* is of vast value on the palette, and one of the most essential of colours.

Essential Colours. Of the greens, apart from those made through an admixture of yellow and blue, two or three are very necessary. There are two beautiful and absolutely permanent colours that should be on the palette—*Viridian* (the transparent oxide of chromium, which has an emerald hue), and the opaque *oxide of chromium.* Oil painters often use the old and useful *terre verte*, a permanent ochre. These three colours save the artist from many dangers in mixing yellows and blues. The chrome greens are vicious colours, and are not to be confused with the fine oxides of chromium. Indeed, all the other greens are best avoided.

Of the blues, the very expensive and splendid *ultramarine* (or lapis lazuli) is well replaced by *French ultramarine* (or, as it is sometimes called, "permanent blue"), a permanent and very beautiful dark, vivid blue; whilst *cobalt*, one of the safest and tenderest of blues, should be on every palette. It is best to have no other blue, and especially to avoid the *Prussian* and *Antwerp* blues.

If a purple be required, *purple madder* is the safest.

Of the reds, we are safe in using the dull earth-reds—beautiful low-toned, ochrous colours—such as *light red* or *Venetian red.* But, unfortunately, no mineral or earth rose-red is known. The best, and most nearly permanent, are the *madders, rose madder* and *madder carmine* preferably—rich and beautiful colours. The *crimson lakes* of the old paint-boxes are as bad as they are beautiful.

Scarlet is a necessary colour, but even the best, *Chinese vermilion,* is inclined to go black under certain conditions. The red-leads and orange reds are deadly pigments, bad in themselves and destructive to others.

Burnt sienna is a very fine passage from red to brown.

Of the browns, *raw* and *burnt umber* are safe; neither the *Vandyke brown* in oils, nor the *sepia* of water-colours, is wholly safe. But there is a warm brown—the *Caledonian brown*—that has a good reputation. Never, under any consideration, use the beautiful, glowing bitumen, or asphaltum, which spells ruin to a picture.

Of the blacks all are safe, *ivory black* being the usual one.

Colours to be Avoided. Colours to be avoided in oils and in water-colours are the following: the chrome yellows, Naples yellow, orpiment, the yellow pinks, brown pink, alizarine yellow; verdigris green, emerald, sap, Hooker's green; Prussian blue, Antwerp blue, Royal blue, indigo, verditer; the lakes, orange, vermilion, dragon's blood; bitumen, asphaltum, Vandyke brown, sepia, Payne's grey, and the like. It is bitumen, or asphaltum, that causes those great cracks and the utter destruction of so many old masters.

Having settled upon the gamut of his palette, the student has to decide on the vehicle he will use to thin his paint, and to make it flow when so required. Now, in choosing a vehicle, one requires something that will bind the paint so as to save it from contact with air and damp. The best medium is copal and Venetian turpentine. But the drawback to the use of a medium is that it yellows with time. Some artists use none, painting with solid paint. Some, like Whistler, only use turpentine and linseed-oil to thin the colour. Others use a vehicle like the copal medium sold by Newman, of Soho; but there are many upon the market, and in this matter the student must decide for himself. An excellent book, both on medium and colour, is Professor Church's "Chemistry of Paints and Paintings," which no artist should be without.

A word should perhaps be said before proceeding to the painting. To get the colours off the palette and brushes at the end of the day's work, it is best to clean the palette roughly with the palette-knife, and the necessary rag or "waste" dipped in turpentine will do the rest with ease. The brushes should be rough-cleaned on a piece of paper, then dipped in turpentine and dried; or, to get them cleaner still, wash the remaining matter with soap and warm water. Always dry them on a rag.

In the corn trade oats are generally sold weighing 38 lb. to the bushel, and if dry and hard, they are more often preferred as a food for horses to heavier samples, which so often possess thicker skins. The natural weight of the oat varies from 34 to 48 lb. per bushel; indeed, we have seen a sample weighing less than the former figure. In an average sample there are from 700,000 to 800,000 grains to the bushel, the number varying according to the size of the grain. We once counted 485 grains on a selected ear grown by ourselves. If exceptionally fine-skinned and coarse-skinned samples are examined, their coats removed, and their kernels weighed—a sufficient number of grains being taken for the purpose—it will be found that the husk weighs from about 22 to 30 per cent. of the whole grain.

TARTARIAN OAT
[Avena orientalis]

Oats as Food for Horses. As a food for horses the oat is preferred to any other cereal, chiefly because it is naturally better balanced. The proportion of proteids, or nitrogenous constituents, to carbohydrates, chiefly starch, varies, sometimes largely in different samples. As a stock food the oat should not be used while new, and when given it should preferably be in a crushed condition. The oatmeal of commerce is produced from the kernel of the grain after the removal of the husk, and after artificially drying. The yield of meal varies from 55 to 60 per cent., the proportion naturally depending upon the quality of the oat employed. The ground oats of Sussex, however, so largely used by poultry feeders, are the flour produced by grinding the whole grain between specially prepared stones. In sowing for a crop, the seed used varies from 3½ bushels in the early season with the drill to 5 bushels by hand in the late season, or in ill-prepared or unkind soils.

Barley. Barley (*Hordeum*) is a bearded cereal largely grown in this country chiefly for malting. Its price varies greatly in accordance with its quality and its malt value; hence fine barley is grown in some districts, whereas in others it is almost impossible to obtain a malting sample. Second-class barley is chiefly employed in ground condition for feeding stock. Barley may be two-, four-, or six-rowed, many of the principal varieties grown on the English farm, such as Chevalier, being two-rowed (*H. distichum*). Four-rowed barley, or *Bere*, a grain of a rougher character, is grown in parts of Scotland and Ireland.

Barley is commonly grown after swedes or turnips, or after certain forage crops, that have been eaten off light land by sheep, which were simultaneously fed with rich foods, such as linseed and cotton cakes, grain, and hay. In this way the soil, often thin or of light texture, is enriched by the manure dropped by the flock, and a good crop of grain ensured. Barley is a shallow-rooted plant, hence its adaptability to chalky and other light soils. It may be manured, like oats and wheat, with the artificials which provide phosphates and nitrogen,
soda must be sparingly used, inasmuch as it may depreciate the quality of the grain. Manures are seldom necessary where barley is taken on land upon which sheep have been well fed.

Barley weighs roughly from 48 to 55 lb. to the bushel, a heavy sample bushel containing 550,000 to 665,000 grains. The seed is sown in the spring, often, where the sheep are long on the land, as late as May, the quantity sown per acre varying from 2 bushels with the drill to 4 bushels when broadcasted. The average yield in Great Britain during ten years is 33·17 bushels, the English average reaching 33 bushels, and the

THE COMMON OAT
[Avena sativa]

Scotch, on a much smaller area, 35¾ bushels. The grain weighs about half as much as the total crop, while the straw varies from 12 cwt. to 1 ton per acre. The most suitable temperature for the germination of the grain is that which applies to wheat. The chief barley-growing counties, taking them in order, are Lincoln, Norfolk, Suffolk, the North Riding and the East Riding of Yorks, and Essex.

A fine sample of barley should be plump, covered with a thin, wrinkled skin, the colour of which should be from very pale yellow to light gold colour. It should be dry and sweet, and the ends of the grain finely pointed.

Malt is barley which has been germinated on a malting floor after being soaked in water. A portion of the starch of the grain is converted into sugar in the process. The sprouts—*i.e.*, the *radicle* and the *plumule*, which have developed during germination, are removed as one of the operations of the maltster, and being sweet food, rich in albuminoids, are sold to stockfeeders, to whom they are known as *malt coombs*, or *combs*.

Rye. Rye (*Secale*) is little grown in this country for seed, but 65,000 acres were cropped in the year 1904, the chief object being the production of green fodder for spring use. Rye is largely grown upon the Continent of Europe, especially in the Northern countries, as wheat is grown by us, for the production of bread. Rye resembles wheat more closely than either barley or oats; it is heavier in weight than either of the last-named, while it is better adapted as a food for man. Its chief value to the farm is in the fact that it will grow with success upon poor soils, even those which are extremely sandy in character and at comparatively high altitudes. There is but one species (*S. cereale*), and but few varieties. A crop of rye varies from 3 to 3½ quarters, or 24 to 28 bushels, a bushel weighing about 54 lb. and comprising about a million seeds. The quantity of straw produced, which is about one-third of the total weight of the crop, varies from 1½ to 2 tons per acre.

In sowing rye, from 2 to 4 bushels of seed are used, the quantity depending upon whether the drill is employed or whether the seed is broadcasted by hand. Good seed should be clean, even, bright, and smell sweet; as in other cases it is important to notice whether it is the produce of a crop which has been heated in the stack, or which, having been subjected to frequent rain, has sprouted in the sheaf. Rye is occasionally grown in this country for the sake of the straw, which is the most valuable of any kind for thatching and other purposes where clean, straight, strong, and tough straw is needed. For a green, or catch, crop, rye is sown in the autumn, in September, or October, and may be mown in the early spring, as it is one of the very earliest plants ready for the scythe, in time for turnips, cabbage, rape—maize in the Southern counties—and every other plant which can be sown after the middle of May.

The Pea. The pea (*Pisum*), like the cereals, is an annual, known as a pulse, and belongs to the natural order *Leguminosæ*, the chief feeding constituent of which is legumin, a material resembling the casein of milk. The pod of the pea, as of other plants of this order, is known as a legume. Although there is but one species (*P. sativum*), there are several varieties known to the farmer, these including field peas, which are grey, blue, and maple, or mottled, in colour, and garden peas, which are specially grown for the table. The pea is also grown for cutting green as a forage crop, especially in the United States. The largest crops are grown upon loams which are rich in lime, but the pea thrives on dry clays, sands, and gravels, where lime is present.

On the average of ten years the pea crop of Great Britain has yielded 26¼ bushels per acre, slightly more in England, slightly less in Scotland, and considerably less in Wales, in both of which countries the area sown is small. A bushel of peas weighs from 63 to 65 lb., and contains nearly 100,000 seeds. The yield of straw, which is a valuable food for stock, reaches 1¼ tons to the acre. Peas are now chiefly sown in the months of February and March at the rate of 2 to 5 bushels to the acre, the smaller quantity with the drill, and the larger by hand. Table peas, which are frequently grown in the field, may be sown until the end of April. Good seed may be recognised by its clean, hard, and dry condition, and by its evenness in colour and size.

VETCH
[Vicia sativa]

The Bean. The field bean (*Faba vulgaris arvensis*), also a pulse, is largely grown in this country on the heaviest classes of soil and between two cereal, or white straw crops. It is also a cleaning crop, for, being sown in rows wide apart, the farmer is able to pass the horse hoe between, and thus to cut up the weeds. The average yield of beans covering ten years is 28¼ bushels to the acre, the crop being chiefly grown in England. The bushel weighs from 63 to 65 lb., and contains from 38,000 to 42,000 seeds. The husk of the bean forms about one-seventh of its weight. The straw or haulm, which is useful as a food for stock, reaches from 1¼ to 1½ tons to the acre. The seed is usually drilled at the rate of 2 to 2½ bushels to the acre, but it is sometimes dibbled by hand, when still less is required, and occasionally broadcasted, when as many as 4 bushels are needed. More seed is needed in spring than in autumn. Seed sown in autumn is known as the winter bean, and is specially hardy and vigorous, the plant withstanding severe weather unless the soil is wet.

Good seed is bright and uniformly light brown in colour, well formed, even in size, clean and sweet. Black seeds are objectionable.

THE GRASSES

With the green fields, by which we mean our meadows and pastures, are largely associated buttercups and daisies, that remind us of the misplaced admiration of our youth. Like many other plants, however, these are but indications of poor soils and inferior herbage. The grass field should, as far as man can control it, produce nothing but those among the cultivated grasses and plants of the clover family which are suitable to the soil and the climate. There are cultivated and uncultivated grasses, as there are weeds, which are practically indigenous to particular soils and to the districts in which they grow. The grasses proper belong to the natural order *Gramineæ.* They are grown for the purpose of enabling cattle to feed by grazing, and for mowing for the production of hay.

There is, however, a distinction between the pasture and the meadow. In the former, the plants cultivated should be in such variety, especially as far as their dates of maturity are concerned, that there is a constant succession of young herbage, from the early growing foxtail to the later growing fescues and timothy. Among the cultivated grasses are many which are of quite secondary character, or which are practically worthless, owing, among other reasons, to the small quantity of herbage which they produce, or to the fact that their feeding properties are small. Among these are Yorkshire Fog, darnel, poa annua, quaking grass, tussac grass, barley grass, and the bents. Some grasses, like many weeds which find their way into the meadow and the pasture, are almost as troublesome as couch, or twitch, which, although a grass proper and closely allied to the wheat plant, is one of the greatest opponents of the British farmer, and one which, like weeds and inferior grasses in general, occupies places in which the superior grasses should be growing. The following is a list of the grasses of the first rank, and we supplement them with a few of the best of those of the second rank tabulated below

The chief secondary grasses are fiorin, red fescue, soft brome, Yorkshire Fog, schaders brome, and floating sweet grass.

The ear of a grass plant is known as the *panicle,* while the small ears of each panicle are termed *spikelets,* at the base of which are two small shell-like leaves, which are known as *glumes,* these enclosing the florets. At the base of each floret are two leaf-like structures known as the flowering *glume* and the *palea.* Some of the grasses, like Italian rye grass, are awned, the *awn,* or horn, rising from the back or tip of one of the flowering glumes. The stem of the grass is known as the *culm.* In some instances the stem is prostrate, and know as the *stolon,* travelling underground, and throwing up leaves on its way, as is the case with fiorin.

Perennial Rye Grass. This is usually recognised when flowering by the flatness of the spikelets, which rise alternately on each side of the stem. It is one of the most common as well as the best of all cultivated grasses, growing with great freedom and luxuriance in all rich, deep soils, especially those of the heavier class. It stools freely, throwing up leaves from its roots, and provides abundance of rich, close herbage, for which reason it is an admirable grass, whether for meadows or pastures. Rye grass is sold under various names, but all, Italian excepted, are practically the same. It is useful for leys—*i.e.,* temporary meadows or pastures intended to be left for more than one year. It is hardy, and should form part of all seed mixtures on medium to heavy land.

Italian Rye Grass. This is an early annual and a vigorous grower, responding liberally to liquid manure and irrigation. It is an excellent forage grass for green consumption or hay, and we have known it cut, especially in Scotland, several times in a season after liquid manuring. It makes good silage, produces 30 to 40 cwt. of hay at one cut, or 20 bushels of seed where seed is taken; but, being a coarse feeder, it needs well manuring.

Meadow Foxtail. This is a stoloniferous plant, with a handsome, soft-eared, tail-like head, of a greyish colour. It is one of the earliest grasses to grow, provides plenty of rich herbage, is hardy, and likes deep moist soils not actually wet.

Cocksfoot. This is a big, coarse, bluish grass, sometimes described as orchard grass. It is deep rooted, grows in tufts, provides abundant herbage, and prefers moist soils.

TALL FESCUE

Timothy, or Catstail Grass. The flower of timothy somewhat resembles that of foxtail, but is much greater in length, and is rougher. Timothy is a late flowering grass, quite hardy, bears greyish leaves, and grows well on clays. The best seed comes from America. When sown alone, although this is seldom advisable in England, 18 to 20 lb. a bushel are required per acre.

Smooth-stalked Meadow Grass. This is somewhat shallow rooted, an early grower, and a good pasture grass, which thrives on dry soils.

Rough-stalked Meadow Grass. This is also a good pasture grass, thriving best on rich, heavy soils.

Wood Meadow Grass. This closely resembles the two last named, and, although useful, is but little employed in grass mixtures.

Sweet Vernal Grass. Although early, and, therefore, useful in a pasture, this is of quite second-rate value, owing to the small quantity of the herbage it produces. It has, however, one important virtue—it imparts a sweet odour to the hay in which it is conspicuous.

Golden Oat Grass. This handsome plant, with its bright yellow panicle, is well adapted to soils of medium character; it grows with freedom, and provides abundance of excellent herbage, whether for pasture or for hay.

Tall Oat Grass. This somewhat large plant we have often regarded as a weed when prevalent in hedgerows, and such it then is; but when forming a part of a meadow it is of considerable value, owing to its vigour, its size, and its usefulness as a food. It prefers the medium clays and loams, and is occasionally found in land under the plough with a bulb above its root.

Meadow Fescue. One of the most useful of cultivated grasses for meadows and pastures is meadow fescue. It does not thrive so well in a dry climate, preferring clays and moist soils in general.

Tall Fescue. This is a robust plant of large size, but somewhat closely resembles meadow fescue in its general character.

Sheep's Fescue. Better adapted for downs and other sheep pastures is sheep's fescue. Its herbage is fine and rich, though not abundant in quantity.

Hard Fescue. This somewhat resembles sheep's fescue, is useful in a mixture, and valuable for sowing in the drier soils.

Red Fescue. This is a vigorous grower, resembling the two last-named grasses; it is useful for pastoral purposes, but of little value for hay. It grows well in second-class soils.

Fine and various Leaved Fescues. These may be classed with the other varieties, assisting to form useful herbage.

Crested Dogstail. This is a wiry, deep-rooted grass, not one of the best, but useful on a sheep pasture, and especially on dry and chalky soils. It is common, however, to find the ear untouched by stock when autumn arrives.

Fiorin, or Creeping Bent. Owing to its prostrate stem and underground growth, this grass soon covers a large space of ground, where the soil suits its habit. It prefers damp

situations, and is useful for providing food in late pastures.

As with oats and barley, members of the same order, the seed of most of the best grasses consists of the entire dried flower, or floret, including the glume and the palea. This, however, is not the true seed, which may be regarded as a ripe ovule within the floret.

If grass seed guaranteed 95 per cent. pure has only a germinating power of 80 per cent., we have only 76 per cent. of pure germinating seed, thus $\frac{95 \times 80}{100} = 76$.

The quantity of pure germinating perennial rye grass seed necessary to sow an acre is 38½ lb. = 54 lb. of commercial seed, whose purity is 95 per cent. and germinating power 75 per cent.

Upon this basis mixtures are made as in Dr. Stebler's table, which appears on this page.

Assuming that 40 lb. of seed are used per acre, the variations in the quantity of each leading variety in accordance with different soils are somewhat as follows: less timothy is employed on sand soils, limestones and chalk, and more dogstail, sheep's fescue, and smooth-stalked meadow grass. On the limestones and chalks sainfoin may be added, while red clover and alsike are omitted on sandy soils. Before preparing seed mixtures the wisest course is to inspect good neighbouring pastures or meadows, and to ascertain what course was followed and what grasses thrive the best. It is also well to study the habits of each variety and what soils they prefer [see table below].

Lucerne at the rate of 5 or 6 lb. to the acre may be employed on the heavy and medium soils, which are deep and contain lime, where the grass is to remain three or four years or more.

RECURRING DECIMALS AND PRACTICE

Addition, Subtraction, Multiplication and Division. Examples. Simple and Compound Practice. Key to Examples

By HERBERT J ALLPORT, M.A.

RECURRING DECIMALS

94. In some cases of division, when the quotient is expressed as a decimal, we have found that the quotient does not terminate—for example, Art. 83, Ex. 2.

In such cases, a digit, or set of digits, is repeated continually. The decimal fraction is then called a *recurring*, a *repeating*, or a *circulating* decimal.

The digits which recur are called the *period.*

A *pure* recurring decimal is one in which the period begins immediately after the decimal point. Thus ·3636... and ·7777... are pure recurring decimals.

A *mixed* recurring decimal is one in which the period does not begin immediately after the decimal point. Thus ·23548548..., in which the digits 548 recur but 23 does not recur, is a mixed recurring decimal.

The period is usually indicated by placing a dot over its first and last digits, so that ·363636... is represented by $\cdot\dot{3}\dot{6}$, ·777... by $\cdot\dot{7}$, and ·23548548... by $\cdot 23\dot{5}4\dot{8}$.

95. We can easily tell, without performing the division, whether a vulgar fraction *in its lowest terms* will give a terminating or a repeating decimal; for a terminating decimal is equivalent to a vulgar fraction with 10 or some power of 10, as its denominator. Hence, if we can multiply both numerator and denominator of our vulgar fraction by such a number that the denominator becomes 10, or some power of 10, then the fraction will give a terminating decimal. Now 2 and 5 are the only numbers which can be multiplied so as to become powers of 10. Therefore, if the denominator of the given fraction contains any prime factors which are not either 2's or 5's, the fraction will not form a terminating decimal.

96. Further, we can tell the greatest possible number of digits in the recurring period. Consider the fraction $\frac{2}{7}$. When dividing by 7 the remainder must always be less than 7, so that the only possible remainders are 1, 2, 3, 4, 5, 6. Hence, the next remainder *must* be one which we have already had, and the figures in the quotient will recur, even if they have not done so sooner.

Although the following statements cannot be proved here, a knowledge of them may save much labour.

(1) When the denominator is a prime number, the number of digits in the period is a factor of the denominator-diminished-by-one.

Thus $\frac{1}{13}$ must recur after 1, 2, 3, 4, 6, or 12 digits, since these are the only numbers which are factors of 13 − 1, *i.e.*, of 12.

(2) By division we find $\frac{1}{7} = \cdot\dot{1}4285\dot{7}$. In any multiple of $\frac{1}{7}$, such as $\frac{5}{7}$, these same digits will form the period, and they will follow one another in the same order. By dividing 7 into 50 we see the first digit is 7; hence, we at once know that $\frac{5}{7} = \cdot\dot{7}1428\dot{5}$. This statement is true for any fraction whose denominator is prime, and *the number of digits in whose period is one less than this denominator.*

(3) In $\cdot\dot{1}4285\dot{7}$ we see that, when we have found the first half of the period by division, we can obtain the second half by subtracting the digits already found, in order, from 9. Thus, 8 = 9 − 1, 5 = 9 − 4, 7 = 9 − 2. This fact is of great use in cases such as $\frac{1}{17}$, $\frac{2}{19}$, etc.

For example, we find by division that $\frac{1}{17}$ = ·05882352... and that the quotient does not yet recur. But, by (1) of the present article, since it does not recur after *eight* figures, we know that it *must* recur after 16. Consequently, we can obtain the remaining 8 figures by subtracting the first 8, in order, from 9. Hence, $\frac{1}{17} = \cdot\dot{0}58823529411764\dot{7}$.

97. A pure circulating decimal is converted into a vulgar fraction as follows:

Example 1. Reduce $\cdot\dot{2}$ to a vulgar fraction.

We have $\cdot\dot{2}$ = ·2222 . . . . (1)

There is *one* digit in the period, so we multiply by the *first* power of 10.

Thus $10 \times \cdot\dot{2} = 2\cdot 2222$ . . . . (2)

Subtract (1) from (2), and we get

$$9 \times \cdot\dot{2} = 2$$

Therefore $\cdot\dot{2} = \frac{2}{9}$ *Ans.*

Example 2. Reduce $\cdot\dot{7}1428\dot{5}$ to a vulgar fraction.

$$\cdot\dot{7}1428\dot{5} = \cdot 714285714285\ .\ .\ \ (1)$$

There are *six* digits in the period, so we multiply by the *sixth* power of 10.

Then

$$1000000 \times \cdot\dot{7}1428\dot{5} = 714285\cdot 714285\ .\ .\ \ (2)$$

Subtract (1) from (2) and we get

$$999999 \times \cdot\dot{7}1428\dot{5} = 714285.$$

Therefore,

$$\cdot\dot{7}1428\dot{5} = \frac{714285}{999999} = \frac{5 \times 142857}{7 \times 142857} = \frac{5}{7}\ Ans.$$

Hence we have the rule: *For the numerator, write down the digits which form the period; for the denominator, put down as many nines as there are digits in the period.*

98. Mixed recurring decimals are converted in a similar way.

Example. Reduce $\cdot 3\dot{5}\dot{7}$ to a vulgar fraction

$$\cdot 3\dot{5}\dot{7} = \cdot 3575757\ .\ .\ .\ .$$

There is *one* digit in the non-recurring part, so we multiply by 10, and obtain

$10 \times {\cdot}3\dot{5}\dot{7} = 3{\cdot}575757 \ldots \qquad (1)$

There are *three* digits in the non-recurring part and the period together. Multiply, therefore, by the *third* power of 10.

$1000 \times {\cdot}3\dot{5}\dot{7} = 357{\cdot}5757 \ldots \qquad (2)$

Subtract (1) from (2):

$990 \times {\cdot}3\dot{5}\dot{7} = 357 - 3.$

Hence $\quad {\cdot}3\dot{5}\dot{7} = \frac{357-3}{990} = \frac{354}{990} = \frac{59}{165}$ *Ans.*

We have, therefore, the rule: *For the numerator, write down the number consisting of the digits as far as the end of the first period, and subtract the number consisting of the digits which do not recur; for the denominator, write as many nines as there are recurring digits, followed by as many noughts as there are non-recurring digits.*

99. A decimal whose period is 9 is equivalent to a terminating decimal.

Example. By the above rule

$${\cdot}12\dot{9} = \frac{129-12}{900} = \frac{117}{900} = \frac{13}{100} = {\cdot}13.$$

Or, the same thing may be shown by subtracting ${\cdot}12\dot{9}$ from ${\cdot}13$, the result being zero.

NOTE. From this it appears that ${\cdot}\dot{9} = 1$. This is only true in the sense that the difference between 1 and ·999... becomes less and less as we take more figures of the decimal, until the difference between them is smaller than any assignable quantity. It is, in fact, in this sense that any vulgar fraction is said to be *equal* to a recurring decimal.

100. Addition and Subtraction of Recurring Decimals.

In adding or subtracting recurring decimals, it should be noticed that we can always write the decimals so that their *periods begin at the same decimal place.* For, it is evident that ${\cdot}12\dot{9}3\dot{4}$ may be written ${\cdot}1293\dot{4}9\dot{3}$, since each is equivalent to ·12934934934... We have thus shifted the beginning of the period from the third place to the fifth.

Next, a decimal which has a period of, say, 4 digits, may be considered as having a period of 8, 12, or any other multiple of 4 digits. So that, if we have three decimals, whose periods consist of, say, 2, 3, and 4 digits, we may take the L.C.M. of 2, 3, 4, *i.e.*, 12, and consider that each decimal has a period of 12 digits.

We will now consider examples in addition and subtraction.

Example 1. Add together ${\cdot}25\dot{7}9\dot{3} + {\cdot}124\dot{6}\dot{1} + {\cdot}\dot{3}2\dot{5} + {\cdot}1\dot{2}\dot{4}$.

·257	937937	93
·124	616161	61
·325	325325	32
·124	242424	24
·832	121849	*Ans.*

EXPLANATION. The latest place at which a period begins is the *fourth* (in the second decimal). We therefore, after writing the decimals under one another as in ordinary addition, draw a line in front of the *fourth* place. Next we see that the numbers of digits in the periods are 3, 2, 3, 2 respectively. The L.C.M. of these numbers is 6. Write, then, in each decimal, *six* figures to the right of the line we have drawn, and draw another line after them. Evidently the figures enclosed between the two vertical lines will continually repeat, so that we only need write down two more places of each decimal, in order to find what figure we must "carry," and add the decimals together. The answer will be a decimal of which the part between the vertical lines recurs.

Example 2. Subtract ${\cdot}63\dot{5}6\dot{4}$ from $1{\cdot}\dot{8}7796\dot{8}$.

1·87	796887	79
·63	564564	56
1·24	232323	

Reqd. difference $= 1{\cdot}24\dot{2}\dot{3}$ *Ans.*

EXPLANATION. Make both decimals begin to recur at *third* place. Draw a line in front of the third place. The periods consist of 6 and 3 digits respectively. The L.C.M. of 6 and 3 is 6. Hence, write six figures to the right of the line, draw another line, and continue two places beyond. In this case there is nothing to "carry" from these extra places, and we get for our answer 1·24|232323|, where the figures between the lines form the period. We notice that this period of *six* figures consists of three sets of *two* figures, so that the answer is written $1{\cdot}24\dot{2}\dot{3}$.

101. Multiplication and Division of Recurring Decimals.

Division by a whole number or by a terminating decimal presents no more difficulty than the division explained in Art. 33. We have, of course, to "bring down" the digits which form the period, instead of bringing down 0's.

Example 1. Divide $12{\cdot}\dot{0}\dot{6}$ by 3·7.

```
37 ) 120·606060... ( 3·259623 Ans.
     96
     220
      356
       230
        86
        120
          9
```

EXPLANATION. We have to divide 12·0606... by 3·7, *i.e.*, 120·606... by 37. Proceeding as in ordinary division, we find, after getting six figures of the quotient, that we obtain a remainder 12. This, with the 0 brought down from the dividend, gives 120, and we have already divided 37 into 120, at the beginning of the work. In the first case, however, the division did not give a digit in the *decimal* part of the quotient, so we have to proceed one step further, obtaining 3 in the quotient and 9 remainder. It is clear that all the digits in the decimal part of the quotient will now recur. Hence the answer is $3{\cdot}\dot{2}5962\dot{3}$.

Example 2. Multiply $4{\cdot}\dot{2}1\dot{3}$ by 3·25.

In multiplication by a whole number or by a terminating decimal, we write down the multiplicand as far as the end of two periods, and then two places more, so as to "carry" the correct figure. Write the multiplier with its unit's digit under the last digit of the second period, and proceed as in ordinary multiplication.

Thus:

```
4·|213|213|21
         3·25
 12|639|639|6
   |842|642|6
   |210|660|6*
13·692|942|
```

Or, $13{\cdot}69\dot{2}9\dot{4}$ *Ans.*

N.B. It must be remembered that the last two places of the multiplicand are only used to enable us to carry the correct figure. Thus, in multiplying by 5, we say, five 1's, 5; but *we put nothing down.* Then

five 2's, 10, and again put nothing down; but we now know we must add-in the 1 carried, when we begin the multiplication of the period —*i.e.*, five 3's, 15, and 1, 16. This 6, according to the ordinary rule, would come *under the multiplier* 5, and is not needed in the above example. We proceed, five 1's, 5, and 1, 6; which is the 6 marked * in the working. Again, if there are many digits in the multiplier, it *may* be necessary to fill in one or two more periods of each separate product before adding them together. Thus, in the above example, had there been many more lines of multiplication, we might have had to continue the 639 of the first line, the 642 of the second, the 660 of the third, and so on, in order to find the period of the sum of all the lines.

102. If the multiplier is a recurring decimal, we *must* express it as a vulgar fraction. In some examples the work is simpler if we also express the multiplicand as a vulgar fraction, in which case we proceed as in multiplication of fractions and then convert the result into a decimal. The student must use his judgment as to which method is best suited to any particular example.

The same remarks apply to division by a recurring decimal.

Example 1. Multiply $3{\cdot}\dot{1}4285\dot{7}$ by $\cdot\dot{6}\dot{3}$.

Here it is simpler to reduce both to vulgar fractions.

For $\qquad 3{\cdot}\dot{1}4285\dot{7} = 3\frac{1}{7}$

and $\qquad \cdot\dot{6}\dot{3} = \frac{63}{99}$

Their product $\qquad = \frac{\overset{2}{\cancel{22}}}{\cancel{7}} \times \frac{\overset{\cancel{7}}{\cancel{63}}}{\underset{\cancel{9}}{\cancel{99}}} = \underline{2\ \textit{Ans.}}$

Example 2. Divide $3{\cdot}\dot{1}2\dot{8}$ by $1{\cdot}\dot{3}$.

The divisor $= 1\frac{3}{9} = 1\frac{1}{3} = \frac{4}{3}$. To divide by $\frac{4}{3}$ we multiply by $\frac{3}{4}$.

Thus:

$$\begin{array}{r} 3{\cdot}12812\ldots \\ 3 \\ \hline 4)\overline{9{\cdot}\dot{3}8\dot{4}} \\ \underline{2{\cdot}346\dot{0}9\dot{6}\ \textit{Ans.}} \end{array}$$

EXAMPLES 12

1. Add together $3{\cdot}12\dot{6}\dot{4} + {\cdot}008\dot{3} + 10{\cdot}9\dot{6}1\dot{4}$.

2. Find the value of $7{\cdot}1\dot{2}3\dot{4} - {\cdot}\dot{0}25\dot{7} + 3{\cdot}54\dot{3}2\dot{1} + 11{\cdot}257 - 9{\cdot}\dot{3}\dot{6}$.

3. Express $2{\cdot}25\dot{2}8571\dot{4}$ as a vulgar fraction in its lowest terms.

4. Express £15 13s. 7½d. as the decimal of £99 6s. 3½d.

5. Find the value of ${\cdot}1\dot{3}\dot{6}$ of £7 14s. 11d. $-$ ${\cdot}0\dot{2}5\dot{4}$ of £6 0s. 3¾d.

6. Simplify, giving the answer as a decimal, ${\cdot}7\dot{3}$ of $1{\cdot}23\dot{4}$ of 12.

7. Show that the decimals equivalent to $\frac{1}{7}, \frac{2}{7}, \frac{3}{7}, \frac{4}{7}, \frac{5}{7}, \frac{6}{7}$, can be arranged in a square so that the sum of each row, of each column, and each diagonal, is the same.

8. Find the greatest decimal fraction which, when divided into ${\cdot}13\dot{6}$ and into ${\cdot}\dot{8}\dot{2}$, gives a whole number for quotient in each case.

9. A warehouse consists of three floors; the rent of each floor is ${\cdot}\dot{8}\dot{1}$ of the rent of the floor below; that of the top-floor is £51 6s. What is the rent of the ground floor?

10. A train puts down ${\cdot}\dot{3}8461\dot{5}$ of its passengers at its first stop, and 57 people at its second stop. It now has ½ of the original number left. How many passengers were there when the train started?

PRACTICE

103. Practice is a convenient method by which we find the value of any quantity when we know the value of one of the units in terms of which the quantity is expressed.

In *simple* practice we have to find the value of a *simple* quantity; in *compound* practice, the value of a *compound* quantity.

The method is as follows:

In simple practice we break up the value of a single unit into component parts, each of which *measures* [see Art. 57] one of the preceding component parts. It is then easy to obtain the value of the given quantity when the value of a unit is each of these component parts, in turn; after which, we add the several results.

In compound practice we break up the given compound quantity into components in the same way, and, after finding the value of each component, we add the results.

Such components are called *aliquot parts.* Thus, an aliquot part of a quantity is a part which measures that quantity, and therefore it is a fraction of the quantity whose numerator is 1.

Examples.

3s. 4d. is an aliquot part of £1, since 3s. 4d. $= \frac{1}{6}$ of £1.

14 lb. is an aliquot part of 1 cwt., since 14 lb. $= \frac{1}{8}$ of 1 cwt.

104. A few examples will make the method clear.

Example 1. Find the value of 3128 tons at £1 8s. 6d. per ton.

Here we have a simple quantity, *viz.*, 3128 tons, and we are given the value of a unit.

The work is arranged thus:

	£	s.	d.	
	3128	0	0	= cost at £1 per ton
5s. = ¼ of £1	782	0	0	= ,, 5s. ,,
3s. 4d. = $\frac{1}{6}$ of £1	521	6	8	= ,, 3s. 4d. ,,
2d. = $\frac{1}{20}$ of 3s. 4d.	26	1	4	= ,, 2d. ,,
	£4457	8	0	*Ans.*

Explanation. The cost of 3128 tons at £1 per ton is evidently £3128. Next, 5s. = ¼ of £1, and therefore the cost at 5s. a ton will be one quarter of the cost at £1, so that we obtain the cost at 5s. by dividing £3128 by 4. Again, 3s. 4d. = $\frac{1}{6}$ of £1, therefore, divide the cost at £1 by 6 to obtain the cost at 3s. 4d. Similarly, since 2d. = $\frac{1}{20}$ of 3s. 4d., we divide the cost at 3s. 4d. by 20 to obtain the cost at 2d. Finally, we add the several costs, *viz.*, at £1, at 5s., at 3s. 4d., and at 2d. to obtain the cost at £1 8s. 6d.

Example 2. Find the cost of 7692¼ articles at £3 16s. 4½d. each.

	£	s.	d.	
10s. = $\frac{1}{2}$ of £1	7692	5	0	= cost at £1 each
			3	
	23076	15	0	= „ £3 „
5s. = $\frac{1}{2}$ of 10s.	3846	2	6	= „ 10s. „
1s. 3d. = $\frac{1}{4}$ of 5s.	1923	1	3	= „ 5s. „
$1\frac{1}{2}$d. = $\frac{1}{10}$ of 1s. 3d.	480	15	$3\frac{3}{4}$	= „ 1s. 3d. „
	48	1	$6\frac{3}{8}$*	= „ $1\frac{1}{2}$d „
£	29374	15	$7\frac{1}{8}$	*Ans.*

* In dividing the previous line by 10, we obtain 3d. remainder from the pence. This, with the $\frac{3}{4}$d. makes $\frac{15}{4}$d., and $\frac{15}{4} \div 10 = \frac{15}{40} = \frac{3}{8}$d.

Sometimes the work is considerably shortened if we *subtract* one or more aliquot parts, as in the next example.

Example 3. Find the cost of 107 things at £17 17s. $10\frac{1}{2}$d. each.

Here, the value of each article is 2s. $1\frac{1}{2}$d. short of £18. We find the cost at £18, and subtract the cost at 2s. $1\frac{1}{2}$d.

	£	s.	d.	
2s. = $\frac{1}{10}$ of £1	107	0	0	= cost at £1 each
			3	
	321	0	0	
			6	
	1926	0	0	= „ £18 „
$1\frac{1}{2}$d. = $\frac{1}{16}$ of 2s.	10	14	0	= „ 2s. „
		13	$4\frac{1}{2}$	= „ $1\frac{1}{2}$d. „
£	1914	12	$7\frac{1}{2}$	*Ans.**

* Subtract the two lines from £1926 by the method of Art. 43.

Example 4. Find the cost of 4 tons 12 cwt. 80 lb. at £3 15s. per ton.

	£	s.	d.	
10 cwt. = $\frac{1}{2}$ of 1 ton	3	15	0	= cost of 1 ton
			4	
	15	0	0	= „ 4 tons
2 cwt. = $\frac{1}{5}$ of 10 cwt.	1	17	6	= „ 10 cwt.
70lb. = $\frac{1}{16}$ of 10 cwt.		7	6	= „ 2 cwt.
10 lb. = $\frac{1}{7}$ of 70 lb.		2	$4\frac{1}{8}$	= „ 70 lb.
			$4\frac{1}{56}$	= „ 10 lb.
£	17	7	$8\frac{1}{7}$	*Ans.*

Example 5. Find the cost of 15 miles 6 fur. 200 yd. at £31 6s. 8d. per mile.

Here 240 yd. more would make 16 miles. Therefore, we have:

	£	s.	d.	
160 yd. = $\frac{1}{11}$ of 1 mile	31	6	8	= cost of 1 mile
			4	
	125	6	8	
			4	
	501	6	8	= „ 16 miles
80 yd. = $\frac{1}{2}$ of 160 yd.	2	16	$11\frac{7}{11}$	= „ 160 yd.
	1	8	$5\frac{9}{11}$	= „ 80 yd.
By subtraction £	497	1	$2\frac{6}{11}$	*Ans.*

EXAMPLES 13

1. Find the cost of 3256 head of cattle at £14 17s. 10d. per head.

2. Find the value of $729\frac{1}{2}$ dozen walking-sticks at £3 4s. $7\frac{1}{2}$d. per dozen.

3. What will it cost to fence 6 fur. 72 yd. at £3 15s. a furlong?

4. A bankrupt pays 14s. $5\frac{1}{4}$d. in the £. How much will a creditor receive to whom the bankrupt owed £743 10s.?

5. Find the value of 743·875 oz. of silver at 2s. 8d. per oz.

6. Find in £ s. d. the value of 32·8625 of £3 11s. 4d.

7. What will be the rent of 5 a. 2 r. 16 p. at £4 2s. 6d. per acre?

8. Find the cost of 33 miles 5 fur. 180 yd. of telegraph wire, at £12 13s. 6d. per mile.

9. What is the value of 1 ton 15 cwt. 91 lb. at £1·4625 per cwt.?

10. Find the cost of 1 a. 3215 sq. yd. at 2s. $2\frac{1}{2}$d. per sq. ft.

Answers to Arithmetic

Examples 4

1. £52 14s. $8\frac{3}{4}$d. 2. £164 18s. $6\frac{1}{2}$d. 3. £381 17s. 3d. 4. £175 12s. 9d. 5. £52 1s. 8d. 6. £2083 6s. 8d. 7. £130 8s. 6d. 8. £3766 2s. 6d. 9. 9 wk. 1 dy. 2 hr. 37 min. 10. 1 wk. 2 dy. 18 hr. 3 min. 18 sec. 11. 3 wk. 2 dy. 3 hr. 33 min. 20 sec. 12. 13 tons 16 cwt. 1 qr. 14 lb. 8 oz. 5 dr. 13. 12 tons 3 cwt. 24 lb. 14. 16 tons 10 cwt. 3 qr. 20 lb. 15. 1 ton. 16. 4 lb. 2 oz. 4 dwt. 6 gr. 17. 10 lb. 6 oz. 9 dwt. 13 gr. 18. 175 lb. 5 oz. 3 dwt. 19. 4 miles 4 fur. 32 po. 5 yd. 6 in. 20. 27 miles 99 yd. 21. 43 miles 1 fur. 9 ch. 24 lks. 22. 48 lea. 7 fur. 25 po. 2 ft. 9 in. 23. 2 a. 1 r. 27 p. 29 yd. 16 in. 24. 46 a. 1918 yd. 8 ft. 143 in. 25. 9 a. 3 r. 14 p. $5\frac{1}{2}$ yd. 26. 6 sq. miles 115 a. 4228 yd. 27. 169 cu. yd. 6 cu. ft. 200 cu. in. 28. 16 cu. yd. 17 cu. ft. 42 cu. in. 29. 30011 bush. 2 pk. 3 qt. 1 pt. 30. 13153 qr. 1 gall.

Examples 5

1. 952 gs. + 8s. 2. 222 fourpences + 3d. 3. 29988 half-crowns. 4. 112 half-guineas + 3 florins 5. 1 cwt. 93 lb. 5000 gr. 6. 5840 poles. 7. 30408 crowns. 8. 2994 lb. 5 oz. 6 dwt. 16 gr.

Examples 6

1. £212 6s. $10\frac{1}{4}$d. 2. £21 12s. 10d. 3. 5 cwt. 15 lb. 15 oz. 4. £17 18s. $11\frac{1}{2}$d. 5. 4 a. 4195 sq. yd. 8 sq. ft. 6. 60 a. 16 p. $29\frac{3}{4}$ yd. 7. 2 bush. 1 pk. 3 qt. 1 pt. 8. £94 13s. 11d.

Examples 7

1. 277 miles 3 fur. 172 yd. 2. 4 tons 19 cwt. 3 qr. 12 lb. 9 oz. 3. £164084 4s. 3d. 4. £16 1s. 9d. + 104 far. rem. 5. 304. 6. 5 half-crowns. 7. Giving 3 men 10s. each first, leaves £53 15s. 10d. − £1 10s. = £52 5s. 10d. to be divided equally amongst the 10 men; which gives £5 4s. 7d. for each. Hence, 7 men have £5 4s. 7d. each and the other 3 have £5 14s. 7d. 8. Giving 2 men out of 7 twice as much as the others makes the share of the others the same as if there were 9 men. ∴ 5 of the men get £11 9s. 6d. ÷ 9 = £1 5s. 6d. each. The other 2 men get 2 × £1 5s. 6d. = £2 11s. each. 9. A bat costs as much as 5 balls. ∴ 1 guinea will buy 6 balls. Hence, the ball costs 21s. ÷ 6 = 3s. 6d. The bat costs 21s. − 3s. 6d. = 17s. 6d. 10. At the lower price she saves 3d. on each dozen. ∴ On 12 dozen she saves 3d. × 12 = 3s. Hence, at the lower rate, she

could have bought 2 dozen eggs for this 3s., *i.e.*, the lower rate = 1s. 6d. per dozen. ∴ The original price = 1s. 6d. + 3d. = 1s. 9d. per dozen. **11.** Selling price of 1 cwt. = 19d. × 112 = 2128d. = £8 17s. 4d. ∴ The gain on 1 cwt. = £8 17s. 4d. − £6 10s. = £2 7s. 4d. **12.** A packet is given for 5 coupons, so that 5 coupons = 5 cigarettes + 1 coupon. ∴ 4 coupons are worth 5 cigarettes—*i.e.*, a coupon is worth $1\frac{1}{4}$ cigarettes. Hence, $5 + 1\frac{1}{4} = 6\frac{1}{4}$ cigarettes should be sold for 1d., and ∴ $6\frac{1}{4} \times 12 = 75$ for a shilling. **13.** See correction of this example on page 708; the £29 15s. should read £29 5s., and the answer to the corrected sum is 1 sov. + 1 half-sov. + 1 crown + 1 half-crown + 1s. + 1 sixpence = £1 19s. Now, £29 5s. ÷ £1 19s. = 15. ∴ there are 15 coins of each sort.

Examples 8

1. 17948·6 + 29510 + 307 + 5400 + 729·825 = 53895·425 litres. **2.** 1·2345 + 4300 + 3529 + 71·46 = 7901·6945 sq. metres. **3.** 42 + 62·4 + 27·5 + 4200 = 4331·9 ares. **4.** 2450·4 × 63 = 154375·2 centigramme. **5.** 90 Hm. 7 Dm., etc. = 9072350 mm. This, divided by 47 mm., gives 193028 quotient, and 34 mm. remainder. Required answer is therefore 193028 times, and ·034 metre remainder. **6.** 124·305 Kg. at 25 centimes per Kg. = 3107·625 centimes = 31·07625 francs. **7.** 275 litres at 3·50 francs per litre = 275 × 3·5 = 962·5 francs = 962 fr. 50 cent. **8.** No. of sheets = 2700 mm. ÷ 1·5 mm. = 27000 ÷ 15 = 1800. **9.** 4 miles per hr. = 5 miles in $1\frac{1}{4}$ hr. ∴ I walk 8 kilo. in 75 min., *i.e.*, 1 kilo. in 75 min. ÷ 8 = 9·375 min.

Examples 9

1. 587 and 997 are primes. [745 is 5 × 149; 1073 is 29 × 37]. **2.** (i) 165 = 3 × 5 × 11; 341 = 11 × 31; 1302 = 2 × 3 × 7 × 31. There is, therefore, no common factor except unity. (ii) 373. **3.** (i) 17640, (ii) 58497, (iii) 5012280. **4.** 1 lb avoir. = 7000 gr. 1 lb. Troy = 5760 gr. The L.C.M. of 7000 gr. and 5760 gr. is found to be 144 × 7000 gr. ∴ Reqd. answer = 144 × 7000 gr. = 144 lb. Avoir. **5.** Least no. which leaves no remainder = L.C.M. of 42, 63, 81 = 1134. ∴ Least no. which leaves 40 rem. = 1134 + 40 = 1174. **6.** Req. no. = 17 eights + 17 nines = 17 × 17 = 289 pencils. **7.** Ring together after L.C.M. of 2, 3, 5, 9 seconds = 90 secs. = $1\frac{1}{2}$ min. **8.** Greatest weight of a coin = H.C.F. of 38875 gr. and 2605 gr. = 5 gr. **9.** L.C.M. of 30 in. and 33 in. = 330 in. But in this distance first man takes 11 steps and the second 10, so that they are not "in step" till they have gone 2 × 330 in. ∴ Required no. of times = 1 mile ÷ 660 ins = 96.

Examples 10

1. $\frac{13}{35}$, $\frac{8}{21}$, $\frac{11}{28}$. **2.** $\frac{46}{57}$, $\frac{31}{38}$, $\frac{97}{114}$, $\frac{81}{95}$. **3.** $\frac{31}{322}$, $\frac{41}{300}$, $\frac{23}{222}$. **4.** $11\frac{2}{35}$. **5.** $1\frac{121}{252}$. **6.** $5\frac{311}{420}$. **7.** 1. **8.** $\frac{13}{336}$. **9.** $2\frac{5}{8}$. **10.** 1. **11.** $1\frac{1}{24}$. **12.** 1. **13.** 12. **14.** $\frac{2}{3}$. **15.** $2\frac{1}{2}$.

Examples 11

1. ·524. **2.** 560 min. **3.** Share of third = $(1 - \frac{1}{4} - \frac{2}{9})$ of whole = $\frac{19}{36}$ of whole. ∴ $\frac{1}{36}$ of sum = 2s., *i.e.*, sum = 72s. = £3 12s. **4.** Half-a-crown = $\frac{5}{4}$ of the cost. ∴ Knife cost $\frac{4}{5}$ of 2s. 6d. = 2s. Hence, if the boy sells it to gain $\frac{1}{4}$ of the selling price, this 2s. will be the remaining $\frac{3}{4}$ of the selling price. Hence he must sell it for $\frac{4}{3}$ of 2s. = 2s. 8d. **5.** Since the eldest had as much as the other two together he must have had half the entire sum. The second son had $\frac{3}{8}$. ∴ Youngest had $1 - \frac{1}{2} - \frac{3}{8} = \frac{1}{8}$ of the sum. ∴ Sum the father left = 8 × £450 = £3600. **6.** Second has $\frac{5}{8}$ eldest; youngest has $\frac{5}{8}$ of this, *i.e.*, $\frac{25}{64}$ of the eldest. ∴ The eldest has a sum equal to $1 - \frac{25}{64} = \frac{39}{64}$ of his own share more than the youngest. ∴ Eldest's share = $\frac{64}{39}$ of £73 2s. 6d. = £120. The second has $\frac{5}{8}$ of £120 = £75. The third has $\frac{5}{8}$ of £75 = £46 17s. 6d. ∴ The total money = £120 + £75 + £46 17s. 6d. = £241 17s. 6d. **7.** 3·016. **8.** Between 2 and 2·15, *i.e.*, in $\frac{1}{4}$ hour he does $\frac{1}{3} - \frac{1}{4} = \frac{1}{12}$ of his journey. But at 2.15 he still has $\frac{2}{3}$ to do. This will take him $\frac{2}{3} \div \frac{1}{12} = 8$ quarter hours. He thus finishes 2 hours after 2.15, *i.e.*, at 4.15. **9.** 3 oranges = 1 orange less than half the number she had before selling to D, *i.e.*, 4 was half the number she had. She therefore sold D 5 out of the 8 she had on leaving C. Similarly, she sold C 10 out of 18 she had on leaving B; she sold B 20 out of 38 she had on leaving A; and she sold A 40 out of 78 she had at first. Thus, required number = 78. **10.** $\frac{4}{5}$ of distance gone = $\frac{1}{2}$ distance left. ∴ Distance gone = $\frac{1}{2} \times \frac{5}{4} = \frac{5}{8}$ of distance left. He must therefore have already gone $\frac{5}{13}$ of the whole distance. Now, $\frac{5}{13}$ is $(\frac{1}{2} - \frac{5}{13}) = \frac{3}{26}$ of the whole distance short of half-way. Hence, $2\frac{1}{4}$ miles = $\frac{3}{26}$ of the whole distance. ∴ Whole distance = $\frac{26}{3} \times \frac{9}{4}$ miles = $19\frac{1}{2}$ miles. ∴ Reqd. answer = $\frac{8}{13}$ of $19\frac{1}{2}$ miles = $\frac{8}{13} \times \frac{39}{2}$ = 12 miles.

[*The answers to other examples will appear in due course.*]

Continued from page 704.

AGRICULTURAL IMPLEMENT DEALERS

The mere buying and selling of implements offers scarcely sufficient scope for a really smart man. Indeed, it is doubtful whether it would yield a living at the outset. It must be supplemented by a working department in which estate engineering finds a place, or, on the other hand, the implement business may form part—as it frequently does—of a general ironmongery concern.

The implement dealer will find his work change with the recurring seasons. Stock suitable for display in May is very different from that sold in October. For all practical purposes, an agent has to be conversant with and hold stocks of four or five classes of machines.

Classes of Machines. Starting with Michaelmas, the demand will be for what are categorically classed as cultivating implements. In October he will be pushing ploughs, harrows, cultivators, scarifiers, chain harrows, hand rollers, and the like. A month or six weeks later these will give place to food-preparing implements, a class which includes such machines as chaff-cutters, turnip-cutters, oil-cake mills, corn-kibblers and grinders, root pulpers and slicers. About the same time, and right on with the new year, seeding implements will be in demand.

This carries us to March, when the agent begins to lay his plans for selling harvesting machinery, which includes grass-mowers, hay-rakes, hay-tedders and haymakers, the almost obsolete self-raking reaper, and the now universally employed self-binding harvester. Then, after harvest, there is the rather small, but always possible, chance of getting an order for a threshing plant, including an engine, the total price of which may be between £200 and £400. As, however, the makers of such plants prefer to do business direct with the purchaser, only a well-established firm of implement agents stands much chance of getting such orders.

Regular Selling Stock. Then all the year round there is the sale of dairy utensils, butter-making churns, milk separators, tinware, including milk-cans in districts in close proximity to large towns, and cheesemaking plant in others. Besides, in certain parts of England the agricultural engineer is mixed up with cider making, and in nearly all he must needs sell galvanised iron feeding-troughs, skeps, pails, etc.

It is difficult to decide with how little capital an agent can start with reasonable prospect of success. If the business is developed as one department of a more comprehensive concern, £200 would purchase a well-assorted season's stock; but to start with anything less than £500 as an independent venture in selling, repairing, and manufacturing, in even a small way, would be to court failure.

The cost of equipping a workshop in which the repairing of mowers, binders, and general implements could be carried on would run into £200, for besides such simple tools as a drilling-machine and a smithy forge, a lathe and grinding machine would be necessary, and for producing power a small oil or gas engine would be required. An implement business without a workshop department would not be practical, and the better the shop equipment the greater the prospects of success. A large part of an agent's business consists in supplying wearing parts, and in maintaining the farmers' machines in good repair. The life of a plough, for example, is likely to extend to from ten to fifteen years in the hands of a careful farmer, and during that period it is a source of revenue to the agent, if the farmer remains one of his customers.

Renewal Parts. In our estimate we have accounted for £400 of the suggested £500 capital. Some money must be sunk in a stock of renewal parts, which need not necessarily be purchased from the actual makers of the implements. Castings, of course, should be obtained at first hand, made from the original patterns, as otherwise they will not fit the old parts without a lot of fitting, which involves expense. Other wearing parts are obtainable to standard gauge from firms to be found chiefly in and around Sheffield, who specialise in such things as the sections of mower and harvester knives, malleable parts which wear out, brass bushes in which the various shafts and axles work, the fingers on the bars of mowers and harvesters, the knives of root-machines and chaff-cutters.

The Manufacture of Parts. Many parts can be made in the agent's own shops during the slack seasons—spindles for mowers and crank-pins, for example, while some of the castings can often be obtained locally and finished to gauge or template in the shop. This course does not invariably mean economies in production and extra profits, but it often pays to make up in slack times goods which could otherwise be bought as cheaply from the large

manufacturers, because thereby the services of good mechanics can be retained all the year round.

Fields of Enterprise. The workshop also enables the agent to extend his operations, and under the direction of a "live" man it affords opportunities of securing contracts which are only indirectly connected with agricultural implements.

In the present transitional stage of agricultural methods, the business in oil and petrol engines of small power offers great possibilities. A reputation for fixing small internal combustion engines is well worth winning, for there follow not only farmers' orders, but others from butchers, printers, saw-mill owners, millers, builders, and turners, to mention only half a dozen trades in which low-power engines are used.

Windmills, or, as the makers prefer to call them, wind-engines, are coming more and more into favour for pumping water, and for these the farmer and estate agent looks to the implement dealer. Each order for a windmill necessitates pipe-laying and the supplying and fixing of pumps, storage reservoirs and, at times, the sinking of wells.

Yet again, water supply in country districts is often secured by means of the hydraulic ram. Here, again, the pipe service would fall into the hands of the dealer.

Sole Agencies. To get back to the commercial side of the business, a dealer must decide whether he will secure sole agencies or transact his trade on the open system. In the former case he bargains to sell this man's ploughs and the other's mowers, and no other. In the latter he buys and sells what he chooses or his customers want. A mixed policy is usually the best course. There is little to be gained, except a bare margin of extra profit, in hampering one's self with such machines as chaff-cutters, and food-preparing machinery generally. One manufacturer's productions are about as good as another's. It adds variety to the stock to show machines by two or more makers. The same remark applies to implements of cultivation and seeding, but not to harvesting machinery. By taking up the sole agency for a binder, and even for a mower, the dealer keeps down the stock of repair parts, and is enabled to win a reputation for promptness in breakdown emergencies, which frequently occur in the harvest-field.

Finance of Implement Dealing. The dealer in agricultural implements is not at present in a very strong position. A few years ago unsuccessful efforts were made in several parts of England to form associations to prevent price-cutting, which had grown serious.

The financial practice of implement dealing is out of date. Long credit, which would not be tolerated in many other trades, is demanded by the farmer. A year is not at all uncommon; and the agent, unless well backed with capital, has seldom the ability to take the cash discounts manufacturers are ready to allow for prompt settlements. Since he cannot get payment of accounts, the dealer must perforce be in debt. The terms of trade between the manufacturers and the agents are nearly all on the basis of list prices subject to fixed discounts, which, however, vary with the price of raw materials. Thirty or thirty-five per cent. is a common gross discount for food-preparing machines; but that does not represent the profits of the business. The British farmer expects substantial discounts from makers' list prices, and the working expenses of an agent are so large that the agent is fortunate if he can make 10 per cent. profit on his capital after having allowed himself only a small sum for personal management.

ANIMAL AND BIRD DEALERS

By this heading is meant, not the sellers of farm stock and poultry, but the retailers of fancy birds and animal pets. The business is a minor one, and may be classed among those purveying luxuries. The former fact explains why so little is known about it outside the ranks of those who seek a livelihood by its agency, and the latter causes it to respond to depression and prosperity more than do those shopkeeping trades which cater to everyday wants.

The Decline of the Trade. Should the aspirant hankering after the possession of an animal and bird shop seek advice from those who have been in the trade for a quarter of a century or more, he will almost certainly receive the counsel, "Don't." A few decades ago birds were in fashion as household pets. Other interests have superseded the taste for birds of song and brilliant plumage, and from being the toys of the classes they have fallen to be the pets of the masses. This decline has made the bird and animal trade more than ever the sport of general trade depression. It also means that prices have fallen. From the frequent price of £5 to £10 the parrot has got down to 15s. to 30s. Also, the breeder and the private owner have come into direct contact more than formerly, so that the dealer has little chance of making money out of show birds and animals.

Present Condition. Yet, although the tendency of this trade for many years past has been far from encouraging, it is possible to make a livelihood in it if the district be favourable. An essential condition of profitable result is that the man who takes up the business should have a genuine love for animals and birds. Without such a love, he is certain to neglect them, and neglect means the sickness and death of his stock and pecuniary loss.

Buying Stock. Many an entrant into the trade begins business with only £25-£50 to spend, and this notwithstanding that he must pay cash down for this stock. Often the smallness of the capital is the best thing possible for the man. It prevents him from overstocking, and for an obvious reason the trade is one which should be worked upon the smallest stock possible. In the first place, the chief loss incurred in the business is by the death of stock, and the smaller the stock the smaller the risk of loss from death. In the second place, live animals are different from ordinary stock. The money which birds and animals cost in food

reduces the profit upon their sale, and the longer they remain unsold the greater is this expense.

There is no on and off season in the bird trade. It may be that occasionally—as, for example, when a dealer has developed a connection among the frequenters of a summer resort—there are a few months of the year which may be reckoned the harvest time, but the man who depends for custom upon the non-migratory residents in his neighbourhood finds his returns distributed fairly evenly over the twelve months. Exotic birds are sold in the spring and summer, and British wild birds trapped in summer and autumn sustain the business during autumn and winter. Then the return of spring sees the opening of the trade in exotics again. It would be possible, but unprofitable, to bring exotic birds into this country during the winter months. The change in climate would be too severe, and the death-rate would be high.

Wholesale Importers. The wholesale merchants through whose agency the birds, particularly foreign birds, reach the retailer, are located chiefly in our ports London and Liverpool. They do not hold general stocks all the year round. The usual custom is that every week the merchant issues a circular to his customers giving a list of the birds he has and offering them subject to being unsold upon receipt of order. Then it is a question of first come, first served. The birds are usually despatched by passenger train, and the railway companies charge rates 50 per cent. higher than those prevailing upon ordinary parcels, and assume responsibility for safe custody up to five shillings per bird. Ordinary parcel rates only may be paid if desired; but in such a case no responsibility attaches to the carriers, and most dealers find it profitable to pay the higher rate.

Sick birds may, according to the rule of the trade, be returned to the wholesale importer, who seldom refuses to accept return.

Profits. A trade with the risks and expenses which pertain to the sending of birds demands higher profits than belong to most departments of shopkeeping. It is usual to charge double cost price, but it is always well to get more when possible. One hundred per cent. on cost price may yield a living, but little more. But there are side lines which belong naturally to the trade, and these may be made to help considerably the annual balance-sheet. There is the trade in cages and aviaries. Many retailers of birds are makers of cages also. The ability to undertake the manufacture of cages is not given to every retailer of birds. It requires a deftness in wirework which one may acquire only by a practical training or a natural aptitued But anyone may at least sell the cages. They yield fair profit, seldom less than 50 per cent. on cost price, and often more. As they do not occasion the expenses necessary to the handling of live stock, they may well be sold on smaller profits.

Side Lines. The bird seed and food trade also naturally falls to the province of the retailer of birds, and returns about the same profit as cages. There are several firms who make a specialty of putting up bird food and bird medicines in convenient retail packages, and an account with one of these is all that the retailer need open in this department. Advice will often be asked regarding the care of birds and the treatment of sick birds. The dealer recommends what he has to sell, and reaps a profit thereby. Another trade is naturally allied to the selling of live birds—the stuffing of dead ones. Yet the two are found united less frequently than they ought to be. They go well together. The one supplements the other, and skill in the art of stuffing is not difficult to acquire. For information on both its technical and commercial sides, readers may refer to the chapter on TAXIDERMY, which will follow in this course.

Care of Stock. The care of stock is the most important department in the bird-dealer's business. A bird worth twenty shillings when alive is not worth twenty pence when dead, and the chief aim is a low death-rate. The birds and their cages must be kept clean; the cages should be cleaned out every other day. Care in feeding is also essential. Many dealers think it necessary to study the food of each class of bird; others, recognising that about half of the birds thrive best on canary seed and the other half on millet, feed all upon a mixture of the two. Hemp seed must be given sparingly. It is not desirable as a single diet.

Most foreign birds breed in captivity, but not many dealers adopt the breeding of exotic birds as a serious business. They prefer to turn over their stock rapidly, and regard it as the more profitable plan. Prize and show birds are also considered unprofitable as merchandise. Those who buy such birds are too expert in what prize birds ought to be and too exacting in their requirements. Also, the money sunk in prize birds per head is much more than in common varieties, and loss by death is much greater. While talking parrots fetch much more than others in which this ability is latent, few dealers set themselves to teach parrots the art of speech. It seems to require more patienc and perseverance than is possessed by the average dealer. There is no reason, however, why teaching birds to acquire linguistic ability should not be turned to more profitable account than it is.

Animals. The heading of this article was "Animal and Bird Dealers," but the treatment, so far, has concerned birds chiefly. There is reason in this. The major part of those who sell pets sell birds only, and those who deal in animals as well find birds the most important part of their business. The general trading conditions which we have recited as applying to birds refer to animals as well.

The trade in wild animals is in few hands, and while the subject might have an academic interest for the reader, it can scarcely concern him practically. There is not room in these islands for many Jamrachs.

But retailers of dogs, cats, rabbits, and other live pets, find the business not so profitable as those whose energies are chiefly occupied with

birds. Buyers are, as a rule, more critical. The breeding of dogs is often extremely profitable, and is not attended with much expense. A business which naturally springs out of the handling of animals is that of conducting an animal hospital. There are a few of these throughout the country, and, judging by appearances, nearly all are lucrative concerns. The wealthy who travel, or who migrate to the hills or the seaside annually, and who do not wish to take their pets with them, do not object to pay a good price to have these tended during their absence. The services of a man professing to make this a business are often more acceptable than those of an obliging friend who seeks no fee for acting as temporary custodian of the animals.

ART DEALERS

The trade of art dealing is, under certain circumstances, one of the most lucrative that can be followed, though in some respects there is none so precarious. With the necessary knowledge, taste, and, what is even more important, capital, the profits that can be made far surpass those made in the average business, but without all these qualifications it is practically impossible for one to succeed as an art dealer. Granted that a man has the capital, he, to be successful, must possess that inborn sense of *flair* which will enable him to differentiate between the genuine and the bogus. This cannot be learnt; it must be born in a man. And if he does not possess it, it is useless for him to contemplate becoming an art dealer.

As an instance, a certain well-known dealer has had with him for four or five years as his right-hand man one who will never be competent as a dealer. Though in close touch with hundreds of objects daily, he knows really little more than when he entered the business. In fact, he lacks the required *flair*, or instinct. This same dealer, too, has a porter who, through merely handling the objects when dusting or packing them, can tell at a glance a piece of Worcester, Sèvres, or Nankin porcelain, although he has been in the business only a year or two. Though practically an uneducated man, he has this instinct, and had he the necessary capital, would undoubtedly prove a successful dealer.

The Knowledge Necessary. The acquisition of a knowledge of the peculiarities of the different objects that may pass through his hands is the first thing that the prospective dealer has to seek. Whether he intends to become a picture dealer, printseller, or a dealer in china and furniture, the routine is the same. He may learn from books particulars regarding the lives of artists and engravers, information as to the periods of the leading craftsmen of past times, and particulars as to the foundation and distinguishing marks of the various china factories, all useful and necessary information in his business. But no amount of reading will explain to him the peculiarities of the different schools of painting, or the difference in the paste or glaze of the porcelain of one factory from that of another. This information can be obtained only by actual examination of the objects, and there is no better school than the museum. In the National Gallery, for instance, one can find pictures out of number, all of undoubted authenticity, and splendid examples of each master's work. And in the South Kensington Museum or the Wallace Collection will be found specimens of every kind of furniture, china, or art object in which a dealer is likely to trade.

Experience and foresight are two necessary qualities. The former can only be gained by time, and the latter by watching the public taste. It is necessary not only to know what the public want, but one must also learn to know what the public will want ten years hence. A remarkable instance of the lack of this last quality can be given. When the Pre-Raphaelite movement was in its infancy, perhaps the most famous firm of art dealers in the world would have nothing to do with its productions. In fact, they ignored the artists and discouraged all intending purchasers. Time has proved how wrong their estimation was.

The Auction-room as a School. Besides the galleries, a splendid school is Messrs. Christie, Manson & Woods' famous rooms in King Street, St. James's, London. There, during a season, hundreds of pictures, engravings, and art objects of every class and quality come up for sale, and by constant attendance one may learn what class of works are in demand and which are in disfavour. The prices obtained at these rooms, however, must not be too carefully noted, for many things have to be taken into consideration. If the object sold comes from a collection of repute, it is practically certain to fetch a good figure, merely owing to the prestige of its owner; whilst a similar object, sold with little or no pedigree, may not fetch more than a tithe of the sum

Having gained the necessary knowledge, especially where pictures are concerned, the dealer must have the courage of his convictions. If his judgment tells him a certain artist's work is really good, he must not be affected by outside influences. The majority of his rivals are like sheep following each other's lead, and have little ability to recognise real talent. This foresight is really the faculty of applying experience to present circumstances, or in other words, discerning qualities which are bound to make the picture a saleable object. In pictures there should be something besides sentiment. There should be a strength, a force in the design which displays the handiwork of a capable artist. Other points must be noted by the dealer, which are that each work purchased is by the artist assigned to it, that it is not an early and unimportant canvas touched up to give it an increased value. Pedigree plays a large part in the value of a picture, and one should be ever wary of acquiring a picture of which the past history is at all doubtful.

Engravings. As regards engravings, Christie's sales are a splendid opportunity for one to come into touch with the work of the leading English and Continental engravers. For real study, however, the Print Room at the British

Museum cannot be surpassed. There can be found engravings of every period and every state. State is everything in a print, and unless one can distinguish one state from another, it is impossible ever to attempt to deal in prints. Engravings, more especially of the eighteenth-century English School, form a splendid example of the flights of Fashion. There is no possible reason why such prints should realise the huge sums which are given for them at present, for they are not unique, like a fine picture. Let some other copies of one of them come to light, and its rarity is gone, and the dealer is left with a print for which he can never hope to get the money paid. At present certain schools of engravings are altogether ignored, though the work is undoubtedly superior to that done by the later men; but even if a man has scores of these prints in his shop, he may not be able to sell them, although it is an absolute certainty that they will one day regain their lost favour and return him ample interest on his money.

Art Furniture and China. To deal in furniture, china, and objects of art generally, requires perhaps as much knowledge as any branch of dealing, besides much taste and decorative instinct. Every year fashion changes, and what may be in demand one season may be unsaleable the next, and this has to be guarded against. Really good furniture by the leading masters of the craft will never depreciate. But there are certain styles which, with the taste of the moment, rise enormously in value, and then as suddenly decline.

At the South Kensington Museum and the Wallace Collection magnificent examples of the work of the leading English and foreign masters will be found, and there are no better schools in which to learn. Study each piece and note its peculiarities. Notice the workmanship, the material, and finish. In this way only can the requisite knowledge be obtained; and in time the earnest student will find himself unconsciously becoming familiar with the distinguishing features of each maker and period. Many items at the South Kensington Museum are priced, but these prices should be ignored, as they are no guide to valuation, for frequently their value since the price was affixed has, through change of fashion, largely increased or decreased. In the space of ten years a certain class of furniture may jump into favour, reach enormous prices, and just as suddenly fall into disfavour, simply owing to fashion. It is this changeableness that forms one of the pitfalls of the dealer. To be successful one must keep in touch with the market. Buy that for which you know there is a permanent demand, and leave severely alone anything that is likely to have but a fleeting popularity.

The same remarks apply to the dealer in porcelain and pottery. Study the different factories at the museums. Commence with the English, then continue with the Continental, and conclude with the Oriental factories. The first is the most desirable. It is the easiest to learn, and lacks many of the complications that will be found in the other branches. All china, both English and foreign, is imitated, and only by long practice can the beginner learn to tell the real from the fake. Many English factories reproduce vases and figures in exact facsimile with those issued by the same factory a hundred years before, and though many dealers stock these reproductions, they should be bought and sold on the distinct understanding that they are not original pieces. A splendid school in which to learn the value of English china, furniture, and bric-à-brac are the rooms of such firms as Messrs. Puttick & Simpson, Messrs. Sotheby, Wilkinson & Hodge, and Messrs. Glendining, in London. At these rooms one will find on occasion choice little representative collections realising prices more in accordance with their market value.

Old Silver-plate. The demand for old silver-plate has of recent years made it a most profitable branch of art dealing. But here, too, one needs to be thoroughly in touch with the principal makers of each country and period, their distinguishing features, besides learning all the mysteries of hall-marks and date letters. These latter can be learnt from books, but no amount of reading can teach a man the difference between the silver of Tudor and Stuart periods, or the characteristics of the work of the early silversmiths. This subject, too, can be studied at museums. In fact, the museum should be the home of the prospective dealer. Practically everything he requires can be found at the South Kensington and British Museums.

Personal Relics. Relics of famous people in history are largely dealt in, but no objects are so liable to fluctuation. Personal relics with authentic pedigrees will realise any sum, but only experience will teach the sum to which one should go when acquiring them. Present circumstances are the great factor in affecting their value. The Nelson Centenary, for instance, simply flooded the market with relics both of intimate and slight connection with the famous admiral, and remarkable prices were paid for certain objects. Eventually, however, the market got overstocked, and a slump is practically inevitable. Relics should not only be considered from the point of view of relics, but they should also be viewed from an artistic point of view. A bust of Nelson, for instance, may realise a good price because it is a memento of a great man, or because it is a fine example of the art of sculpture. It is this broad view that the dealer should endeavour to acquire.

In conclusion it cannot be too firmly impressed that art dealing needs much perseverance and patience. It is not like an ordinary trade, where in a few months the whole stock has been sold and replaced. Many things a dealer may buy may remain in his shop for years, and it is this fact which makes capital so indispensable. One must be able to sink a large sum without any absolute certainty as to when it will be returned. Some things are, of course, bought and sold within twenty-four hours, but against such instances there may be a score of objects

purchased for which no immediate buyer can be found.

Imitation Antiques. In no trade, unfortunately, is there so much dishonesty as in that connected with art objects and their sale, and at the very commencement of his career the prospective art dealer is faced with a difficult problem which he is compelled to solve. Does he intend to sell genuine objects only or does he intend to include in his stock items of a doubtful authenticity, and trust to his being able to sell them to gullible collectors as the real thing? There are those who say that art dealing and honesty cannot go together. But this is not true; there are plenty of dealers upon whose integrity one can place absolute reliance. If when starting business you sternly set your face against the fake, and refuse to have anything of the sort in your shop, it is bound to pay you in the end. Though you may by a trifling mis-statement make a few pounds, you may feel almost sure that if your customer discovers that he has been cheated he will never deal with you again; whilst once you get a name for straight and honest dealing you will have little difficulty in getting together a clientèle of a permanent character.

Of the text-books that are almost indispensable the following can be procured with the knowledge that they are reliable:

Bryan's "Dictionary of Artists and Engravers," Whitman's "The Print Collectors' Handbook," Chaeffer's "Marks on Old China," Cripps' "Old Silver-plate," Macquoid's "History of English Furniture," the books of Chippendale, Sheraton, and other masters.

In fact, as regards handbooks there is no end, though the average cheap little text-book so frequently published at present is by no means always reliable.

But no opportunity must be missed of increasing the reference library, and as new editions and new books appear they should, if one wishes to keep in touch with art, undoubtedly be acquired.

ARTISTS' MATERIAL DEALERS

The retailing of artists' materials is a trade which can scarcely stand alone. It is not sufficiently large, and is usually added to some other shopkeeping business—such as that of a stationer and print-seller, a painter and paperhanger, an ironmonger, and we even remember to have seen a chemist who handled artists' colours as a side line.

Time was when technical knowledge of colour grinding and mixing was essential to the successful dealer in artists' materials. These were the days before the collapsible tube had usurped the place of the hog's bladder as the receptacle of mixed paints. Now the manufacturers or wholesale merchants supply everything packed in convenient retail packages, and the retailer need have no special technical acquaintance with the wares he handles.

Ease of Entering the Trade. The trade is one in which little bad stock accumulates. There is therefore little loss on this score. Anyone thinking of embarking on the sale of artists' materials has only to put himself into communication with one of the large wholesale houses and he will be supplied with everything he wants. He need not open more than one account.

The amount required to add an artists' materials department to any business may vary from £20 to £100. Not more than the latter sum should be expended until a firm connection has been established. The keeping of stock would be attended with greater difficulty were it not that here also the manufacturer comes to the help of the retailer and provides him with a cabinet specially fitted for the stocking of the many oddments which artists require. The accompanying illustration shows one of these stock cases. This particular one is by Messrs. Winsor and Newton, London, but all other good houses supply stock cases.

The case illustrated is for the cautious man who is content to spend £25 on a stock of artists' materials. The cost is £18, with the glazed top compartment fitted with a representative assortment of the necessary sundries. The size of the case is 41 in. long, 30 in. wide, and 55 in. high at the back. The gross retail value of the articles which it contains is about £18, so that the man who has sold the contents with which he started, or their equivalent, has earned the case.

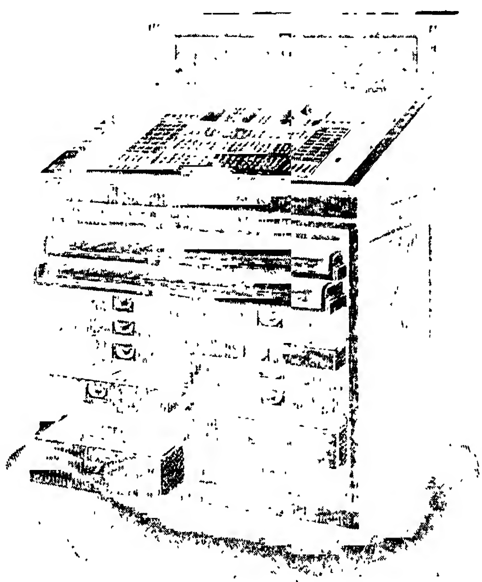
Nature of Stock. The stock contained in such a case when purchased comprises a good assortment of cake, moist, and oil colours, water-colours, liquids, oils and varnishes, pencils, chalks, and crayons, and brushes for oil and water painting. Besides these things the retailer must purchase canvases, easels, drawing-boards, T and set squares, paper blocks, and sketch-books. The £7 left after spending £18 out of the allotted £25 upon the fitted case will furnish a sufficient assortment of all these. Then the would-be artists' colourman is ready to inform brush wielders in his neighbourhood that he is ready for their assault.

Profits. The profits carried by goods such as we are discussing is in the region of 33⅓ per cent. on retail price, or 50 per cent. on cost price. That is to say, that the 1s. article costs 8s. per dozen, and things at other prices proportionate to this profit. To some traders in other branches of shopkeeping the profits may seem high, but they are not more than remunerative. The dealer in artists' materials may turn over the worth of his stock only once a year. The man who enters the trade thinking to make a connection for himself by giving part of his fourpence in the shilling to the public makes a great mistake. He will find that the trade is far too slow to make cutting tactics profitable. It is far more necessary to give the goods wanted exact to requirements than it is to sell 5 per cent. cheaper. In other words, quality is far more important than price. But, however much he may try to maintain catalogue prices, he will find it impossible in every case. The casual customer may be made

to pay them, but professional artists have succeeded in instituting the practice of discount allowances, varying with the nature and price of the articles, ranging up to 25 per cent. Thus, when requested, the dealer must allow these artists discounts.

The terms of payment usual in the artists' material trade depend upon the district. Accounts are usually journey accounts collected by the commercial travellers. This means three, four, or six months, according to the frequency of the travellers' visits to the town where the retailer resides. Some districts will not stand more than semi-annual journeys.

A Department Worth Pushing. The selling of artists' colours proper is a trade where enterprise cannot carry a man to the high success possible of achievement in many other branches of shopkeeping. The consumption of such goods in any district is strictly limited, and no amount of advertising or other methods of self-assertion on the part of the retailer will appreciably augment the volume of trade of the district. But one branch of the business which can be extended is that of supplying artists' materials for students and children. A wave of desire for culture in the several grooves of art is at present inundating our country, and, indeed, the world, as never before, and is a field prepared for the artists' colourman.



STOCK CASE FOR ARTISTS' MATERIALS

Students' colours, as they are called, are not of the quality necessary for the work of experienced artists. The student's efforts are not intended to be permanent. Indeed, as he attains experience and ability he frequently finds the records of his early clumsiness far too permanent to be agreeable. Thus, students colour-boxes are inexpensive. They are more profitable than regular goods, and 40 per cent., and sometimes even 50 per cent., of the retail price is profit. Formerly, manufacturers of the first rank held aloof from this department, believing that their reputation as makers of high qualities would suffer if they descended to the qualities necessary for cheap colours. But wiser counsels now prevail, and the best firms in the trade no longer hesitate to attach their names to materials for the use of the student and schoolboy artist.

Other Possible Departments. Students have need of copies from which to work and the dealers find this a profitable department. A drawing copy, costing sixpence, or sometimes only half that amount, may be hired at a penny a week, and if the hirer forgets to return it for a few weeks, the price paid for its use may represent the price of the article. For coloured reproductions let out as copies the price i higher, usually threepence a week for good copies, and their cost seldom exceeds a half-crown. The hire of copies is a department which ought to be encouraged. Payment is in pence, but pence mak pounds.

Many colourmen share in the present enormous trade in picture postcards, which yield from 50 to 150 per cent. profit. The department yields some soiled stock, which, however, can usually be cleared. In any event, the profits can stand some loss of this nature.

The department of art dealing — that is, in pictures and prints—falls naturally to the share of the artists' colourman. It h s been treated in the article immediately preceding this one.

Tools and material for clay and wax modelling, for poker-work, for fret-saw work, and designs for amateurs in these arts, are also proper branches for cultivation by the artists' colourman. They require only moderate outlay for stock, and yield about the same rate of profits as pertain to artists' materials.

Stock of a more expensive nature may be attempted in drawing and mathematical instruments. Some localities—as, for instance, those in proximity to a technical school, engineering works, and architects' offices—are specially favourable for such a trade.

Selling on Commission. It frequently happens that the artist customers request the dealer in materials to undertake the sale of their work. Sometimes this is embarrassing; more often it is welcome, as it enables the retailer, without the capital necessary for the purchase of such things, to show them. Customers' work should not be purchased. It may be shown with an understanding of commission in the event of sale. No definite rule can be laid down regarding commissions in such cases. It varies between 10 and 50 per cent., its size usually being in inverse ratio to the prominence of the artist and the quality of the work.

ROCKS AND THEIR CHARACTERISTICS

The Geologist's Equipment. Classification of Rocks. The Two Great Divisions—Igneous or Crystalline, and Sedimentary or Stratified Rocks

By W. E. GARRETT FISHER

WE made acquaintance in the last chapter with the chief minerals of which the rocks of the earth's crust are composed. We have now to study those rocks themselves. They are divided into three main classes: *igneous* rocks, *sedimentary* rocks, and *metamorphic* rocks.

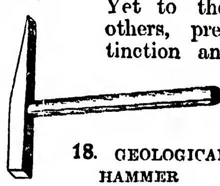
What is a Rock? In the first place, the student must disabuse his mind of the ideas commonly attached to the word *rock*. Ordinary language associates the idea of hardness with a rock. Geology takes no account of such a qualification. If the student looks back to the definition of a rock given in the last chapter he will see that it applies to all the types of matter which are to be found naturally existing in the crust of the earth. The bed of pebbles left on the convex side of a river bend, the great masses of loose sand which compose the sea-beach or the desert of the Sahara, the lumps of coal in the domestic scuttle, the clay and loam in our garden beds, the stone flags of the street pavements, the precipitous granite cliffs of Cornwall and the chalky heights of Beachy Head, are all equally rocks in the geological sense of the word. There is not even any scientific distinction between a *mineral* and a *rock*. Calcium carbonate is a mineral if we consider a single crystal of Iceland spar, a rock if we go to Carrara and look at the gigantic masses of marble of which the hills are there composed. Salt is a mineral in our salt-cellars, a rock when we think of the great beds of rock-salt which underlie parts of Cheshire. But, as a rule, a rock is composed of more than one mineral, and the study of mineralogy is thus a necessary preliminary to that wider branch of geology which deals with the rocks of which the earth's crust is variously built up.

19. PETERHEAD GRANITE, POLISHED

How Rocks are Studied. Rocks differ so widely in character that at first sight it might seem hopeless to devise any method of *classification* which should include them all under any moderate number of heads. The beginner sees little in common between sea-sand and a piece of flint, the columnar basalts of Staffa and the clay of a newly ploughed field, the tailor's French chalk and the coal in the grate.

17. MICACEOUS SANDSTONE FROM COAL MEASURES, BURNLEY, LANCASHIRE

Yet to the geologist these rocks, like all others, present well-marked points of distinction and similarity, according to which they can be arranged in a very small number of classes. He is guided by various considerations. First comes the *structure* of a rock under examination, as visible to the naked eye (*macroscopic*), or to the eye aided by lenses (*microscopic*). Then the *chemical composition* has to be investigated. Lastly comes the manner in which the *rock-masses* are arranged in Nature. All these ways of looking at rocks afford a clue to their classification, and throw light upon the history of the earth.



18. GEOLOGICAL HAMMER

The Geologist's Tools. The geologist in the field, armed with such tools as he can conveniently carry, aims chiefly at studying the *macroscopic* characters of the rocks with which he meets. These tools include a geological *hammer* [18], with its head prolonged into a chisel edge at the back, used for chopping off fragments of rocks, and so finding out what their internal appearance is—this often differs considerably from the appearance of the outside, which has been exposed to all atmospheric changes and has weathered into a modified form. To this hammer, the geologist's chief instrument, he adds a *pocket-lens*, a *knife* with a hard steel blade for scratching rocks, a *magnet*, and a vial of dilute *acid*—usually hydrochloric acid or spirits of salt (H Cl). With these instruments

20. BELEMNITES FROM THE LOWER LIAS.
Remains of internal bones of extinct cuttlefish

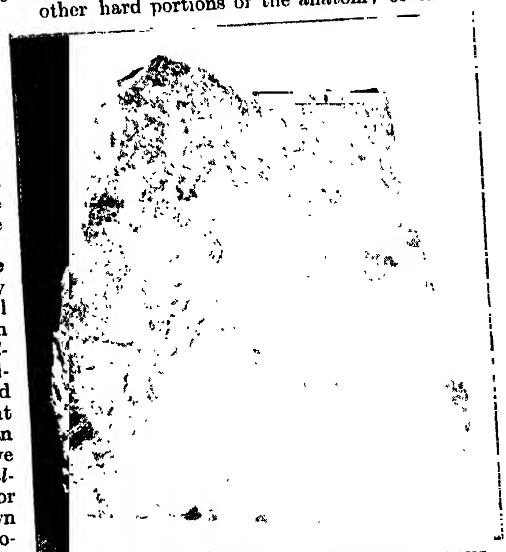
he can generally make a rough guess at the nature of any rock which he is likely to meet, and can collect specimens for the more detailed analysis of the laboratory. In addition, he carries a map of the district which he is examining, on the largest convenient scale—the Ordnance Survey sheets, one inch and six inches to the mile, are the best for this country. With the aid of a pocket *compass* and a *clinometer* [59, page 803], or instrument for measuring slopes, he can orient himself in the field and calculate the *dip*, or angle, at which the beds of rock are inclined to the level surface. We shall see later on how these latter instruments are used; they belong to the wider study of *geotectonics*, or the fashion in which the crust is built up of the rocks which we have first to question of their individual structure.

Classification of Rocks. The *system of classification* which is now universally adopted depends upon a natural distinction between the ways in which the two main classes of rocks came into existence, which has been worked out by the labour of several generations of patient students of the rocks, both in small specimens and in the great masses of Nature. We can but give here the briefest sketch of the conclusions which were thus reached.

Crystalline and Non-crystalline Rocks. If the student has access to any small collection of rock specimens, he will speedily notice one great distinction between them. Some of them show a distinct *crystalline* structure—that is, they consist of well-marked crystals of all sorts and sizes, held together by a more or less abundant cement or paste. Ordinary granite [19] affords an admirable example. Other rocks, again, have no such structure, but consist of *non-crystalline* particles held together by a cement, or packed so closely as to adhere by their own cohesion. Sandstone [17], flint, and conglomerate or pudding-stone afford good instances. Sometimes the crystals of which a rock is composed are so tiny that they can only be recognised by a microscope. But it is generally safe to say that any given specimen of rock is either crystalline or non-crystalline, and this distinction affords us the first possibility of classification.

Stratified and Unstratified Rocks. The second principle of rock classification must be studied in the field. If the student will visit a quarry or railway cutting, where he can see below the normal surface of the ground, he will soon notice a well-marked difference between various kinds of rocks. Some rocks are always arranged in distinct layers or beds parallel to one another—though not necessarily parallel to the surface of the ground—which are known as *strata*. These may be compared to the bricks in the work of a house. These strata [23] may be seen in a chalk pit, or where the railway runs through banks of sandstone, or on the seashore in the face of the cliffs along the greater part of the South Coast. But they will be vainly sought in a granite or marble quarry, or where the sea breaks, as in Cornwall or North-east Scotland, against precipices of living granite. The existence or non-existence of these layers in a rock afford another basis of classification into *stratified* and *unstratified* rocks.

Fossiliferous and Non-Fossiliferous Rocks. The third line on which we may draw our classification is that of the presence or absence of organic relics or *fossils* in a rock. Some rocks, like chalk and coal, are composed almost entirely of such organic remains, though they may, as in chalk, be only visible through a microscope, or, as in coal, be so thoroughly altered that their organic nature is only evident in exceptional cases. It is on the skeletons and bones, shells and teeth [20 and 21], and other hard portions of the anatomy of extinct



21. FOSSIL FISH FROM THE CRETACEOUS ROCKS, MOUNT LEBANON

animals thus preserved in the heart of the rocks that we depend for nearly all our knowledge of the history of life upon the earth. We shall see later how they came there. Just now it is enough to observe that it is only in certain kinds of rock that these fossils are ever found, and so we may make a third distinction between *fossiliferous* and *non-fossiliferous* rocks.

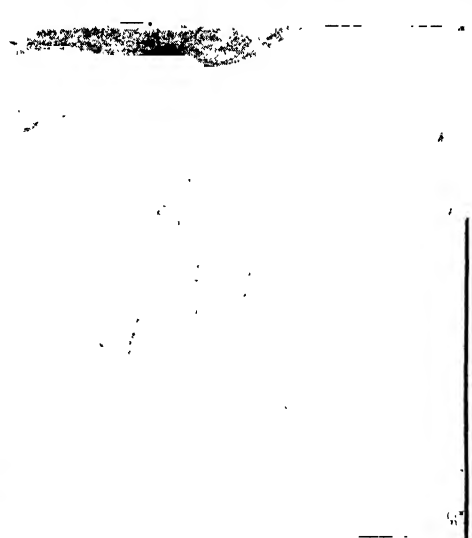
Now, if we study all the rock specimens that we can obtain in the light of these three different principles, a very curious and interesting fact emerges from obscurity. The three methods of classification all lead to the same result. With certain exceptions, which have led to the establishment of a third intermediate class, we find that a rock which is crystalline is also unstratified, and contains no fossils or relics of organic life. A stratified rock is almost always non-crystalline, though there are exceptions to this rule, which we shall encounter later, and we may expect to find organic remains in it, though it must be understood that by no means all stratified rocks are fossiliferous. Lastly, if we find a tiny specimen of rock which contains a fossil, we may predict almost with certainty that the rock from which it came is non-crystalline in structure, and arranged in layers or strata.

Thus, we have now arrived at two great main classes into which rocks may be divided:

1. Crystalline, unstratified, non-fossiliferous.
2. Non-crystalline, stratified, fossiliferous.

Igneous Rocks. The names usually given to these families are derived from a consideration of the manner in which they were formed. This is not difficult, even for the beginner, to perceive. We know, from physical science [see course on PHYSICS] that crystals are formed when a body which has been molten or dissolved solidifies. Consequently, we say at once that the first class, or crystalline rocks, must once have been molten, since the only possible solvent (water) has little or no action upon them. These rocks, in fact, are all the product of something akin to what we now know in a degenerate form as volcanic action; they must have been poured forth from the earth's interior in a liquid form, and have solidified in the place where we now find them. This also explains why they are not arranged in strata, any more than pig-iron or the slag of the blast-furnace, and why they contain no relics of organic life. These rocks, then, are usually called *igneous*, as having their origin in fire, or *eruptive*. We shall use the former term.

Sedimentary Rocks. The stratified rocks must have been produced in a different fashion. We can see how it was if we take a slab of sandstone, with its distinct beds or layers, and compare it with the sand of the seashore. The only way in which sand can be arranged in regular strata is by the action of water. The winds and tides churn it up till it floats for a while, then it gradually settles down and is deposited as a layer or stratum on the ocean bed. Another layer is deposited on that, and then another, till the first layers have sunk so far that the pressure of the sand and the ocean above consolidates them into a soft kind of rock. Meantime the living creatures in the sea have been dying and sinking down into the soft sand, where their perishable part decays and the hard part is left, to reappear as a fossil in the sandstone of a future age. Wherever there is a piece of water that is sometimes comparatively quiet this action must go on. When the water is disturbed, it sweeps up particles of sand or clay or earth; when it is quieter, they are dropped as a layer of practically equal thickness all over the bed. The sea, with its winds and tides; lakes, with their periodical storms; rivers, which run faster and fuller at one season than at another — all contribute to the formation of stratified rocks. And since these rocks all originate from hardened sediments, the name usually chosen to describe them is *sedimentary*.



22. GEOLOGICAL STRATA

Metamorphic Rocks. There is a third class of rocks, which is due to the fact that the original formations have been altered by various agencies. Sedimentary rocks may have been baked or even melted by later heat, like marble, which is merely limestone crystallised in solidifying under pressure. Igneous rocks may have obtained a falsely stratified structure, in conquence of pressure. Thus we find many rocks, of which the Gneisses and Schists are the best examples, and which seem to form a class intermediate between the other two. These are called *metamorphic* rocks, since they have been *metamorphosed* or changed from their original nature.

The igneous rocks are the oldest. The sedimentary rocks were formed from them by their gradual attrition to dust by natural processes of weathering, and the new manufacture of this dust into sedimentary rocks by water. Thus, the igneous rocks are also called *primitive*, and the sedimentary and metamorphic rocks *secondary* or *derivative*.

SECTION I. GRAMMAR.

Anomalous Verbs are verbs that do not form all their parts according to rule. The following are the most common:

Possum (*Pote sum*) = I am able; *Volo* = I wish; *Nolo* (*Ne-volo*) = I am unwilling; *Malo* (*Magis-volo*) = I prefer; *Fero* = I bear; *Fio* = I am made, I become (used as the passive of *Facio*, I make); *Eo* = I go; *Queo* and *Nequeo* = I can and I cannot; *Edo* = I eat.

Scheme of Conjugation.

INDICATIVE MOOD.

Present.

	Singular.	*Plural.*
1.	possum	possumus
2.	potes	potestis
3.	potest	possunt
1.	volo	volumus
2.	vis	vultis
3.	vult	volunt
1.	nolo	nolumus
2.	nonvis	nonvultis
3.	nonvult	nolunt
1.	malo	malumus
2.	mavis	mavultis
3.	mavult	malunt
1.	fero	ferimus
2.	fers	fertis
3.	fert	ferunt
1.	fio	—
2.	fis	—
3.	fit	fiunt
1.	eo	imus
2.	is	itis
3.	it	eunt

Future Simple.

Pot- ..	ero	eris	erit	erimus	eritis	erunt
Vol-, Nol-, Mal-, Fer-, Fi-	am	es	et	emus	etis	ent
I- ..	bo	bis	bit	bimus	bitis	bunt

Imperfect.

Pot- ..	eram	eras	erat	eramus	eratis	erant
Vole-, Nole-, Male-, Fere-, Fie-, I-	bam	bas	bat	bamus	batis	bant

Perfect, Future Perfect, and Pluperfect.

Potu-, Volu-, Nolu-, Malu-, Tul-, —— Iv-

1.	i	isti	it	imus	istis	erunt *or* ērĕ
2.	ero	eris	erit	erimus	eritis	erunt
3.	eram	eras	erat	eramus	eratis	erant

SUBJUNCTIVE MOOD.

Present.

Poss-, Vel-, Nol-, Mal-	im	is	it	imus	itis	int
Fer-, Fi-, E-	am	as	at	amus	atis	ant

Imperfect.

Poss-, Vell-, Noll-, Mall-, Ferr-, Fier-, Ir-	em	es	et	emus	etis	ent

Perfect and Pluperfect.

Potu-, Volu-, Nolu-, Malu-, Tul-, —— Iv-

1.	erim	eris	erit	erimus	eritis	erint
2.	issem	isses	isset	issemus	issetis	issent

IMPERATIVE MOOD.

Possum, Volo, Malo, have none.

Present.		*Future.*		
2nd Sing.	*2nd Pl.*	*2nd Sing.*	*2nd Pl.*	*3rd Pl.*
noli	nolite	nolito	nolitote	nolunto
fer	ferte	ferto	fertote	ferunto
fi	fite	—	—	—
i	ite	ito	itote	eunto

INFINITIVE MOOD.

Present.	*Pres. ptc.*	*Supines.*
posse	potens (used as adj. = powerful)	—
velle	volens	—
nolle	nolens	—
malle	—	—
ferre	ferens	latum, latu
fieri	—	—
ire	iens (*genitive* euntis)	itum, itu

Perfect Participle Passive.

Fio and *Fero* have perf. ptc. pass. *factus* and *latus*. *Factus* is used with *sum*, etc., to form the perfect tenses of *Fio*.

Feror (passive of fero) has pres. indic.: 2. ferris. 3. fertur.

Queo and *Nequeo*: Conjugated like *Eo*.

Edo (I eat) often changes some of its forms:

Ind. Pres. 2nd Pers. Sing.	*Ind. Pres.* 3rd Pers. Sing.
edis or es	edit or est

Infin.
edere or esse

Deponent Verbs. These are chiefly passive in form, but active in meaning—*e.g.*, *venor, venari* = to hunt; *utor, uti* = to use. They are found in each of the four conjugations. They are conjugated like the passive voice of a verb of the same conjugation: thus, *Venor* (like *amor*), *venari, venatus sum.* In the infinitive, however, they combine active and passive forms—*e.g.*, *Utor*:

Pres. infin.	uti, *to use*
Perf. infin.	usus esse
Fut. infin.	usurus esse
Supines.	usum, usu
Pres. ptc.	utens, *using*
Perf. ptc.	usus, *having used.*
Fut. ptc.	usurus
Gerunds.	utendum, -i, -o
Gerundive.	utendus

The fact of their having a perfect participle with an active meaning makes them very useful for translating the English "having used," "having hunted," etc. Thus, for "having spoken thus, the queen died," if we use the deponent *loquor, loqui, locutus* for "to speak," we can say *Ita locuta, regina mortua est.*" But if we used "*dico*" for "to speak," we could not use "*dictus*," which means "having been spoken." We should then have to say either (1) *his dictis* (these things having been spoken, abl. abs.) regina mortua est; or (2) *quum ita dixisset*, regina mortua est.

Semi-deponent Verbs. A few verbs have an active present, and a perfect of passive form; these are called "semi-, or half-deponents":

Audeo, *I dare*	*Perf.* ausus sum, *I dared*
Fido, *I trust*	,, fisus sum, *I trusted*
Gaudeo, *I rejoice*	,, gavisus sum, *I rejoiced*
Soleo, *I am wont*	,, solitus sum, *I was wont*

Section II. SYNTAX.

The Dative Case. 1. The dative is often used after the gerundive ptc. in —*dus* (and sometimes after other passive participles) where we should expect the ablative of the agent with the prep. *ab*—*e.g.*, *Hoc mihi faciendum est* = this is to be done (must be done) by me.

2. Predicative dative: that which a thing or person serves as, or occasions; much used with *sum, do, duco*, and (especially with military terms, *auxilio, praesidio, subsidio*) with verbs of motion—*e.g.*:

Quinque cohortes castris *praesidio* reliquit.
He left five cohorts as a guard to the camp.
Quae res *saluti nobis fuit.*
Which thing was for a safety to us—*i.e.*, saved us.
Ipse sibi *odio* erit.
He will be an object of hatred to himself; *lit.*, he will be for a hatred.
Impedimento esse = to be a hindrance.
Detrimento esse = to be hurtful, etc.

3. The dative is sometimes used where we should use a possessive pronoun or the genitive, to give greater emphasis to the person mentioned: *Tum Pompeio ad pedes se projecerunt* = then they threw themselves at Pompey's feet.

4. The dative is used after several verbs: With *sum* it denotes possession—sunt nobis mitia poma = we have mellow apples. All the compounds of *sum* (except *possum*) take a dative.

Verbs signifying to Aid, Favour, Obey, Please, Profit, Injure, Oppose, Displease, Command, Persuade, Trust, Spare, Envy, Be angry, etc., take the dative, because they are really intransitive—*e.g.*, *Parce pio generi* = spare a pious race, *lit.*, "be sparing to."

[Although *Impero* (I command) takes a dative, *Jubeo* (I order) takes the acc.]

These verbs that take a dative cannot be used personally in the passive, but only impersonally—*e.g.*, *mihi persuasum est* = I have been persuaded, *lit.*, it has been persuaded to me.

A few impersonal verbs take a dative: *libet* (it pleases), *licet* (it is lawful), *accidit* (it happens), etc.—*e.g.* *libet mihi* = I am pleased; *lit.*, it is pleasing to me.

The Genitive Case. This denotes:
1. Possession: this is the simplest and most natural use of the genitive—*Cæsaris uxor* = Cæsar's wife.

The gen. sing. of a substantive is often used as a predicate with a copulative verb, to denote such English ideas as Nature, Token, Function, Duty, Part, Mark, etc.—*e.g.*, *Sapientis est tempori cedere* = it is (the mark) of a wise man to yield to circumstances. *Cujusvis* (gen. of *quivis*) *hominis est errare* = any man may err, it is (of the nature) of any man to err.

2. The relation of whole to part: Partitive Genitive—*e.g.*, *multi vestrum* = many of you. *Fortissimus Græcorum* = the bravest of the Greeks. *Duo horum* = two of these. Often used after the neut. sing. of adjectives and pronouns expressing quantity or degree, and with *nihil* (nothing), *satis* (enough), *parum* (too little)—*e.g.*, *parum prudentiae* = too little prudence. *Aliquid pulchri* (something beautiful); *quid novi*? (what news?).

Also used after some adverbs, *quo, eo, tum, ubi*, etc.—*e.g.*, *ubi gentium* = where in the world? *lit.*, where of nations?; *eo miserarium* = to such a pitch of misery; and even *ad id temporis*, to that point of time.

Note. (*a*) The whole of the city = *tota urbs* (not *totum urbis*); all of us = *nos omnes*—*i.e.*, we all. For in these instances we are not dealing with a part.

(*b*) It is equally good Latin to say "*viginti e suis servis misit*" as to say "*viginti servorum misit.*"

3. Quality or Definition. This is very like the ablative of quality, and the substantive

in the genitive is *always* accompanied by an adjective: *homo infimi generis* = a man of the lowest race; *vir summae fortitudinis* = a man of the highest courage; *puer sedecim annorum*, = a boy of sixteen years.

4. Price. Used especially with verbs of Valuing and Esteeming; confined to *pluris*, *minoris*, *tanti*, *quanti* (and their compounds), *magni*, *maximi*, *parvi*, *minimi* (probably through confusion with the old locative, which was the case used in expressions of value)—*e.g.*, *Parvi sunt foris arma, nisi est consilium domi* = of little value are arms abroad, unless there is a policy at home. [An old form *nihili* is used in this connection.]

5. The genitive is used after verbs and adjectives signifying power and impotence, innocence, condemnation, acquittal, memory and forgetfulness, and compassion—*e.g.*, *Parricidii eum incusat* = he taxes him with parricide. *Alii reminiscentes veteris famae, aetatis miserabantur* = others remembering their former renown, pitied their age. *Capitis* (or *Capite*) *damnatus est* = he was condemned to death.

[For the genitive of the object exciting mental emotion after certain Impersonal Verbs, see next lesson.]

Subjective Genitive and Objective Genitive. Such a phrase as "the love of God," is capable of two meanings. (1) God's love for us, in which case "of God" is subjective genitive; (2) Our love for God, when "God" is objective genitive. In other words, if the genitive represents the subject of a verb it is subjective; if it represents the object, it is objective. Both of these genitives may be combined in a single phrase: *Helvetiorum injuriae populi Romani* = the wrongs done by the Helvetii (subjective) to the Roman people (objective).

Sentences to be turned into Latin.

[There are no actual words for Yes and No in Latin. An affirmative answer is expressed by *etiam*, *ita*, *factum*, *vero*, *verum*, *sane*, *ita vero*, *ita est*, *sane quidem*, etc., or by the proper pronoun, as *ego vero*; or by the verb repeated in the proper person—*e.g.*, *sentio*. A negative answer is expressed by *non minime*, *minime vero*; or with the pronoun, *minime ego quidem*; or with the verb, *non sentio*. When the contrary is asserted by way of reply, we have *immo*, *immo vero*, "No, on the other hand," "Nay rather."]

1. Do you think (begin the question with Num) God to be like me (genitive, after *similis*), or you? Certainly you do not think so. What then? Am I to call the sun or the moon or the sky God? No, assuredly not.

2. Why do you not enjoy what you have bought (say "the bought things," perf. ptc. pass. of *emo*)? Because I have bought them very dear.

3. I was persuaded to remain ten days at Cicero's house.

4. What is harder than a rock? What is softer than a wave?

5. He had come to such a pitch of boldness that (*ut*) he was unwilling to obey the general.

6. Always in a State those who have no wealth (say, those to whom there are no resources) envy the good (citizens).

7. In (*apud*) Vergil we read about the taking of Troy.

Key to above Sentences.

1. Num tu mei similem putas esse aut tui deum? Profecto non putas. Quid ergo? Solem dicam aut lunam aut cœlum deum? Minime vero.

2. Cur non emptis (*abl. after* fruor), frueris? Quod (or quia), maximi (or maximo), emi.

3. Mihi persuasum est ut decem dies apud Ciceronem manerem.

4. Quid est durius saxo, quid mollius unda?

5. Eo audaciæ venerat ut imperatori parere nollet.

6. Semper in civitate, quibus opes nullæ sunt, bonis invident.

7. Apud Vergilium de capta Troja legimus.

Section III. TRANSLATION.

Put into English:

Si linguis hominum loquar et angelorum, caritatem autem non habeam, factus sum aes resonans aut cymbalum tinniens. Et si habeam prophetiam et noverim mysteria omnia, omnemque cognitionem, et si habeam totam fidem, adeo ut montes transferam, caritatem autem non habeam, nihil sum. Et si insumam *alendis egenis*[a] omnia quæ mihi suppetunt, et si tradam corpus meum ut comburar, caritatem autem non habeam, hoc nihil mihi *prodest*[b]. Caritas iram cohibet, benigna est caritas, non invidet caritas, non agit perperam, non inflatur: non agit indecore, non quærit quæ sua sunt, non exacerbatur, non cogitat malum. Non gaudet injustitia, gratulatur autem veritati; omnia tegit, omnia credit, omnia sperat, omnia sustinet: caritas nunquam excidit: sed et prophetiæ evanescent, et linguæ cessabunt, et cognitio evanescet. Ex parte enim cognoscimus, et ex parte prophetamus. Postquam autem advenerit quod perfectum est, tunc quod est aliquatenus, *ut*[c] inutile, tolletur. Quum essem infans, ut infans loquebar, ut infans sapiebam, ut infans ratiocinabar: postquam autem factus sum vir, ut inutilia *sustuli*[d] quæ infantis erant. Cernimus enim nunc per speculum et per ænigma, tunc autem coram cernemus: nunc novi aliquatenus, tunc vero amplius cognoscam, prout amplius edoctus fuero. Nunc vero manet fides, spes, caritas, tria hæc: maxima autem harum caritas.

NOTES. (*a*) dative of gerundive = for feeding the needy.

(*b*) from *prosum*, *prodesse*, *profui*.

(*c*) *Ut* with indic., or used without a verb, means "as."

(*d*) perfect of *tollo* (borrowed from *suffero*).

[For English of the above, see 1 Cor. xiii.]

VERBS—continued.

COMPLETE CONJUGATION OF THE VERB "TO SEE."

Active Voice.—Infinitive Mood.

Present Indefinite : (To) see
Present Incomplete : (To) be seeing
Perfect : (To) have seen
Continuous Perfect : (To) have been seeing

Participles.

Incomplete : Seeing. *Perfect :* Having seen
Continuous Perfect : Having been seeing

Indicative Mood.

PAST.	PRESENT.	FUTURE.
	Indefinite.	
I saw (*or*, did see)	I see (*or*, do see)	I shall see
	Incomplete.	
I was seeing	I am seeing	I shall be seeing
	Perfect.	
I had seen	I have seen	I shall have seen
	Continuous Perfect.	
I had been seeing	I have been seeing	I shall have been seeing

Imperative Mood.

Singular : See (thou). *Plural :* See (ye)

Subjunctive Mood.

PAST.	PRESENT.
Indefinite.	
I saw	I see
I should see	I may see
I might see	
Incomplete.	
I were seeing	I be seeing
I should be seeing	I may be seeing
I might be seeing	
Perfect.	
I had seen	I have seen
I should have seen	I may have seen
I might have seen	
Continuous Perfect.	
I had been seeing	I have been seeing
I should have been seeing	I may have been seeing
I might have been seeing	

Passive Voice.—Infinitive Mood.

Indefinite.	*Perfect.*
To be seen	To have been seen

Participles.

Indefinite : Being seen.
Perfect : Seen, *or* having been seen.

Indicative Mood.

PAST.	PRESENT.	FUTURE.
	Indefinite.	
I was seen	I am seen	I shall be seen
	Incomplete.	
I was being seen	I am being seen	I shall be being seen
	Perfect.	
I had been seen	I have been seen	I shall have been seen

(No Continuous Perfect in the Passive.)

Imperative Mood.

Singular : Be (thou) seen
Plural : Be (ye) seen

Subjunctive Mood.

PAST.	PRESENT.
Indefinite.	
I were seen	I be seen
I should be seen	I may be seen
I might be seen	
Incomplete.	
I were being seen	I be being seen
I should be being seen	I may be being seen
I might be being seen	
Perfect.	
I had been seen	I have been seen
I should have been seen	I may have been seen
I might have been seen	

The four simple tenses of the Active Voice are now given in full :

Indicative Mood.

PAST INDEFINITE.		PRESENT INDEFINITE.	
I saw	We saw	I see	We see
Thou sawest	You saw	Thou seest	You see
He saw	They saw	He sees	They see

Subjunctive Mood.

PAST INDEFINITE.	PRESENT INDEFINITE.	
(Same as Indicative.)	I see	We see
	Thou see	You see
	He see	They see

The Compound Tenses are conjugated exactly like the corresponding tenses of "be" and "have," except those tenses of the subjunctive containing *may, might,* and *should.* These will be dealt with below.

Impersonal Verbs. In such expressions as "it thunders," "it hails," "it behoves," "it seems," the subject is general and undefined. The *it* does not represent any definite noun as the subject. In "it thunders," for example, there is no particular *it* that is thundering : we simply mean "there is thunder somewhere." These verbs are therefore called *Impersonal,* there being no person expressed or understood as subject. They are always in the third person singular, though, of course, they can be of different tenses—*e.g., it thundered, it will hail.* While *it* is usually employed as the grammatical subject of such verbs, occasionally there is no subject expressed at all : as, *methinks* (= it seems to me), *meseems, maybe* ; also, *if you please,* which strictly means *if it please you, it* being subject and *you* object.

Auxiliary and Notional Verbs. If we compare the sentences "I have lost sixpence" and "I have sixpence," we see a great difference in the two uses of *have.* In the first sentence it has no meaning of its own, but simply "helps" to form the Present Perfect tense of "lose." In the second sentence, it has a meaning of its own, namely, "I possess." In the first case it is an *Auxiliary* (helping) Verb, in the second a *Notional* Verb (sometimes called *Principal*). The same applies to *shall, will, may, do, be—e.g.,* "I shall go to-morrow"

(*auxiliary*), and "You shall (*i.e.*, must) do it" (*notional*). "I will see you before long" (*auxiliary*), and "I will have my own way" (*notional*). "It may be wet to-morrow (*auxiliary*), and "You may (*i.e.*, are permitted to), go" (*notional*). "Do you think so?" (*auxiliary*), and "What will you do?" (*notional*). "I am coming (*auxiliary*), and "I *am* a man" (*notional*).

Defective Verbs. All the abovementioned verbs (except *have* and *be*), when used as auxiliaries, are "deficient" in certain tenses. They have no infinitive and no participles (*e.g.*, we cannot say "to shall" or "shalling"), and, therefore, have no compound tenses. Of course, when used as notional verbs, they are not necessarily defective. Thus, "to will" (meaning "to resolve") has all the compound tenses, "I have willed," etc.

1. DO.

Infinitive Mood.

Indefinite, (To) do; *Incomplete* (or *Imperfect*), (To) be doing; *Complete* (or *Perfect*), (To) have done.

Participles.

Imperfect, doing; *Perfect*, done; *Compound Perfect*, having done.

Indicative Mood.

Past Indefinite.		*Present Indefinite.*	
I did	We did	I do	We do
Thou didst	You did	Thou doest *or* dost	You do
He did	They did	He doeth *or* doth *or* does	They do

When used as a notional verb, *do* is conjugated in full; but when as an auxiliary, only the present and past indefinite are used (*do* and *did*). *Doest* and *doeth* are only used in the notional sense—*e.g.*, "*Doest* thou well to be angry?"

In such phrases as "That will *do*," "How does this *do*?" the *do* is quite a different verb, meaning "to suit, to avail" (from Anglo-Saxon *dugan*). We ought not to use *did* as the past tense of this *do*, though we are constantly using phrases like "I was anxious to see how it *did*."

2. WILL.

Indicative Mood.

Past Indefinite.

I would	We would
Thou wouldst	You would
He would	They would

Present Indefinite.

I will	We will
Thou wilt *or* willest*	You will
He will, willeth*, *or* wills*	They will

Subjunctive Mood.

Past Indefinite, I would, etc. (same as Past Indicative).

(No Present Tense.)

* The forms *willest*, *willeth*, and *wills* are not used when the verb is an auxiliary. When *will* means "to exercise the will," or "to bequeath by will," it has a full conjugation—*e.g.*, "This property *was willed* to me by my uncle," "It is not of him that *willeth*, nor of him that runneth," etc. (Romans).

The past indicative *would* is used as an auxiliary only in reported (or indirect) speech, to take the place of *will* in direct speech—*e.g.*, "He *will* come soon" (*direct*); "He said that he *would* come soon" (*indirect*).

Will is also used to express a customary or frequently repeated action—as: "He *will* play for hours," "When he was young, he *would* spend whole days in the fields and hedgerows."

Won't comes from *wol*, an old form of *will*.

When *will* is an auxiliary verb, it has no infinitive, no imperative, and no participles (consequently, no compound tenses).

3. SHALL.

Indicative Mood.

Past Indefinite.

I should	We should
Thou shouldst	You should
He should	They should

Present Indefinite.

I shall	We shall
Thou shalt	You shall
He shall	They shall

Subjunctive Mood.

Past Indefinite.

I should	We should
Thou shouldest *or* shouldst	You should
He should	*They should*

Present Indefinite.

(None.)

No Infinitive, Imperative, or Participles, whether used as auxiliary or as notional verb.

The past indicative *should* is used as an auxiliary only in reported speech, representing *shall* in direct speech.

Shall comes from Anglo-Saxon *sculan* = to owe, and hence arose the meaning of obligation—as: "He *shall* do it," "You *should* answer when your mother speaks." When *shall* retains this idea of "obligation" it is a notional verb; used as an auxiliary, it loses this force.

Both *shall* and *will* are followed by the infinitive without *to*—as: "He *will* not *come*."

4. MAY.

Indicative Mood.

Past Indefinite.

I might	We might
Thou mightest	You might
He might	They might

Present Indefinite.

I may	We may
Thou mayest *or* mayst	You may
He may	They may

Subjunctive Mood.

(Same as Indicative.)

Might gets the *g* from the Anglo-Saxon form of *may*, which was *maeg* (German, *mögen*).

May has no infinitive, imperative, or participles; and in its indicative mood it is never

auxiliary, but always notional—*e.g.*, "You may go" (*i.e.* "You are permitted to go"). "The fish might be seen rising at any hour almost" (*i.e.*, it was possible to see them). In the subjunctive mood, of course, it can be an auxiliary—*e.g.*, "We eat in order that we may live," "May it be so," "I am come that they might have life."

[There is a totally distinct verb "to may," meaning "to gather may-blossom." This verb is fully conjugated in the active voice, as "O that we two were maying." Being intransitive, it has no passive.]

We have now discussed all the auxiliary verbs, namely, *be*, *have*, *do*, *will*, *shall*, and *may*. The following three verbs, *can*, *must*, and *ought*, are sometimes called auxiliaries: but they do not help to form any tense, mood, or voice of any verb.

5. CAN.

Indicative Mood.

Past Indefinite.

I could	We could
Thou couldest *or* couldst	You could
He could	They could

Present Indefinite.

I can	We can
Thou canst	You can
He can	They can

Subjunctive Mood.

Past Indefinite.	*Present Indefinite.*
(Same as Indicative.)	(None.)

No Infinitive, Imperative, or Participles.

Can is from an old verb *cunnan*, meaning "to know" (German, *können*). "I can read" therefore really means "I know how to read"—*e.g.*, *Lycidas*, "He knew to sing." We have this meaning still preserved in "to con," and in the Scotch "to ken." "Cunning" is the old imperfect participle of this verb, and *couth* the past participle (*cf.* *uncouth*, which means *unknown* and therefore *strange*).

As *can* originally meant "to know," it required no infinitive—*cf.* *Hamlet*, "They *can* well on horseback"; *Lay of the Last Minstrel*, "Other prayer *can* I none." Bacon even has "not to *can*."

The *l* of *could* does not belong to the verb; it was inserted owing to a false analogy with *should* and *would*. It should strictly be spelt *coud*.

Can is always a notional or principal verb—*e.g.*, "I *can* write" (*i.e.*, "I am able to write"); "I would if I *could*" (*i.e.*, "I would if I were able"). To call such sentences examples of the "Potential Mood" is absurd; in the first sentence *can* is a simple indicative, and in the second, *could* is a simple subjunctive.

[*To can*, meaning "to put into a can," is, of course, quite regular.]

6. MUST.

Like *can*, this is always a notional verb. It has no inflexions for tense or person, all the persons of each number of each of the two indicative tenses being alike *must*. It has no subjunctive, infinitive, imperative, or participles.

The old form of the present indicative was: I *mot*, Thou *most*, He *mot*, which shows that the *s* does not strictly belong to the first and third persons singular.

The past indicative *must* is used only in reported speech—*e.g.*, "I *must* go" (direct speech, present tense), "He said that he *must* go" (indirect, past tense, meaning "that he *was* obliged to go").

7. OUGHT.

Ought is the past indefinite tense of *owe*. Thus, in Shakespeare's "King Henry IV." the hostess says, "He said this other day you *ought* (= owed) him a thousand pounds." It is now used as a present, in the sense of moral obligation, as "I *ought* to be a better man."

With both *must* and *ought*, to express a past tense the verb following requires to be in the perfect infinitive, as "I *ought* to *have done* it at the time," "You *must have enjoyed* your trip."

Owe originally meant *to own*, *to possess*, as "This is no mortal business, nor no sound that the earth *owes*" ("Tempest"); "I am not worthy of the wealth I *owe*" ("All's Well"), and the modern adjective *own* is the past participle of this verb ("Give me back my *own* money" means "Give me back the money you possess for me").

Owe, "to be in debt," is quite regular: *I owed*, *I shall owe*, etc.

8. DARE (*to venture*).

The third person singular of the present indicative is properly "he dare," *not* "he dares." The reason is that "I dare" is an old *past* tense, and is not really a present at all—*e.g.*, "Mine unworthiness, that *dare* not offer, etc." ("Tempest"). We now use "I durst" as the past tense of *dare*, followed by the infinitive without *to*, as "He durst not do it." When *dare* is a transitive verb meaning "to challenge," it is perfectly regular (past tense *dared*, as "She dared him to come on").

9. NEED

When *to need* means "to lack, to be in want of," it is perfectly regular. But when it means "to be under the necessity of doing a thing," the third person singular present indicative is often "he *need*," not "he *needs*," as, "He need not go just yet." Contrast this with "He *needs* brains"—*i.e.*, "he lacks brains." Note that *needs* in sentences like "Such things must needs be" is an adverb. In the Authorised Version of the Bible the usual form of the third person singular present indicative is *needeth*.

10. WIT (*to know*).

Indicative Mood.

Past Indefinite.

I wist	We wist
Thou wist	You wist
He wist	They wist

Present Indefinite.

I wot	We wot
Thou wottest *or* wost	You wot
He wotteth *or* wot	They wot

Present Infinitive—To wit.

Present Participle—Witting *or* wotting (*cf.* *unwitting*, Milton *unweeting*).

Examples:

"'Twas I did the thing you wot of" ("Two Gentlemen of Verona").

"My master wotteth not what is with me in the house" (Genesis).

"He that was healed *wist* not who it was" (St. John).

This verb is hardly ever used now, except the infinitive *to wit* in the sense of "namely," "that is to say," representing the Anglo-Saxon gerund *to witanne*.

11. QUOTH.

Quoth is the past tense of *cwethan* (= *to say*—note the infinitive termination *an*). It is used only in this tense, and only in the first and third persons singular. It always comes before its subject, as *quoth he*, and is used parenthetically for "said I," "said he." Examples: "*Quoth* the raven, 'Nevermore'," "'To tame your fierce temper,' *quoth* she" (Browning).

12. ME-THINKS.

This is not "I think," but "it seems to me," the *me* being dative or indirect object, and *thinks* being third person singular present indicative of *thyncan* = *to seem*. The only forms in use are *me-thinks* and *me-thought*. Milton has the form *him thought*—"Him thought, he by the brook of Cherith stood." In "Richard III.," Act iii. Scene 1, some read "Where it *thinks* best unto your royal self."

13. LISTS.

In *me-lists* = *it pleases me*, and *him-listed*, lists is an impersonal verb (*cf.* "when and where *likes* [pleases] me best"—"Paradise Regained"). *List* is also used personally, as "The wind bloweth where it *listeth*," "Whithersoever the *governor listeth*."

14. WORTH.

This verb is used only in the third singular present subjunctive, expressing a wish, as, "Woe *worth* the day" = "May woe befall the day" (*day* being indirect object or dative). It is from the old verb *weorthan* = to become (German, *werden*).

15. HIGHT.

Hight means "was called," "was named." It is from an old verb *hatan*, "to be named" (German, *heissen*)—*e.g.*, "That shallow vassal . . . *hight* Costard" ("Love's Labour Lost").

16. DIGHT.

This is past participle of *dihtan* = to deck, to adorn—*e.g.*:

"With their small feet purple-sandal'd
And their arms with bracelets *dight*."

"Who checks at me, to death is *dight*."
(Marmion.)

EXERCISE.

Explain every *should* and *would* in the following:

She would often say "Would I were a man! I *should* have been, for then I would have shown the world a lesson it would never forget." I would reply that I should not attempt to argue with her lest she should get angry; but I now often think that I should have done so. For perhaps I should have convinced her that it would not have been so easy. Should I, or should I not, I wonder?

FRENCH

Continued from page 752

By Louis A. Barbé, B.A.

THE NOUN.

Gender.

1. In French there are only two genders, masculine and feminine (*le masculin, le féminin.*) The rules for ascertaining the gender of nouns are based on their meaning or on their ending.

GENDER ACCORDING TO MEANING.

1. MASCULINE.

(*a*) Nouns indicating males are masculine: *le soldat*, the soldier; *le marin*, the sailor; *le capitaine*, the captain; *le laboureur*, the husbandman.

Exceptions are: *une connaissance*, an acquaintance; *une dupe*, a dupe; *une personne*, a person; *une victime*, a victim; and some military terms, such as: *une sentinelle*, a sentry; *une recrue*, a recruit, which are feminine.

(*b*) The names of the days of the week, of the months, and of the seasons are masculine. They are:

dimanche, Sunday.	*mercredi*, Wednesday.
lundi, Monday.	*jeudi*, Thursday.
mardi, Tuesday.	*vendredi*, Friday.
samedi, Saturday.	

janvier, January.	*juillet*, July.
février, February.	*août*, August.
mars, March.	*septembre*, September.
avril, April.	*octobre*, October.
mai, May.	*novembre*, November.
juin, June.	*décembre*, December.
printemps, spring.	*automne*, autumn.
été, summer.	*hiver*, winter.

The mid-month is formed by prefixing *mi-*, and in that case the noun becomes feminine: *la mi-janvier, la mi-août*.

(*c*) The names of trees and shrubs are masculine: *le chêne*, the oak; *le hêtre*, the beech; *le pommier*, the apple-tree; *le rosier*, the rose-bush.

Exceptions are: *une aubépine*, a hawthorn; *la bruyère*, heather; *la bourdaine*, the black alder; *une hièble*, a dwarf elder; *la ronce*, the briar; *la vigne*, the vine; *une yeuse*, an evergreen oak, all of which are feminine.

(*d*) The names of metals, minerals, gases, and chemical substances are masculine: *le fer*, iron; *le mercure*, mercury; *l'oxygène*, oxygen; *le nitrate*, nitrate; *l'étain*, zinc; *le manganèse*, manganese; *le jais*, jet.

Exceptions are: *l'argile*, clay; *l'agate*, agate; *la craie*, chalk; *la houille*, sea-coal; *la chaux*, lime.

(*e*) The names of colours are masculine: *le rouge*, red; *le bleu*, blue; *le blanc*, white.

An exception is *la sépia*, sepia—*e.g.*, *un dessin à la sépia*, a sepia drawing.

(*f*) Names of languages are masculine: *le français*, French; *l'anglais*, English.

(*g*) Names of weights and measures (in the decimal system) are masculine: *le mètre*, *le litre*.

Exceptions: Some of the old names that are occasionally used, particularly for the literal translation of English weights and measures, are feminine:

une aune, an ell.	*une livre*, a pound.
une brasse, a fathom.	*une once*, an ounce.
une coudée, a cubit.	*une pinte*, a pint.
une lieue, a league.	*une quarte*, a quart.

(*h*) The points of the compass are masculine:

le nord, north.	*l'est*, east.
le sud, south.	*l'ouest*, west.

(*i*) The names of mountains are masculine, except in some plural forms, as: *les Alpes*, *les Pyrénées*, *les Vosges*, *les Cévennes*, which are feminine.

(*j*) All words belonging to other parts of speech are masculine when used as nouns: *le sublime*, *un sixième* (one-sixth), *le manger et le boire* (eating and drinking), *les mais et les si* (but's and if's).

2. Feminine.

(*a*) Nouns indicating females are feminine: *la mère*, the mother; *la sœur*, the sister.

Exceptions: The following nouns remain masculine even when applied to women:

un amateur, a lover or fancier (of animals, art, etc.).	*un peintre*, a painter. *un philosophe*, a philosopher.
un ange, an angel.	*un possesseur*, a possessor.
un artisan, an artisan.	*un poète*, a poet.
un auteur, an author.	*un professeur*, a professor.
un censeur, a censor.	*un sauveur*, a saviour.
un chef, a chief.	*le successeur*, the successor.
le défenseur, the defender.	*le témoin*, the witness.
un docteur, a doctor.	*un traducteur*, a translator.
l'écrivain, the writer.	*un tyran*, a tyrant.
l'imposteur, the impostor.	
un partisan, a partisan.	

(*b*) Abstract nouns, the names of arts, science, professions, virtues, and vices, are feminine:

la sagesse, wisdom.	*la chimie*, chemistry.
la peinture, painting.	*la charité*, charity.
la poésie, poetry.	*l'avarice*, avarice.

The following, all of which are masculine, are exceptions to this rule:

le courage, courage.	*l'orgueil*, pride.
le dessin, drawing.	*le péché*, sin.
le jeu, gambling.	*le plaisir*, pleasure.
le mensonge, lying.	*le vice*, vice.
le mérite, merit.	*le zèle*, zeal.

Note. The gender of most words included in both the rule and the exceptions can also be determined by their endings.

(*c*) The names of diseases and ailments are feminine: *la toux*, cough; *la fièvre*, fever; *la rougeole*, measles; *la petite vérole*, small-pox; *une migraine*, headache; *la coqueluche*, whooping-cough; *la grippe*, influenza; *la goutte*, gout.

Exceptions are: *le choléra*, cholera; *un rhume*, a cold; *le rhumatisme*, rheumatism; *le typhus*, typhus.

(*d*) The names of fruits are feminine: *la pomme*, the apple; *la cerise*, the cherry; *la prune*, the plum; *la poire*, the pear.

Exceptions are: *un ananas*, a pineapple; *le brugnon*, the nectarine; *un abricot*, an apricot; *un coing*, a quince; *un citron*, a lemon; *des cassis*, black-currants; *un raisin*, a grape, all these being masculine.

(*e*) The names of festivals and saints' days are feminine, even when the saint's name is masculine: *La Toussaint*, All Saints' Day; *La Saint-Michel*, Michaelmas.

An exception is *le Noël*, Christmas.

Gender according to Termination.

1. Masculine.

(*a*) Nouns ending in *b*, *c*, *d*, *g*, *l*, *p*, *q*, or *z* are all masculine:

le plomb, lead.	*le baril*, the barrel.
le bac, the ferry.	*le coup*, the blow.
le bord, the edge.	*le coq*, the cock.
le rang, the rank.	*le nez*, the nose.

(*b*) F is a masculine ending, except in *la clef*, the key; *la nef*, the nave; *la soif*, thirst.

(*c*) M is a masculine ending, except in *la faim*, hunger, and the place name *Jérusalem*.

(*d*) N is a masculine ending except in *la fin*, the end; *la main*, the hand.

(*e*) R is a masculine ending, except in *la chair*, flesh; *la cour*, court, courtyard; *la cuiller*, spoon; *la mer*, sea; *la tour*, the tower.

(*f*) S is a masculine ending, except in *la brebis*, sheep (ewe); *la fois*, time (as in *une fois*, once = one time); *la souris*, mouse; *la vis*, screw.

(*g*) T is a masculine ending, except in *la dent*, tooth; *la dot*, dowry; *la forêt*, forest; *la gent*, race; *la hart*, halter; *la nuit*, night; *la part*, share. *Jument*, mare, is the only word ending in *ment* that is feminine.

(*h*) X is a masculine termination, except in *la chaux*, lime; *la croix*, cross; *la faux*, scythe; *la noix*, walnut; *la paix*, peace; *la perdrix*, partridge; *la poix*, pitch; *la toux*, cough.

(*i*) A is a masculine ending, except in some names of dances, as *la polka*, polka.

(*j*) É (not preceded by *t*) is a masculine ending, as *le thé*, *le café*.

(*k*) I is a masculine ending, except in *la fourmi*, ant; *la merci*, mercy; *une après-midi*, afternoon.

(*l*) O, which only occurs as final in *l'écho*, echo, is a masculine ending.

(*m*) U and *ou* are masculine endings, except in *la bru*, daughter-in-law; *la glu*, birdlime; *la tribu*, tribe; *la vertu*, virtue.

(*n*) *Eau* is a masculine ending, except in two words, *l'eau*, water; *la peau*, skin.

(*o*) *Oi* is a masculine ending, except in *la foi*, faith; *la loi*, law; *la paroi*, partition wall.

(*p*) **Nouns ending in *acle* and *ocle* are masculine, except *la débâcle*, breaking-up of the ice, and, figuratively, downfall.**

(*q*) Nouns ending in *age*, *ège* and *ige* are masculine, except *la cage*, cage; *la nage*, swimming; *la plage*, shore; *la rage*, rage and rabies; *la page*, page (of a book); *une image*, image; *une allège*, a lighter; *la tige*, stalk.

(*r*) Nouns in *aume* are masculine, except *la paume*, palm (of the hand), tennis.

(*s*) Nouns in *aire* are masculine, except *une affaire*, affair; *la circulaire*, circular; *la chaire*, pulpit; *la paire*, pair; *aire*, area.

(*t*) Nouns in *asme* and *isme* are all masculine.

(*u*) Nouns in *âtre*, *itre*, *iste* and *ogue* are masculine, except *la marâtre*, stepmother; *une huitre*, oyster; *la vitre*, window-pane; *la piste*, track; *la vogue*, vogue; *une églogue*, eclogue.

2. Feminine.

(*a*) Nouns ending in mute *e* preceded by *é* are feminine, except a few proper names, such as *Amédée*, *Persée*, and words in which *ée* represents *eum*, as *la musée*, museum; *la Colisée*, Colosseum.

(*b*) Nouns ending in mute *e* preceded by *i* or *u* are feminine, except *le génie*, genius; *un incendie*, fire; *le parapluie*, umbrella.

(*c*) Nouns ending in mute *e* preceded by a double consonant are mostly feminine. The chief exceptions are *le beurre*, butter; *le lierre*, ivy; *le parterre*, flower-bed, also pit (in a theatre); *le tonnerre*, thunder.

(*d*) Nouns in *ade* and *ude* are feminine, except *le grade*, grade, degree; *le camarade*, comrade; *un interlude*, *le prélude*.

(*e*) Nouns in *ure* are feminine, except *un augure*, augury; *le murmure*, murmur; *le parjure*, perjury and perjurer; and words belonging to the terminology of chemistry, as *le cyanure*, cyanide.

(*f*) All nouns in *aille* and *ouille* are feminine.

(*g*) All nouns in *ette* are feminine, except *le squelette*, skeleton.

(*h*) All nouns in *ance*, *ense*, and *ence* are feminine, except *le silence*.

(*i*) Nouns in *té* are feminine, except *le côté*, side; *le comité*, committee; *le comté*, county; *été*, summer; *en pâté*, a pasty; *un traité*, a treaty, also treatise; and a few more not of frequent use.

(*j*) All nouns in *tion* are feminine, with the one exception of *le bastion*, bastion.

(*k*) Nouns in *aison* are feminine.

(*l*) All abstract nouns in *eur* are feminine, except *l'honneur*, honour; *le labeur*, toil; *le bonheur*, happiness; *le malheur*, misfortune.

Double Gender.

Some words that are spelt alike differ in meaning according as they are masculine or feminine. Of such words the following occur frequently:

le crêpe, crape.	*le mode*, mood.
la crêpe, pancake.	*la mode*, fashion.
le livre, book.	*le mousse*, ship-boy.
la livre, pound.	*la mousse*, moss.
le manche, handle.	*le page*, page (boy).
la manche, sleeve,	*la page*, page (of a book).
le mémoire, memorandum.	*le pendule*, pendulum.
la mémoire, memory.	*la pendule*, timepiece.
le poêle, stove, pall.	*la tour*, tower.
la poêle, frying-pan.	*le vase*, vase.
le poste, post, station.	*la vase*, ooze, mud.
la poste, post-office.	*le vapeur*, steamboat.
le somme, nap.	*la vapeur*, steam.
la somme, sum.	*le voile*, veil.
le tour, turn, trick, tour.	*la voile*, sail.

Exercise V.

Vocabulary.

année (f.), year. (*a-ney*)
arbre (m.), tree. (*ar-br*)
arbrisseau (m.), shrub. (*ar-brees-so*)
fleur (f.), flower. (*flĕr*)
fruit (m.), fruit. (*frü-ee*)
leçon (f.), lesson. (*leh-song*)
mois (m.), month. (*mwah*)
neige (f.), snow. (*nayj*)
saison (f.), season. (*say-zong*)
derrière, behind. (*der-ree-err*)
premier (m.), first. (*prĕ-mee-ey*)
première (f), first. (*prĕ-mee-err*)
quatre, four. (*kăhtr*)

1. There are four seasons: [the] spring, [the] summer, [the] autumn, and [the] winter. 2. Spring is the first season of the year. 3. Winter is not the season of [the] flowers. 4. In (*en*) summer there is no snow. 5. The month of December is one of the months of winter. 6. The apple is the fruit of the apple-tree. 7. The briar has no fruit. 8. The oak is a tree, [the] heather is a shrub. 9. There are a beech and a hawthorn behind the house. 10. He has a plum, she has an apricot, and we have some cherries. 11. There is a bird in the cage. 12. The children are on the shore. 13. The brother and sister have the measles. 14. I have a headache. 15. Lying is a vice. 16. The sentry is not a recruit. 17. There is a picture on the first page of the book. 18. I write with chalk. 19. The sailor and the cabin-boy love (*aiment*) the sea. 20. The end of the lesson.

KEY TO EXERCISE IV.

1. Le papier du livre. 2. Le héros de l'histoire. 3. Le haut de la maison. 4. Le crayon de l'enfant. 5. Voilà la plume. 6. Voilà la règle. 7. L'encre est dans l'encrier. 8. L'encrier est sur la table. 9. Il y a un encrier sur la table. 10. La hauteur de la maison. 11. Il y a un livre, un encrier, un buvard, une règle et un cahier sur la table. 12. De la chaise à la table. 13. Le père et la mère sont dans la maison. 14. La charité est une vertu. 15. Le fer est un métal. 16. L'homme a un frère et une sœur. 17. Les enfants ont des grammaires. 18. Voilà le livre d'un des enfants. 19. J'ai parlé aux enfants de la femme. 20. J'écris au frère et à la sœur. 21. J'ai des crayons. 22. Elle n'a pas d'encre. 23. Vous avez besoin de plumes et de papier. 24. Il a de bons livres. 25. Vous avez des crayons et du papier; nous n'en avons pas. 26. Vous avez de bonnes plumes. 27. Le père de l'enfant a une maison. 28. Voilà le père de l'enfant. 29. Elle a besoin d'encre et de papier. 30. L'or et l'argent sont utiles aux hommes. 31. Les enfants n'ont pas de patience. 32. La patience est une vertu.

Group 23 NATURAL HISTORY 6

Continued from page 732

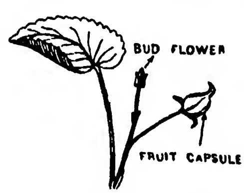
HOW FLOWERS COVER THE EARTH

Natural Agents Engaged in Dispersing Seeds. Action of Water and Wind. The Part Played by Insects, Birds and Animals

By Professor J. R. AINSWORTH DAVIS

Bees and Butterflies as Guests. We may give the name "Bee-Butterfly Flowers" to such as primrose (*Primula vulgaris*) and dog-violet (*Viola canina*), which are visited chiefly by bees and butterflies. The former is of great interest, because it possesses two kinds of blossom [**104**]. In one ("thrum-eyed"), the five anthers occupy the mouth of the corolla tube, and the rounded stigma is borne upon a shorter style. In the other kind ("pin-eyed"), the anthers are deep down in the tube, while the stigma is on a long style and occupies its entrance. It naturally follows that the pollen from one kind of flower is likely to be transferred to the stigma of the other. This sort of arrangement is carried still further in purple loosestrife (*Lythrum Salicaria*), where the flowers are of three different kinds—*i.e.*, with long style, medium stamens and short stamens; with long stamens, medium style, and short stamens; and with long stamens, medium stamens, and short style. The best seeds are produced when a flower with style of given length is crossed by pollen from another stamen of corresponding length.

In dog-violet (*Viola canina*) [**119**, p. 730] the irregular purple flower presents an alighting platform, and well-marked streaks, together with an orange-coloured patch, serve as nectar-guides, marking the entrance to the spur in which nectar is stored. The curious hood-shaped stigma is placed at the entrance of the blossom, and the five anthers surround the style, shedding their dusty pollen into the space so enclosed. An insect visitor is pretty certain to get dusted with this pollen, and to transfer some of it to the stigma of the next flower visited.



129. DOG-VIOLET

The Fly's Visit to the Speedwell. Among the higher two-winged insects known as flies there are some called "hover-flies," on account of the peculiar way in which they remain suspended, as it were—*i.e.*, hover—at a particular spot, and then dart away rapidly in a sidelong fashion. The germander speedwell (*Veronica chamædrys*) [**128**, page 730] is one of our native flowers adapted to the visits of guests of this kind. It is of a beautiful blue colour, and slightly irregular, with only two stamens instead of the five possessed by its relative the mullein, or the four to be found in the allied foxglove and snapdragon. The last two have lost the top stamen, to allow of the style with its stigma pressing up against the upper side of the corolla; but speedwells have lost two more, so as to fit them for the kind of visit to be now described.

The flower is flat when expanded, and dark-blue lines converge to the white centre of the corolla, indicating very clearly where the nectar is to be found. The long style with its stigma projects obliquely forwards and downwards, and the two long stamens project outwards and somewhat sideways. The insect guest first hovers in front of the flower, apparently delighted with its bright hue, and then darts forward to suck the nectar, seizing the two filaments as it does so, and drawing them under its body to serve as a support. Being very attenuated at their bases they are easily moved. The two anthers are thus brought into contact with the body of the insect, and dust it with pollen, some of which is almost certainly transferred to the stigma of the next flower visited.

Flowers with Fly Traps. A number of flowers possess traps by which small flies are caught and held prisoner until they have done the work required of them. Our common wild arum (*Arum maculatum*) [**111**], or cuckoo-pint, presents us with a striking arrangement of the kind. The flowers are enclosed in a chamber formed by the lower part of a large green bract (*spathe*), which opens to display a thickened purple stem (*spadix*), upon the base of which these flowers are arranged in two crowded sets, of which the lower ones are female and the upper ones male.

Above the last are a number of downwardly directed trap-hairs, which are no other than modified male flowers which have lost their original function. Small flies are attracted by the dull purple colour of the spadix and by an ammoniacal odour which is exhaled. Creeping down the spadix or inner side of the spathe they easily make their way past the trap-hairs, and find themselves prisoners in the chamber containing the flowers. At this time the stigmas are mature, and should any arum pollen be sticking to the bodies of the little visitors they are likely to receive some of it.

When this takes place the stigmas wither, and each of them exudes a drop of nectar as payment for services rendered. The stamens next shed their pollen, and some of this is likely to stick to the guests, who are at last allowed to escape, since the trap-hairs wither [**112**]. The pollen is carried by them to another arum in a certain proportion of cases.

The Disappointed Foxglove. In many of the less specialised flowers the chances of cross and self-pollination are about equal, while some of the more inconspicuous forms rely very largely upon the latter, as, for example, chickweed (*Stellarix media*), and the smaller kinds of wild geranium. And a very large proportion even of irregular specialised flowers are self-pollinated as a sort of last resort. A good instance of this is afforded by the foxglove (*Digitalis purpurea*), for in the last stage of flowering, should humble-bees have failed to visit it, the purple corolla falls off and drags the pollen-covered anthers over the stigma.

In the daisy and dandelion order (*Compositæ*) there is a pretty arrangement which may be illustrated by sunflower (*Helianthus annuus*). Here the central disk-florets pass through the following stages [106, read from left to right]. The anthers are united into a hollow cylinder, into which the pollen is shed. From this it is pushed out by the two stigmas, which are provided with sweeping hairs for the purpose, but, being pressed close together, are not self-pollinated. This pollen is more or less carried off by insects. The stigmas now diverge, laying themselves out to receive pollen from another flower. Failing this, they curl back, and are self-pollinated by some of the grains which reman clinging to the sweeping hairs.

There are some species which go still further, for in addition to the ordinary flowers they produce small bud-like ones, which never open, and fertilise themselves with their own pollen. Such flowers are easily to be seen on the dog-violet (*Viola canina*) [129] towards the end of summer, at the time when the fruits produced by the ordinary conspicuous flowers are ripe. The wood sorrel (*Oxalis acetosella*) is another example of the same kind.

DISPERSAL OF SEED-PLANTS

We have now considered in some detail the means by which the continuance of the species is effected. But as plants are not able to move about actively, it is necessary that there should be some provision for dispersal of their offspring, so that some at least of them may be able to find a suitable spot where they can grow up. Certain species actively disperse themselves, while others are scattered by water, wind, or animals.

How the Plants form Colonies. There are many plants which send off more or less horizontal branches below or above the ground, from the nodes of which roots grow down and shoots grow up, so that a sort of colony is produced, with members which may be arranged in a row or in a cluster. The cases of the sand sedge (*Carex arenaria*) and strawberry (*Fragaria vesca*) have been spoken of elsewhere. Other familiar examples with underground stems are mint (*Mentha*), millefoil (*Achillea millefolium*), reed (*Phragmites communis*), couch-grass (*Agropyrum repens*), stinging nettle (*Urtica dioica*), butterbur (*Petasites officinalis*), and coltsfoot (*Tussilago Farfara*). The last four are well-known weeds which it is very difficult to eradicate, owing to the way in which their numerous underground stems tunnel through the ground.

A variation on the arrangement just described is seen in tuberous plants such as the potato (*Solanum tuberosum*), where underground branches swell up into tubers from the "eyes" or buds of which new plants arise. If forms such as these are left to themselves, clustered colonies will soon be produced.

The dark-green rings in pastures with which we are familiar in this country are mostly formed by toadstools, which spread outwards from a centre, exhausting the ground as they do so.

There are, however, some seed-plants in which the same habit is observable, the ring being due to the death of older members of the colony which once occupied the middle of the patch. The Swedish fairies are popularly supposed to be especially fond of holding their midnight revels within the rings formed by a kind of grass (*Sesleria cærulea*).

Plants which Sow their Own Seeds. There is a kind of clover (*Trifolium subterraneum*) in which the pods produced on the lower part of the plant bend down towards the ground, into which they are forced by the growth of the branches that bear them. While in a kind of vetch (*Vicia amphicarpa*), native to South Europe, some of the flowers are self-fertilised and borne on underground shoots.

Some detached fruits bury themselves in the ground. That of storksbill (*Erodium*), for instance, possesses a spirally twisted awn, which uncoils when moist, and pushes the fruit into the earth [130].

The fruits of a number of plants are in a state of tension when ripe, and finally open or split suddenly in such a way as to eject the seeds to a considerable distance. One of the commonest examples is afforded by broom (*Sarothamnus scoparius*), the flat, black pods of which may often be heard exploding in late summer, the two halves curling up so that the seeds are scattered in all directions [136]. A similar case is that of balsam (*Impatiens noli-me-tangere*), the ripe capsules of which split into four twisting strips at the least touch, with the same result [131]. The seeds of wood sorrel (*Oxalis acetosella*) suddenly fly out from the mature capsule, owing to the rapid swelling up of a layer of the seed-coat, which is in a state of compression. The squirting cucumber (*Ecballium elaterium*) of South Europe presents us with a different kind of mechanism, for when ripe, it is, so to speak, over-full of fluid, and, as a result, the stalk is suddenly forced off and the seeds squirted out [137].

How Seeds Spread Over the Earth. *Sling fruits* resemble some of the preceding in certain respects, but owe their name to the way in which the seeds are propelled. In the marsh cranesbill or geranium (*Geranium palustre*), for example, each of the five compartments of the fruit is continued into an elastic fibre running up the beak like a prolongation, which has suggested the popular name. The compartments with their fibres ultimately curl up suddenly, owing to the elasticity of the latter, and the seeds are flung for a considerable distance [138].

In many *catapult fruits*, the ripe seeds, or, it may be, parts of the fruit, are contained in an open cup, and get thrown out by the quick recoil of the very elastic stems and flower-stalks when these are moved by the wind or brushed against by animals. In wood-sage (*Teucrium*) and other members of the dead-nettle order (*Labiatæ*) this cup is the calyx, in which the little separate divisions (nutlets) of the fruit are contained [139]; while in various species of the poppy [140], lily, iris, pink, primrose, or foxglove kind the dry fruit splits or opens to form a cup or hole-pierced capsule, and it is the seeds which are shot out.

Flipping fruits include cases where the fruits are exceedingly smooth, and are pinched by contracting parts of the open fruit so as to be flipped to some distance, just as orange-pips can be shot from between the thumb and forefinger. An easily-observed instance is that of dog-violet (*Viola canina*), where the capsule splits into three parts, within each of which are two rows of shining seeds [141].

The Coco-nut Palm's Sea Voyage. The dispersal of plants by water is the method naturally adopted in the case of some of the plants which live and ripen their fruits in running water, but the method is not limited to them alone, for it may occur in some land forms. A notable case is that of the coco-nut palm, the fruits of which are invested in a thick fibrous husk, entangling hair, and covered with a tough skin. They may be carried for thousands of miles by ocean currents without getting water-logged or losing their power of germination, and it naturally follows that this palm is one of the commonest forms of vegetation in the coral islands of the Pacific.

The name *roses of Jericho* was applied in the Middle Ages to two plants native to the steppes of south-east Asia and North Africa. One of them (*Anastatica hierochuntica*) [142] belongs to the wallflower order (*Cruciferæ*), and, when its fruits are ripening during the dry season, the branches curl over them so as to give a remote resemblance to a rose that has not yet opened. When the rainy season sets in, the branches spread out, the fruits open, and the seeds are washed out.

Plants Dispersed by the Wind. Some of the plants native to the steppes of Russia and South-west Asia form a rounded branching mass, which is easily detached from the root at the time when the fruits are maturing, and gets rolled like a ball along the ground by the wind. A good example is a species of plantain (*Plantago cretica*), and there are a good many others. As great numbers of such plants often stick together to make up a very large and increasing mass, which may at times be caught up into the air, they have become objects of superstition, and have given rise to legends of wind or steppe witches. Other species growing in similar localities produce round and very light fruits, which are easily blown along the surface of the ground for great distances.

There are some plants which produce innumerable flattened seeds of such small size that they can be blown about like grains of dust. Orchids afford the best example, and it is easy to see how the tropical members of the group get dispersed among the branches of the trees where they mostly grow. For an extreme case, it has been calculated that over 30,000 seeds only weigh 1 grain (437½ grains = 1 oz. avoirdupois).

In a large number of trees, tall shrubs, and herbs, the fruits or seeds are provided with membranous expansions which are easily caught by the wind. The "keys" of maple, sycamore [143], ash [144], and elm [145] are common examples of winged fruits, while in hop, lime [146], and hornbeam [147] a bract serves as a sail.

The Scotch pine (*Pinus sylvestris*) and Abies will serve as good examples of winged seeds [132].

In many members of the dandelion order (*Compositæ*) the calyx is transformed into a beautiful crown of hairs ("pappus"), which serves as a parachute. The dandelion itself (*Taraxacum officinale*) is a particularly instructive example. While the head of crowded yellow florets is maturing the stalk is short and near the ground, but it elongates and stands erect when the florets open to attract insects. Pollination and fertilisation accomplished, the stalk moves down so that the fruits can ripen in comparative safety close to the earth. When they are ripe the stalk once more becomes vertical, the crowns of hair spread out, and the fruits of the "dandelion clock" are blown hither and thither by every wind that blows. Equally familiar and of the same nature is "thistledown," while the parachutes of goatsbeard (*Tragopogon*) are noticeable on account of the extreme beauty of the feathery hairs which compose them [133]. The elegant fruits of clematis [134] are also wind-dispersed. Of tufted seeds it may suffice to mention willow (*Salix*) [148], cotton (*Gossypium*), and willow herb (*Epilobium*) [149].

The Ant as a Farmer. The chief groups of animals which unconsciously assist plants to colonise in favourable places are insects, birds, and mammals.

In warmer climates than our own there are several species of ants which may almost be described as farmers, since they collect and store various grains and seeds for consumption during hard times. A certain proportion of these must frequently escape being eaten and have the opportunity of growing up into young plants.

A very extraordinary case is afforded by the seeds of violets and pansies, each of which possesses a small fleshy knob (caruncle), which serves as a sweet and toothsome food that appeals to the taste of certain ants [150]. They are thus tempted to carry off these seeds, which remain quite uninjured when their little knobs have been gnawed away, and germinate if surrounding conditions are favourable.

The earth which often clings to the feet and feathers of birds, especially those which seek their food in damp places, often contains large numbers of small seeds, which thus stand a chance of getting carried to spots where they may successfully germinate and grow up. But a more frequent and more important case is that of succulent fruits, such as grapes, sloes, and a large assortment of berries, which attract birds by their often brilliant colours and minister to their appetites. In such fruits we find that the seeds are commonly protected by strong coverings, which escape the processes of digestion and are voided in a fit state for germination.

How Plants Distribute their Fruit. Many of the brightly coloured edible fruits of hot climates appeal to monkeys as much as birds, and thus get their seeds distributed in similar fashion. We also find a great variety of fruit and seed upon plants of low stature, provided with devices of various kinds by which they are enabled to cling to the coats of their unconscious friends.

It has been estimated that some 10 per cent. of all flowering plants produce fruits provided with hooks or spines by which they easily get attached to fur or hair. Familiar examples among our native plants are burdock (*Arctium lappa*) [151], agrimony (*Agrimonia eupatoria*) [152], avens (*Geum urbanum*) [153], and cleavers or goose-grass (*Galium aparine*). Some arrangements of the kind possessed by foreign forms are of truly formidable nature, such as the strong curved hooks of martynia [154], native to Louisiana, and the numerous formidable claws of harpagophyton [155], a plant which flourishes in South Africa, and is said to be fatal to the lion by producing festering sores.

Nature's Ingratitude. We also find that the spiked iron balls known as caltrops, which mediæval generals scattered on the ground for the entertainment of hostile cavalry, have been anticipated by some plants for the more useful purpose of dispersing their fruits. In Hungary and elsewhere, for example, there are forms (species of *Tribulus*) in which the fruits break up into pieces that lie on the ground and are liable to penetrate the feet of sheep and horned cattle by means of a sharp, brittle spine which sticks up from each of them [156]. After being carried away, the seed-containing part breaks off, while the spine remains embedded in the foot of the friendly animal, setting up a painful, festering wound—a very ungrateful return for services rendered.

Sticky Fruits are provided with sticky patches or hairs which easily adhere to the coats of passing animals. Typical examples are a kind of sage (*Salvia glutinosa*), and plumbago [157], a plant often grown in greenhouses in this country. It may be well to add that hooked and sticky fruits often attach themselves to the feathers of birds as well as to the fur of mammals.
